intraoperative instrumentation of the vagina or proctoscopic evaluation of the rectum may help to avoid iatrogenic injury to these structures. Finally, minimizing tissue trauma with gentle handling will decrease adhesions and maximize potential fertility.

All patients undergoing surgery for advanced endometriosis, either by an open or laparoscopic approach, should have a full mechanical and antibiotic bowel preparation. Prophylactic antibiotics and other appropriate practices for patients undergoing major abdominal or pelvic surgery are standard. Patients are positioned in the low-lithotomy position with access to both the vagina and rectum for instrumentation. Ureteral stents are liberally used and are especially useful in women with severe obliterative disease in the cul-de-sac and in reoperative pelvic surgical procedures.

Provided that complete removal of the endometriosis is performed, no specific technique or approach has been proven to be superior. With endometriosis, the surgeon's experience and skill are paramount. In experienced hands, laparoscopic removal of extensive endometriosis can be accomplished. However, removal of deep lesions in the rectovaginal septum necessitating bowel resection still often requires open laparotomy to safely and completely excise the endometrial implant with restoration of intestinal continuity.

The management and techniques concerning the surgical treatment of ovarian and ureteral endometriosis are extensively discussed in the appropriate gynecologic and urologic literature. This discussion on surgical therapy will concentrate on management of intestinal lesions.

Rectovaginal Endometriosis

Endometriosis of the cul-de-sac of Douglas that extends into the rectovaginal septum is the most common site of intestinal involvement and may require intestinal resection. These lesions are often deep fibrotic nodules that extend from the posterior vagina and anterior rectum to the uterosacral ligaments (Figure 25-6). Small superficial lesions involving the
FIGURE 25-6. Deep infiltrating endometrial implant of the recto-sigmoid.

intraperitoneal rectum may be vaporized with the CO_2 laser or electrocautery. When using either technique, it is critical to initially outline the lesion to be removed to ensure complete extirpation, because distortion of the planes and tissue can otherwise make it difficult to assess the completeness of excision. Cutting current as opposed to coagulating current is preferred. The former technique minimizes carbonization that can make it challenging to recognize when an adequate depth has been achieved by the appearance of normal tissue. After the lesion is removed, the bowel wall is carefully assessed. Since most of these superficial lesions can be removed without entering the mucosa, the defects can be closed with interrupted transversely placed Lembert stitches.

Surgical treatment of the deeper lesions is more controversial. Removal of the rectosigmoid with reanastomosis is technically demanding and should be performed by skilled intestinal surgeons to minimize complications in these young patients. As experience has grown, there has been a shift to more aggressive therapy, usually in conjunction with gynecologists who remove endometrial deposits on the ovaries, fallopian tubes, and uterosacral ligaments. Medical treatment has not proven adequate for infiltrating intestinal or urologic lesions, so it is no surprise that castration alone has also proven ineffective.[53] Many of these women suffer from chronic pain or partial colonic obstructive symptoms following bilateral salpingo-oophorectomy when the endometrial implant is not resected. As a result, excision of the implant either with a disk of rectal wall or a formal anterior resection is recommended for women with symptoms related to the endometriosis. Both procedures can occasionally be performed laparoscopically, if the endometriosis is completely removed. Unfortunately, laparoscopy may miss lesions that are not visually apparent and discernible only by palpation. It should be noted, however, that for severe disease laparoscopic ablation, when possible, had similar crude pregnancy rates in comparison to laparotomy, and both techniques were clearly superior to medical management alone.[54]

The infiltrating nodular endometrial implants involving the rectovaginal portion of the cul-de-sac often invade both the vagina and rectum. Since the removal of the implant will require resection of a portion of the rectal wall, dissection of the lesion from the vagina allows for en bloc removal of the lesion with the rectal wall. There is often no discernible plane between these lesions and the walls of the rectum or vagina. Care must be taken to avoid the penetration of the vaginal wall with possible injury to the cervix, especially in women desiring eventual pregnancy. Often it is advantageous to mobilize the rectum in the posterior and lateral tissue planes to adequately define the lesion before attempting the anterior dissection. Blunt dissection of the rectovaginal plane below the area of involvement may help clarify the distorted anatomy and avoid inadvertent entry into the bowel lumen. After careful dissection of the lesion from the vagina, the normal rectovaginal plane is reached,
FIGURE 25-7. Disk excision of an endometrial implant.

and the fixed, hard mass may suddenly become mobile and amenable to resection.

Disk excision of the anterior rectal wall, by either laparoscopic or open technique, is performed for single lesions usually less than 3 cm in diameter (Figure 25-7A–D). After marking the lesions circumferentially with electrocautery, stay sutures are placed on either side of the endometrial implant. Full-thickness bowel wall excision is then performed with the cutting current electrocautery. Interrupted transverse absorbable sutures are subsequently placed to close the resulting defect. It is critical that a rim of normal bowel wall be removed with the lesion to ensure complete removal of the lesion. Remorgida et al.[55] in 2005 evaluated full-thickness disk excision of bowel implants and discovered that 40% were incomplete. They postulated that not all endometriotic lesions are surrounded by fibrosis and consequently not included in the specimen.

Segmental resection of the rectosigmoid is performed for larger lesions or when neoplasia is a concern. Margins are to grossly normal colon, and unless there are multiple lesions, a large colonic resection is not required. High ligation of the sigmoid vessels is also unnecessary, and the anastomosis may be either hand-sewn or stapled. When resection is performed laparoscopically, the involved segment may be removed by extending one of the port sites. Nezhat and colleagues[56] have described a technique of prolapsing the lesion outside the anus for resection. Redwine et al.[57] described a transvaginal approach for specimen removal. Open or laparoscopic excision of these deeply infiltrating rectovaginal lesions is very technically demanding. The lack of discernable tissue planes, the intimate association of the rectum and vagina, and the frequent occurrence of distal infiltration of

endometriosis down to the mid-to-lower rectum makes laparoscopic resection possible only by surgeons very experienced in complex intestinal laparoscopy. Even in the hands of experienced laparoscopists, rectovaginal fistula requiring ileostomy has been reported to occur following these resections.[56] In fact, Darai et al.[58] in 2007 recommended that a protecting ileostomy be performed when combined resection of the vaginal and rectal walls is performed laparoscopically to minimize the high risk of anastomotic complications. Our current approach is to place omentum between the rectum and the vagina, if the suture lines are in contact. Proctoscopic insufflation to assess for leak is practiced routinely by the authors with all rectal anastomoses, whether performed open or laparoscopically.

Small Bowel and Appendiceal Endometriosis

While endometriosis involving the small bowel or appendix is much less common than rectosigmoid disease, careful inspection of these organs is critical in patients with advanced endometriosis to ensure complete removal of all gross disease and to minimize recurrence. Superficial small bowel implants may be treated with sharp excision, electrocautery, or the laser, as described above. Deeper implants may require small bowel resection, and, if within 5 cm of the ileocecal valve, may need an ileocecectomy. Appendiceal endometriosis is treated with appendectomy. Occasionally, a surgeon will encounter a patient with an endometrial implant while operating for another condition. While the lesion may exhibit a classic visual appearance consistent with endometriosis, a biopsy to confirm the diagnosis and exclude malignancy is important. Several studies have suggested that few patients with small asymptomatic endometrial implants of the appendix will become symptomatic, but no study has yet defined the natural history of these lesions. As a result, for those patients with asymptomatic endometriosis observation is probably sufficient, but hormone replacement therapy should be avoided.

Results After Surgical Therapy

Recurrence of endometriosis after surgical excision is difficult to assess because of a wide variability in the operative approach to endometriosis by various authors and the obvious need for postoperative laparoscopy to document asymptomatic recurrence. While there are no long-term prospective studies to date, the larger studies suggest a histologically confirmed rate of recurrent endometriosis of approximately 19%.[59] Gauging the response to surgery by the resolution of preoperative pelvic pain or infertility is easier to measure. The largest series of intestinal resections for advanced intestinal endometriosis by Bailey et al.[60] found that 86% of patients had complete or near complete relief of their preoperative pelvic pain. In addition, a 50% crude pregnancy rate was achieved which was comparable with rates found when treating much lower stages of disease. These results in over 130 cases with a median follow-up of 5 years were

achieved with minimal morbidity, no anastomotic leaks, and no documented instance of recurrent colorectal endometriosis. Laparoscopic series of intestinal resections performed for extensive endometriosis have reported similar pregnancy rates albeit with smaller number of cases, higher complication rates, and shorter long-term follow-up.

Combined Medical and Surgical Therapy

Both medical and surgical therapies for endometriosis have potential reasons why each treatment alone may not be successful in eradicating the disease and minimizing recurrence. Medical therapy affects endometrial implants variably, and there is a high instance of recurrence following cessation of therapy. Surgery may not remove microscopic disease, and postsurgical adhesions may contribute to postoperative pelvic pain and infertility. For these reasons, combination therapy either pre- or postoperatively has been used for several years, although with a paucity of prospective randomized data to conclusively prove long-term improvement in recurrence and symptoms.

The rationale for preoperative medical therapy conducted over a period of 3–6 months is principally to decrease the inflammation and possibly the size of the endometrial implants. Presumably, this therapy will allow easier excision with diminished adhesion formation. Medical therapy may also reduce the vascularity of endometrial implants. A prospective study by Buttram et al.[61] in 1985 revealed an improvement in pregnancy rates with 6 months of danazol given preoperatively with all stages of endometriosis. The optimal length of therapy and long-term (and not just delayed) recurrence rates must still be elucidated. Postoperative treatment with danazol and oral contraceptive pills has not been shown to have durability, and the initial excitement over improved recurrence rates at 12 months has not been duplicated after longer follow-ups. Our current use of combined therapy is a 3–6 month course of a GnRH-a prior to definitive surgery.

Conclusion

The diagnosis and management of intestinal endometriosis has evolved tremendously over the last 20 years with the widespread availability of laparoscopy and a clear understanding of the necessity to remove all endometrial implants in symptomatic patients. With the advent of stapling devices that facilitate low pelvic anastomoses, the intestinal surgeon should be able to resect the endometrial implants and restore bowel continuity in virtually all patients with minimal morbidity and preserved fertility, when desired. Further improvements in outcomes will probably not occur until a better understanding of the precise etiology and growth of the endometrial implant is discovered.

Trauma of the Colon and Rectum

David B. Hoyt and Michael E. Lekawa

Colon Injuries

Optimal management of colon injuries continues to be an evolving and controversial topic. Despite the dramatic reduction of colon-related mortality from about 60% during World War I to about 40% during World War II to about 10% during the Vietnam War and to lower than 3% in the last few decades, the colon-related morbidity remains high. The abdominal sepsis rate has remained significant at about 20% in a large prospective study in 2001 (Table 26-1).[1–6] No other organ injury is associated with a higher septic complication rate than colon injury. In the subgroups of patients with colon injuries with a Penetrating Abdominal Trauma Index (PATI) ≥25 or with multiple blood transfusions, the incidence of intraabdominal sepsis has been reported to be as high as 27%.[7] In patients with destructive colon injuries requiring resection, the reported incidence of abdominal complications is about 24%.[6] Many studies have attempted to identify risk factors for complications and create an optimal management strategy.

Epidemiology

The vast majority of colon injuries are due to penetrating trauma. In American urban centers, firearms are by far the most common cause of injury. In anterior or posterior abdominal gunshot wounds, the colon is the second most commonly injured organ after the small bowel, and it is involved in about 27% of cases undergoing laparotomy.[8,9] In anterior abdominal stab wounds, the colon is the third most commonly injured organ after the liver and small bowel, and an injury is found in about 18% of patients undergoing laparotomy. In posterior stab wounds, the colon is the most commonly injured organ and is injured in about 25% of patients undergoing laparotomy.[10] In abdominal gunshot wounds, the transverse colon is the most commonly affected segment. In stab wounds, the left colon is the most commonly injured segment, probably due to the predominance of right-handed assailants.

Blunt trauma to the colon is uncommon and is diagnosed in about 0.5% of all major blunt trauma or in 10.6% of patients undergoing laparotomy.[11,12] Most of these injuries are of partial thickness, and only 3% of patients undergoing laparotomy have full-thickness colon perforations.[11,13] Motor-vehicle trauma is the most common cause of blunt colon injury. Deceleration injuries may cause avulsion of the colon from the mesentery, resulting in ischemia but blowout perforations due to transient closed loop formation may occur as well. Seat belts increase the risk of hollow viscous perforations, and the presence of a seat-belt mark sign is a predictor of hollow viscous injury. In rare cases, colonic wall hematoma or contusion may result in delayed perforation, several days after the injury. The left colon is the most commonly injured segment followed by the right colon and the transverse colon.[11]

Diagnosis

The diagnosis of colon injury is almost always made intraoperatively. However, with the introduction of selective nonoperative management of penetrating abdominal trauma, there has been a concern of missing colon injuries. This is particularly important in penetrating injuries of the back because small retroperitoneal colon injuries may not give early clinical signs. A rectal examination may show blood in the stool, especially in cases with distal colon or rectal injuries. A preoperative upright chest film may show free air under the diaphragm. The colon can reliably be evaluated by water-soluble contrast enema studies or abdominal CT scan with soluble rectal contrast. Retroperitoneal gas or contrast extravasation is diagnostic and an exploratory laparotomy should be performed. Otherwise, one trial from Grady Memorial Hospital found that all significant injuries were clinically evident within 18 h.[14] Other investigations such as ultrasound or diagnostic peritoneal lavage are unreliable in the evaluation of suspected colon injuries due to its retroperitoneal location. The preoperative diagnosis of colon injury following blunt trauma can be a major challenge, especially

TABLE 26-1. Incidence of abdominal septic complications in colon injuries (prospective studies)

Author, year	Number of patients	Abdominal sepsis (%)
George, 1989[1]	102	33
Chappuis, 1991[2]	56	20
Demetriades, 1992[3]	100	16
Iratury, 1993[4]	252	17
Gonzalez, 1996[5]	114	24
Demetriades, 2001[6]	297	24
Overall	921	22

TABLE 26-2. American Association for the Surgery of Trauma (AAST) colon injury scale

Grade	Injury description
I	(a) Contusion of hematoma without devascularization
	(b) Partial thickness laceration
II	Laceration ≤50% of circumference
III	Laceration >50% of circumference
IV	Transection of the colon
V	(a) Transection of the colon with segmental tissue loss
	(b) Devascularized segment

if the patient is unevaluable due to associated head injuries. The diagnosis may be suspected by the presence of free air or thickened colonic wall on the routine abdominal CT scan. In some cases, the diagnosis may be delayed by many days with catastrophic consequences. Intraoperatively, every paracolic hematoma due to penetrating trauma should be explored and the underlying colon should be evaluated carefully. Failure to adhere to this important surgical principle may lead to serious complications. Paracolic hematomas due to blunt trauma should not undergo routine exploration unless there is evidence of colon perforation.

Colon Injury Scale

The American Association for the Surgery of Trauma (AAST) developed a grading system for organ injuries to have objective criteria for the classification of the severity of the injury and enable reliable comparisons of results. On the basis of the injury grade, an abbreviated injury score (AIS) is assigned and may be used for the calculation of the injury severity score (ISS). The AAST colon injury scale is shown in Table 26-2.

Operative Management

Historical Perspective

The first guidelines regarding the management of colon injuries were published by the United States Surgeon General

in 1943 and mandated proximal diversion or exteriorization of all colon wounds.[15] This unusual directive was initiated because of the very high mortality of colorectal injuries during the early years of World War II. The mortality in both civilian and military reports exceeded 50%.[16,17] Although these guidelines were not based on any scientific evidence, they were credited for the significant reduction of mortality in the last years of the war. However, during this period, many other major changes in trauma care took place. Faster evacuation from the battlefield and early definitive care, improved resuscitation protocols, and the introduction of penicillin and sulfadiazine could all have contributed to the reduction of mortality. The policy of mandatory colostomy for all colon injuries remained the unchallenged standard of care until the late 1970s. Stone reported the first major scientific challenge of this policy in 1979.[18] In a prospective randomized study, which excluded patients with hypotension, multiple associated injuries, destructive colon injuries, and delayed operations, the authors concluded that primary repair was associated with fewer complications than colostomy. The exclusion criteria were perceived as risk factors for anastomotic leak and were absolute indications for diversion.

With mortality rates due to colon-related complications improving over the next few years, surgeons challenged the validity of the "standard" contraindications for primary repair or resection and anastomosis. A few prospective randomized studies with no exclusion criteria (class I evidence) confirmed the safety of primary repair, at least in nondestructive colon injuries. Another alternative to primary repair or colostomy was exteriorized repair, which was introduced in the 1970s. With this technique, the sutured colon was exteriorized and observed for 4–5 days. If the repair remained intact during this period of observation, the colon was returned to the abdominal cavity. If the repair leaked, it was converted to a loop colostomy.[19,20] The enthusiasm for this approach waned in the 1980s due to the overwhelming evidence of the superiority of primary repair.

In the 1990s and 2000s, primary repair became the standard of care in most cases, although there is still some skepticism by many surgeons, especially in the presence of certain risk factors such as destructive colon injuries, severe contamination, multiple injuries, and delays in treatment.

Nondestructive Colon Injuries

There is now enough class I evidence (prospective randomized studies) supporting primary repair in all nondestructive colon injuries (injuries involving <50% of the bowel wall and without devascularization, i.e., AAST Grade I or II, irrespective of risk factors.) In a randomized study of 56 patients with no exclusion criteria, Chappuis et al. concluded that primary repair should be considered in all colon injuries irrespective of risk factors.[2] In another landmark study, Sasaki et al.

randomized 71 patients with colon injuries to either primary repair or diversion, without any exclusion criteria.[21] The overall complication rate was 19% in the primary repair group and 36% in the diversion group. In addition, the complication rate for colostomy closure was 7%. The authors concluded that primary repair is the method of choice of treatment of all penetrating colon injuries in the civilian population despite any associated risk factors for adverse outcome.

In 1996, Gonzalez et al.[5] published another important prospective study in which 109 patients were randomized to primary repair or diversion, independent of any risk factors. The sepsis-related complication rate was 20% in the primary repair group and 25% in the diversion group. In the presence of certain risk factors, such as severe fecal contamination, shock on admission, blood loss of 1,000 ml, or more than two associated organ injuries, the diversion group still had a higher complication rate, although this difference did not reach statistical significance. The authors continued their study until the series increased to 176 patients with penetrating colon injury and concluded again that in civilian trauma, all penetrating colon injuries should be primarily repaired.[22]

Overall, collective review of all available prospective randomized studies (class I evidence) identified 160 patients with primary repair and a 13.1% incidence of abdominal sepsis complications. In the group of 143 patients treated with diversion, the abdominal sepsis complication rate was 21.7% (Table 26-3). In addition to the available class I evidence, numerous prospective observational studies (class II evidence) demonstrated the superiority of primary repair over diversion in nondestructive injuries.[1,3,4,23] In conclusion, there is sufficient class I and II data to support routine primary repair of all nondestructive colon injuries, irrespective of risk factors for abdominal complications. No study has ever shown that colostomy is associated with better results than primary repair.

Despite the available scientific evidence, there is still some skepticism about liberal primary repair, and many surgeons still consider colostomy as the procedure of choice in many colon injuries. In a survey of 317 Canadian surgeons in 1996, 75% of them chose colostomy in low-velocity gunshot wounds to the colon.[24] In a 1998 survey of 342 American trauma surgeons, members of the AAST, a colostomy was the procedure of choice in 3% of colon perforations with minimal spillage, in 43% of perforations with gross spillage, in 18% of colon injuries involving >50% of the wall, and in 33% of cases with colon transection.[25] More recently, in a review of 99 colon injuries treated at one center from 1996 to 2006, 31% of patients have been treated with diversion.[26] It is obvious that dogma still plays a significant role in modern trauma surgery.

Destructive Colon Injuries

Until recently, there was no sufficient class I or II data regarding the management of destructive colon injuries requiring resection (loss of >50% of bowel wall or devascularization). Until the last decade, the available prospective randomized studies included only 36 patients with colon resection and anastomosis. The overall incidence of anastomotic leak was 2.5% and no deaths occurred. All these studies recommended primary anastomosis irrespective of the presence of any risk factors for abdominal complications.[2,21,22] In a 1998 prospective, but not randomized, study on colon injuries by Cornwell et al.,[7] there were 25 patients with destructive colon injuries treated by resection and anastomosis and two patients treated by resection and colostomy. All patients had a PATI ≥ 25 or were transfused with ≥6 units of blood, or the operation was delayed by ≥6 h from the time of injury. There were two anastomotic leaks (8%) and both were fatal. The study concluded that some high-risk patients with destructive colon injuries might benefit from diversion. Unfortunately, the study did not include enough patients with diversion for comparison with the primary anastomosis group. There are two retrospective studies, which included only destructive colon injuries requiring resection: Stewart et al.[27] analyzed 60 patients, 43 of which were managed by resection and anastomosis and 17 by diversion. The overall anastomotic leak rate was 14%, and in the subgroup of patients with blood transfusion >6 units the leak rate was 33%. The authors suggested that primary anastomosis should not be performed in patients receiving massive blood transfusions or in the presence of underlying medical illness. Another retrospective study from Los Angeles analyzed the complications in a series of 140 patients with destructive colon injuries requiring resection.[28] The incidence of intraabdominal sepsis was similar in the groups with primary anastomosis or diversion. Univariate analysis identified PATI ≥ 25 or hypotension in the emergency room to be associated with increased risk of anastomotic leak. The study suggested that a diversion procedure might be appropriate in these high-risk subgroups of patients.

In summary, until 2000, the available prospective randomized studies, which include only a small number of cases, recommend resection with anastomosis irrespective of risk factors. Two large retrospective studies advocate diversion in the subgroups of patients with certain risk factors such as PATI ≥ 25, multiple blood transfusions, or associated medical

TABLE 26-3. Primary repair versus diversion: prospective randomized studies with no exclusion criteria

Study	Primary repair		Diversion	
	No. of patients	Abdominal septic complications (%)	No. of patients	Abdominal complications (%)
Chappuis[2]	28	4 (14.3)	28	5 (17.9)
Sasaki[21]	43	1 (2.3)	28	8 (28.6)
Gonzalez[22]	89	16 (18)	87	18 (21)
Total	160	21 (1,301)	143	31 (21.7)

illness.[27,28] Subsequently, the guidelines of the Eastern Association for the Surgery of Trauma (EAST) published in 1998 supported resection and primary anastomosis in the subgroups of patients with destructive colon injuries if they (a) are hemodynamically stable intraoperatively, (b) have minimal associated injuries (PATI < 25, ISS < 25), (c) have no peritonitis, and (d) have no underlying medical illness. The guidelines suggest that patients with shock, significant associated injuries, peritonitis, or underlying disease should be managed with resection and colostomy.[29] However, these guidelines were based on class III evidence. In their review of the literature, there were only 40 patients in class I studies with resection and anastomosis, and the anastomotic leak rate was 2.5% without mortality. In class II studies, there were only 12 patients who underwent resection and anastomosis, and the leak rate was 8.3% without mortality. In class III retrospective studies, there were 303 patients with a leak rate of 5.2% and three deaths (1%) due to the leak.

In view of the lack of large prospective studies in the literature, the AAST sponsored a prospective multicenter study to evaluate the safety of primary anastomosis or diversion and identify independent risk factors for colon-related complications in patients with destructive colon injuries requiring resection.[6] This study, published in 2001, included 297 patients with penetrating injuries requiring colon resection (rectal injuries were excluded) that survived at least 72 h. The overall colon-related mortality was 1.3% (4 deaths) and all deaths occurred in the diversion groups ($P = 0.01$). The overall incidence of abdominal complications was 24%, and the most common complication was an intraabdominal abscess (19% of patients) followed by fascia dehiscence (9%). The incidence of anastomotic leaks was 6.6%. Multivariate analysis identified three independent risk factors for abdominal complications: severe fecal contamination, ≥4 units of blood transfusions within the first 24 h, and single-agent antibiotic prophylaxis. If all the three risk factors were present, the incidence of abdominal complications was about 60%; if any two factors were present, the complications rate was 34%; if only one factor was present, this figure was about 20%, and with no risk factors it was 13%. The method of colon management, delay of operation >6 h, shock at admission, site of colon injury, PATI > 25, ISS > 20, or associated intraabdominal injuries were not found to be independent risk factors.

In a second analysis, the group of patients with primary anastomosis was compared with the group with diversion, using multivariate analysis that controlled for PATI > 25, transfusion >6 units of blood, >6 h delay of operation, shock at admission, and severe fecal contamination. These factors have been described in previous studies as significant risks for abdominal complications. With colon diversion serving as reference (RR 1.00) for comparison, the adjusted relative risk of primary anastomosis was exactly the same (1.00).

In a similar analysis according to subgroups with ileocolostomy, colocolostomy, ileostomy, and colostomy, the adjusted relative risk of abdominal complications was similar. In another analysis, all patients were classified into either a high-risk group (if any of the following factors was present: hypotension at admission, blood transfusions >6 units, delay of operation >6 h, severe peritoneal contamination, or PATI > 25) or a low-risk group if none of the above risk factors was present. These risk factors are considered by many surgeons as strong indications for diversion. The colon-related mortality in the high-risk patients was 4.5% (4 of 88 patients) in the diversion group and no deaths in the 121 patients who underwent primary anastomosis ($P = 0.03$). Multivariate analysis showed that the adjusted relative risk of abdominal complication in patients with primary anastomosis or diversion was similar, in both the low-risk and high-risk patients (Table 26-4). There was a trend toward shorter ICU and hospital stay in the primary anastomosis group. The study concluded that "in view of these findings and the fact that colon diversion is associated with worse quality of life and requires an additional operation for closure, colon injuries requiring resection should be managed by primary repair, irrespective of risk factors".[6]

Damage control procedures with abdominal packing and temporary closure of the abdominal wall with a prosthetic material pose a special dilemma regarding the management of destructive colon injuries. No studies have ever addressed this issue, and the existing practices are based on personal beliefs and experience. The authors advocate primary anastomosis because of the theoretical disadvantages of having a colostomy, which is an open source of fecal material, near an open abdomen. The only conditions for which there is agreement for colostomy are the presence of severe colon edema or a questionable blood supply of the colon. In these situations, theoretically, a diversion procedure should be

TABLE 26-4. American Association for the Surgery of Trauma (AAST) colon resection study: comparison of abdominal complications between primary anastomosis and diversion in high- and low-risk patients

Patient population	Primary anastomosis: abdominal complications (%)	Diversion: abdominal complications (%)	Adjusted relative risk (95% CI)	P value
All patients	22	27	0.81 (0.55–1.41)	0.69
Low-risk* patients	13	8	1.26 (0.21–8.39)	0.82
High-risk* patients	28	30	0.90 (0.53–1.40)	0.67

*High-risk patients were those with PATI > 25, severe fecal contamination, 6 h from injury to operation, transfusion of >6 units of blood preintraoperatively, or systolic blood pressure ≤90 mmHg.

*Low-risk patients were those without any of the above risk factors.

a safe option. Despite this evidence, the move away from colostomy formation is slow and ongoing.[26]

Risk Factors for Abdominal Complications

The abdominal complication rate in colon injuries is very high, with a sepsis rate of about 20% (Table 26-1). In destructive colon injuries requiring resection, the prospective AAST colon resection study of 298 patients recorded an overall incidence of 24% of abdominal complications. Many studies attempted to identify risk factors for complications and, on the basis of these risks, to modify the treatment.

Left- Versus Right-Colon Injuries

For many years and until recently, there was an anecdotal perception that left-colon injuries are associated with a higher risk of anastomotic leaks and septic complications than right colon injuries. This perception was based on theoretical reasons (different anatomy and blood supply, higher concentration of bacteria, and poorer healing properties in the left colon) rather than clinical evidence. This perception led surgeons to advocate liberal primary repair of right colon wounds and colostomy in left-colon wounds. However, no clinical or experimental study has ever demonstrated any healing differences between the two sides of the colon or any evidence that the two anatomical sides should be treated differently. Experimental work in baboons, which have very similar anatomy and bacteriology to humans, showed no difference of the healing properties between the right and left colon.[30] The study involved resection of a 10-cm segment of right colon and a 10-cm segment of left colon and primary anastomosis, without any mechanical or chemical preparation of the colon. The healing of the anastomosis was assessed at autopsy 7 days postoperatively for complications (leak, local abscess), mechanically by measuring the breaking strength of the anastomosis and biochemically by measuring the hydroxyproline concentrations at the anastomotic site. The study showed identical healing properties of the two sides of the colon.

In another study using the same model, one of the authors evaluated the effect of hypovolemia (blood loss of 20 ml/kg) on healing of the left and right sides of the colon, and again no differences were found (Figures 26-1 and 26-2).[31]

Associated Abdominal Injuries

Early studies suggested that because multiple or severe associated intraabdominal injuries (PATI > 25) are associated with a high incidence of septic complications, they were considered to be contraindications for primary repair of the colon.[4,7] This factor was considered even more critical in destructive colon injuries and was suggested as an indication for diversion.[29] However, class I and II studies have shown that although multiple associated intraabdominal injuries are significant risk factors for intraabdominal sepsis, the method of colon management does not affect the incidence of abdominal sepsis.[3,5–7,32]
FIGURE 26-1. Hydroxyproline concentration (biochemical marker of wound healing) are similar in both sides of the colon *R* right colon, *L* left colon (values in μg/mg). (Adapted from Sofianos C, Demetriades D, Oosthuizen MM, et al. The effect of hypovolemia on healing of the right and left colon. An experimental study. S Afr J Surg. 1992;30:42–3.[31]).
FIGURE 26-2. Breaking strength of the right and left colon are similar: *R* right colon *L* left colon (values in N/mm²). (Adapted from Sofianos C, Demetriades D, Oosthuizen MM, et al. The effect of hypovolemia on healing of the right and left colon. An experimental study. S Afr J Surg. 1992;30:42–3.[31]).

Some studies have suggested that the creation of an ostomy in these high-risk patients may independently contribute to abdominal sepsis.[32] The current class I and II literature supports primary repair or resection and anastomosis in patients with severe or multiple associated abdominal injuries.

Military Wounds

Recent results from colon injuries incurred during the conflict in South Asia reflect a continued reliance on temporary stoma creation. This is due to a number of issues, including the destructive nature of the injuries, and time to transport to tertiary care centers in Europe and the USA. This illustrates

the continued difficulty with translation of clinical practice to military practice, and vice versa.[33–35]

Shock

There is now sufficient class I and II evidence that preoperative or intraoperative shock is neither an independent risk factor for abdominal sepsis nor a contradiction for primary colon repair or anastomosis.[3,5,6,30]

Blood Transfusions

Multiple blood transfusion (≥4 units of blood within the first 24 h) has been shown to be a major independent risk factor for abdominal septic complications.[6,32] In a large prospective AAST study of 297 patients with penetrating destructive colon injuries requiring resection, blood transfusion was the most critical independent factor for abdominal sepsis (adjusted RR 2.0; 95% CI, 1.31–2.83; $P = 0.001$). However, the method of colon management did not influence the complication rate in this group of patients, and primary anastomosis was recommended.[6]

Injury Severity Score

The injury severity score (ISS) is not an independent risk factor for abdominal sepsis, and high ISS (>15) is not a contraindication for primary repair or anastomosis.[3,6]

Fecal Contamination

Severe fecal contamination of the peritoneal cavity is a major independent risk factor for abdominal sepsis.[1,6,11,28,32,36,37] This finding led some studies to suggest that the presence of severe contamination should be a contraindication for primary repair or anastomosis.[1,11,36,37] However, all prospective randomized studies and recent large prospective observational studies have shown that the method of colon management in this group of patients does not influence the septic complication rate and have recommended primary repair or anastomosis.[2,5,6]

Specific Associated Abdominal Injuries

There is class III evidence that the combination of colon injuries with pancreatic or ureteric injuries is associated with an increased incidence of septic complications.[38,39] However, there is no evidence that the presence of any of these injuries is a contraindication for primary repair or anastomosis.[6] Common sense may dictate that the colon anastomosis should be physically separated from the intraabdominal injury, if possible.

Time from Injury to Operation

The length of delay of surgical repair over which the septic complication rate increases is not well defined. Some studies suggest ≥6 h while others have suggested ≥12 h as the critical delays associated with an increased risk of infections.[7,23,28,40] It seems that the degree of contamination is much more important than the delay in surgical management, and the time delay in itself should not be used as a criterion for primary repair or diversion. In a prospective study of 297 destructive colon injuries, the incidence of abdominal complication was 11.4% (4/35) in the group of patients with preoperative time >6 h and 26.1% in patients with preoperative times ≤6 h. Multivariate analysis failed to identify time delay as an independent risk factor.[6]

Retained Missiles

Missiles that passed through the colon and remained lodged in the tissues are not associated with increased risk of local sepsis, and they should be removed only if the removal is technically easy and does not prolong the operation. In a study of 84 patients with gunshot wounds of the colon, the bullet remained in the body in 40 and was removed in 44. The incidence of local septic complications was 5% in patients with retained bullets and 7% in those without.[41]

Temporary Abdominal Wall Closure

Damage control laparotomy and temporary abdominal wall closure with prosthetic material seem to be associated with increased incidence of abdominal septic complications. The crude relative risk of abdominal sepsis in patients with temporary abdominal wall closure has been reported to be 2.12 (1.32–3.40; $P = 0.005$) in a study of 297 of destructive colon injuries requiring resection. However, multivariate analysis failed to identify this method as an independent risk factor.[6] A recent evaluation of delayed primary anastomosis during damage control laparotomy by Miller et al. illustrated that 11 colon resections treated after damage control laparotomy with primary anastomosis had no suture line breakdown. They concluded that scheduled primary anastomosis is safe.[42] The Denver group also illustrated the safety of delayed primary anastomosis after damage control laparotomy.[26] Another recent retrospective review by Weinberg et al.[43] found that patients who underwent damage control laparotomy have a trend toward higher complications and anastomotic dehiscence than in single laparotomy patients. While this should give pause in making an absolute recommendation for anastomosis after damage control laparotomy, the trend away from colostomy continues in most centers. The anastomosis is usually done on the first return to the operating room.

Anastomotic Leaks

Colon leaks remain the most serious complication in repaired or anastomosed colons. The overall incidence of suture line failures is fairly low. In a collective review of 35 prospective

or retrospective studies with 2,964 primary repairs, Curran reported 66 (2.2%) leaks.[44] In prospective studies including 534 patients with colon repair or resection and anastomosis, there were 17 (3.2%) leaks.[44] The leak rate after resection and anastomosis is significantly higher than in simple repairs. In a 1999 collective review of 362 patients with resection and anastomosis, the overall incidence of anastomotic leak was 5.5%.[44] The same year, in another large retrospective study of 112 patients with penetrating or blunt colonic injuries treated by resection and primary anastomosis, Murray et al.[28] reported a leak rate of 9%. In a more recent multicenter prospective study of 197 patients with penetrating colon injuries who underwent resection and primary anastomosis, the leak rate was 6.6%.[6]

The risk factors for anastomotic leak are not well defined. It seems that colocolostomies are associated with a higher incidence of anastomotic leaks than ileocolostomies. Murray et al.[28] reported a leak rate of 4% in 56 patients with ileocolostomies and 13% in 56 colocolostomies. Univariate analysis identified PATI≥25, ≥6 units of blood transfusion and hypotension in the emergency room as risk factors for anastomotic leak. A multicenter prospective AAST study reported a leak rate of 4.2% for ileocolostomies and 8.9% for colocolostomies.[6] The leaks occurred in patients with or without multiple blood transfusions, severe contamination, and multiple associated injuries. No significant independent risk factors could be identified.

Many cases of anastomotic leak that do not result in diffuse peritonitis can be managed safely nonoperatively with a low-residue diet. In most cases, the leak results in a fecal fistula, which heals spontaneously within a few days. In other cases, the leak results in a local abscess which can be drained percutaneously. However, in some patients, the colonic leak causes severe intraabdominal sepsis, and a proximal diversion procedure may be required. Curran reported no deaths in a collective series of 66 patients who underwent repair for leaks.[44] However, Murray et al.[28] reported 2 colon-related deaths in a group of ten patients with anastomotic leak. The AAST multicenter study reported no deaths in the 13 patients with anastomotic leaks. The overall mortality due to colon leak-related complications in a collective review of 3,161 trauma patients treated with primary repair or resection and anastomosis was only 0.1%.[6,44]

In summary, colonic leaks occur more commonly in patients with colocolostomies than in patients with ileocolostomies. External fecal fistulas can safely be managed nonoperatively with low-residue diet. Localized abscesses are best drained percutaneously by interventional radiology, and the ensuing fecal fistula almost always closes spontaneously. Reexploration of the abdomen and creation of fecal diversion with or without resection of the leaking colon should be reserved only for patients with generalized peritonitis or failed percutaneous drainage.

Technique of Colon Repair

In nondestructive injuries, repair of the injured colon should be performed after debridement of the perforation. This step is critical in gunshot wounds when failure to debride may result in breakdown of the suture line. In destructive injuries, resection to normal and well-perfused edges should be performed, and the anastomosis should be tension-free. The method of anastomosis, hand-sewn or stapled, does not influence the incidence of abdominal complications or leak rate and it should be the surgeon's preference. In a prospective AAST study of 207 patients with penetrating destructive injuries who underwent resection and anastomosis, 128 cases were managed by hand-sewn anastomosis and 79 cases by stapled anastomosis. The incidence of anastomotic leak was 7.8% and 6.3%, respectively. Multivariate analysis adjusting for blood transfusions, degree of fecal contamination, and antibiotic coverage showed identical complication rates (stapled anastomosis adjusted RR = 0.99).[45] Further protection of the anastomosis with adjacent omentum is recommended whenever possible.

Rectal Injuries

The management of rectal trauma has undergone many changes in the same manner as colon injuries, with many of the principles of management evolving from wartime experiences. The mortality related to rectal trauma has decreased dramatically from 67% during World War I down to today's civilian reports of 0–10%.[46–51] Likewise, the morbidity, which was as high as 72% during the Vietnam War, is now as low as 10%.[51,52] The components of management, developed from lessons learned from combat experiences, have remained controversial and include (1) diversion of fecal stream, (2) distal rectal washout, (3) presacral drainage, and (4) debridement and closure of wounds when possible. Because of the paucity of class I and class II data, no consensus has been achieved with respect to the optimal management of rectal trauma.

Anatomy

The anatomy of the rectum makes it difficult to apply the principles of colon trauma management. The majority of the rectum is completely surrounded by the bony pelvis, making injuries infrequent and exposure difficult. The rectum varies in length from 12 to 15 cm, with only the upper two-thirds anteriorly and the upper one-third laterally covered by peritoneum (intraperitoneal rectum). The lower third of the rectum completely lacks peritoneal covering (extraperitoneal rectum), which makes exposure and repair of injuries difficult. Finally, the rectum is easily accessible from the anus, with the anterior peritoneal reflection only

approximately 6 cm from the anal verge. This results in a not uncommon finding of intraperitoneal injury from rectal foreign bodies.

Epidemiology

For various anatomical reasons, injuries to the rectum occur infrequently and are usually the result of penetrating trauma. In most series, gunshot and shotgun wounds account for 80–85% of injuries, and stab wounds for 3–5%.[46,53,54] In a series of 59 patients with gunshot wounds to the buttocks, only 3.4% had rectal injuries.[55] In another series of 192 patients with gunshot wounds to the back, 2.6% had a rectal injury.[9] Interestingly, in a series of 309 anterior abdominal gunshot wounds and a series of 37 transpelvic gunshot wounds, no rectal injuries were identified, reiterating the infrequency of this injury.[8,56]

Other causes include iatrogenic injuries from urologic and endoscopic procedures, sex-related trauma, and anorectal foreign bodies. Blunt trauma accounts for 5–10% of cases, and it is usually the result of pelvic fractures or impalement.[46,49,53,54,57] Rectal injuries have been reported in nearly 2% of all pelvic fractures.[58]

Diagnosis

The diagnosis of intraperitoneal rectal injury, similar to colonic injuries, is usually made intraoperatively. Extraperitoneal rectal injuries may not always be obvious. A high index of suspicion is necessary with both blunt and penetrating mechanisms to avoid missing an injury. The cornerstone for diagnosing an extraperitoneal injury is the combination of a digital rectal exam and rigid proctoscopy. In most series, the diagnostic accuracy of the digital rectal exam and rigid proctoscopy ranges from 80 to 95%.[46,51,54,59–61] However, the false-negative rate of the two has been reported to be as high as 31%.[47] For this reason, any suggestion of a rectal injury, even with a normal rectal and proctoscopic exam, should prompt further evaluation. In hemodynamically stable patients with a mechanism suspicious for a rectal injury (gluteal, perineal, and transpelvic gunshot wounds, pelvic fractures, and foreign body insertion), a digital rectal exam and a rigid proctoscopy must be performed, and in the appropriate cases, further evaluation by means of a water-soluble contrast study should be considered. In mechanisms of injury other than foreign body insertion, intraluminal blood on proctoscopy should generally be considered positive for rectal injury, as the actual injury may be obscured in an unprepped rectum. The first pass of the proctoscope is the critical view, as blood seen on subsequent scans may be iatrogenic in nature.

Rectal Organ Injury Scale

The grading system developed by the AAST for rectal injuries is similar to that of colonic injuries (Table 26-2).

Operative Management

Historical Perspective

The history of rectal trauma parallels that of colon trauma with much of the early management principles evolving from lessons learned from wartime experiences. Mortality from rectal gunshot wounds was as high as 67% in World War I and the early part of World War II, until the Army Surgeon General mandated colostomy for fecal diversion for all colon and rectal injuries.[15,17,46] Subsequently, the mortality dropped down to 35%.[17] Retrorectal drainage was added in 1943, which appeared to bring the mortality down further to approximately 5%.[46,62] Shortly after World War II, several civilian series demonstrated satisfactory results with colostomy and presacral drainage.[63,64] During the Vietnam War, where more destructive injuries were encountered, colostomy and presacral drainage alone were found to be inadequate. Rectal repair and distal rectal washout were added to the management and were associated with improved results.[52] Early postwar civilian studies demonstrated acceptable results when colostomy, rectal repair, presacral drainage, and distal irrigation were all employed.[47,65] Interestingly, there were other studies that also demonstrated acceptable results when only colostomy and presacral drainage were utilized.[49,62,66] Presently, there is no acceptable gold standard for the treatment of rectal injuries, as most studies have been unable to demonstrate any advantage of the various treatment options.

Intraperitoneal Injuries

With no class I or class II data present regarding the management of intraperitoneal rectal injuries and limited class III data that combines both extraperitoneal and intraperitoneal injuries, it is difficult to draw a conclusion regarding management. However, several studies do indicate that injuries to the intraperitoneal rectum can be managed like left-colon injuries with primary repair, and without the need for colostomy.[50,54,59,61,67] No increase in abdominal complications was found in these series when primary repair without colostomy was performed, making primary repair in this group of patients a reasonable option.

Extraperitoneal Injuries

As previously mentioned, there is no agreement in terms of the optimal management of extraperitoneal rectal injuries, but the mainstay of treatment has included four main components: (1) fecal diversion with colostomy, (2) presacral drainage, (3) distal rectal washout, and (4) repair of the injury, when possible. Each component is addressed separately below.

Fecal Diversion with Colostomy

Ever since World War II, the mainstay of management of extraperitoneal injuries has been proximal colostomy.[46,49,50,57,59–61]

The only controversial aspect has been whether to perform a loop colostomy versus an end colostomy. Some argue that a loop colostomy does not offer complete fecal diversion, whereas proponents of loop colostomy argue that a properly constructed loop colostomy will function as a true diverting colostomy, with the added benefit of simple construction and rapid closure.[46,59] In fact, Rombeau et al.[68] demonstrated that a properly constructed loop colostomy, supported by a solid rod above the level of the skin, achieves complete fecal diversion. The authors believe that the type of colostomy performed should be dictated by the operative findings. Extensive destruction of the rectum that requires a resection may best be served with a Hartmann's procedure, whereas injuries that are not repaired or require limited dissection may be addressed by a loop colostomy.

Recently, there have been reports of primary repair without fecal diversion in selected extraperitoneal rectal injuries.[53,54,59,61,69] In a series of 30 patients with extraperitoneal rectal injuries, five were transanally repaired without fecal diversion and with no subsequent morbidity.[54] Similarly, injuries right at the peritoneal reflection, or injuries encountered with minimal dissection, may also be primarily repaired without the need for colostomy.[61]

Presacral Drainage

Presacral drainage was added to the armamentarium in World War II because it was thought to decrease the pelvic sepsis rate.[59,70] It has remained controversial, with many studies showing a benefit with its use,[46,47,49,59,71] whereas other studies have failed to show any benefit.[50,53,60,61,72] In a series published by Velmahos of 30 consecutive patients with extraperitoneal injuries, no benefit was found with the use of presacral drains.[60] Despite the conflicting data, many authors continue to recommend the use of presacral drains for most injuries.[61] This was challenged by a 1998 randomized prospective trial evaluating the importance of presacral drainage.[73] In this series of 48 patients, in which 23 randomized to presacral drainage and 25 randomized to no drainage, no difference in pelvic sepsis was encountered. This represents the first and only class I study involving rectal injuries. Although it was a study with relatively few patients, it convincingly demonstrated that the addition of presacral drainage is unnecessary. Over the last 15 years, the use of presacral drainage has diminished considerably. It involves an additional procedure and dissection into an uninvolved space. The drains that are placed may malfunction or become malpositioned, and most importantly, there is no evidence that their use improves outcome.

Distal Rectal Washout

Distal rectal irrigation was added to the management of rectal injuries during the Vietnam War, when Lavenson and Cohen reported a decrease in morbidity from 72% to 10% with its use.[52] Since then, there have been supporters of rectal washout[47,48,50,65] as well as nonsupporters.[46,49,53,59,72] The overall value of distal washout is questionable. It has been suggested that there may be a benefit in patients with high-velocity wounds,[46,51] and in patients with rectal injuries from pelvic fractures.[74,75] However, this remains controversial. In summary, there is no proven benefit, and it may be associated with a high risk of infection due to spillage of intraluminal contents out of unrepaired rectal injuries.[62]

Rectal Repair

The addition of rectal repair to colostomy was also introduced during the Vietnam War.[52] However, rectal repair with or without a diverting colostomy is infrequently performed for extraperitoneal injuries.[60] In the majority of cases, repair is not technically feasible, with some series reporting successful repair in only 20–37% of cases.[46,50,59] Even when repair is performed, no outcome advantage has been proven.[46,49,50] Attempts at repair are associated with extensive dissection and unnecessary contamination of the peritoneal cavity. Attempts at repair should only be made when the rectal injury is encountered during the exposure of an associated injury such as bladder or iliac vessel, or if the injury is easily accessible at the peritoneal reflection. As previously mentioned, injuries that are easily accessible from the transanal route may also be repaired with excellent results.[54]

Miscellaneous Options

Though extremely rare, abdominoperineal resection has been described for patients with severe bleeding, massive tissue loss, or devascularizing injuries.[47,69,76] Recent reports have introduced laparoscopy in the management of rectal injuries.[77,78] In a prospective study of 20 patients with extraperitoneal rectal injuries, laparoscopy (to rule out an intraperitoneal injury), followed by a diverting loop sigmoid colostomy without laparotomy yielded excellent results.[78]

Associated Injuries

Associated injuries are commonly seen with rectal injuries and have been reported to occur in as many as 77% of cases.[46,60] Genitourinary, and in particular bladder injuries, are usually the most commonly seen associated injuries, occurring in 30–64% of cases.[46,49,53] Every effort should be made to close both injuries and separate both sites with well-vascularized tissues such as omentum. This should reduce the high incidence of rectovesical fistula, which can occur in up to 24% of patients with combined bladder and rectal injuries (Figure 26-3).[59,79]

FIGURE 26-3. Rectovesical fistula following repair of a gunshot wound involving the rectum and the bladder. Every effort should be made to separate the two organs with vascularized tissues such as omentum, to reduce the risk of this complication.

Wound Management

The incidence of wound sepsis in patients with colon or rectal injury is high. In a prospective study of 100 patients with gunshot wounds and routine skin closure, the wound infection rate was 11%.[3] Primary wound closure in the presence of severe fecal spillage is a significant risk factor for wound sepsis and fascia dehiscence. This high-risk group of patients is best managed by delayed primary closure of the skin 3–5 days postoperatively, or closure by secondary intention.

Antibiotic Prophylaxis

In view of the high incidence of septic complications in patients with colon injuries, appropriate antibiotic prophylaxis is critical. It is a standard practice to cover against both aerobes and anaerobes. In early studies, the combination of penicillin/aminoglycoside/metranidazole was a popular antibiotic choice. Subsequent studies showed that in penetrating abdominal trauma, single agents were as good as combination antibiotics.[80,81] However, practically, all available studies included a large number of fairly minor or moderately severe abdominal injuries and only a

small number of severe colon injuries with extensive fecal spillage. The reported overall incidence of intraabdominal abscess in abdominal trauma series is about 3%,[81] while in severe colon injuries it is about 19%.[6] The AAST destructive colon injury study identified single-antibiotic-agent prophylaxis as an independent risk factor for abdominal sepsis. The overall incidence of abdominal septic complications was 31% in patients who received single-agent prophylaxis and 16% in patients who received combination antibiotics (adjusted RR 1.78; 95% CI 1.12–2.67; $P = 0.02$). Further comparison of the two agents used for single-antibiotic prophylaxis (cephalosporin versus ampicillin/sulbactam) showed an abdominal infection rate of 37% in the cephalosporin group and 22% in the ampicillin/sulbactam group. (crude RR 1.67; 95% C1, 0.93–2.99; $P = 0.07$). It is possible that although single agents may be effective in minor or moderate trauma, they might be suboptimal in severe colon injuries. It is also possible that it might be necessary to cover against *Enterococcus*. Weigelt et al.[82] in a prospective randomized study of 595 abdominal trauma patients compared ampicillin/sulbactam with cefoxitin. The wound infection rate was significantly lower with ampicillin/sulbactam. The study suggested that the lower infection rate with ampicillin/sulbactam was due to better *Enterococcus* coverage.[82] The issue of antibiotic coverage in colon injuries merits further investigation. However, ampicillin/sulbactam (or similar antibiotics with *Enterococcus* coverage) prophylaxis in all suspected abdominal hollow viscous injuries is a reasonable choice.

The duration of antibiotic prophylaxis has been a controversial issue. There is now class I evidence that 24-h prophylaxis is at least as effective as prolonged prophylaxis for 3–5 days, even in the presence of major risk factors for abdominal sepsis, such as colon injury, multiple blood transfusions, and high abdominal trauma index. In a prospective randomized study of 63 patients with penetrating colon injuries and associate Abdominal Trauma Index ≥25 or ≥6 units of blood transfusions or delay of operation ≥6 h, Cornwell et al. reported an abdominal infection complication rate of 19% in patients who received 24 h antibiotic prophylaxis and 38% in patients who received 5 days prophylaxis.[7] With respect to rectal injuries, no study has addressed the type or length of antibiotic therapy. In the available studies that have even mentioned antibiotics, the length of therapy has been at least 2 days using single or double agents covering both aerobes and anaerobes.[46,73,78]

Stoma Related Complications

When deciding about the method of management of a colon or rectal injury, the surgeon should take into account the problems related to the creation of a stoma, and later on, the

FIGURE 26-4. End Colostomy in the presence of a complicated abdominal wound with protruding mesh. Closure of this colostomy is a high-risk procedure.

complications associated with the subsequent operation for colostomy closure. The presence of an ostomy is, in itself, a significant emotional trauma, especially in an image-conscious young person. In addition, the incidence of complications directly related to the ostomy construction is a significant one. The most common serious complications include necrosis, retraction, prolapse, parastomal abscess, and parastomal hernia. Less serious complications include troublesome skin irritation and poor location with difficulties in the application of the collection bag. Park et al., in a series of 528 stomas created for trauma, reported an incidence 22% of severe or minor early complications and 3% of late complications directly related to the stoma.[83]

The morbidity of colostomy closure is significant (Figure 26-4). In a collective review of 809 colostomy closures in trauma patients during the period of 1970–1990, the overall incidence of colon-related complications was 13.1% (major complications 5.3%, minor complications 7.8%).[44] Another study of 110 colostomy closures reported an overall local complication rate of 14.5%, including 2.7% colon leaks.[84] In a more recent collective review of 1,085 colostomy closures, the overall complication rate was 14.8%.[85]

The timing of colostomy closure does not seem to play an important role in the incidence of complications. Early studies had suggested colostomy closure should be performed after 3 months from the original operation to allow time for the colostomy to "mature".[86,87] Subsequent studies showed that closure of the stoma earlier than 3 months is safe and not associated with increased complication rates.[84,88] Some studies even recommended closure during the same admission of the injury, which is usually within 2 weeks of the colostomy construction.[89] The optimal time for colostomy closure should be individualized, and time should be allowed for wound healing and nutritional recovery. This might require only a few weeks for some patients or many months in severely injured patients.

Rectal Foreign Bodies

Rectal foreign bodies represent an uncommon cause of rectal injury, accounting for less than 5% of cases.[46,49,59] More commonly, patients present to the hospital with a retained foreign body. These patients present a surprisingly common management dilemma.[90] Most objects can be safely removed in the emergency department. However, a small percentage of patients will require general anesthesia and operative management with or without laparotomy. In one review of 87 patients presenting with a retained foreign body, 75% were successfully retrieved at the bedside while 8% required laparotomy with colotomy for foreign body extraction.[91] The only independent risk factor for operative intervention was if the foreign body was located in the sigmoid colon (OR 2.25; 95% CI, 1.1–4.4; $P = 0.04$). Abdominal films with AP and lateral views are helpful to define the foreign body and the orientation in the colon, in addition to excluding free intraperitoneal air.

Patients with a history of retained foreign body who present with peritonitis should be taken directly to the operating room. Without peritonitis, patients should have an attempt at retrieval at the bedside. If unsuccessful, patients should be taken to the operating room with an attempt at transanal extraction under intravenous sedation. As mentioned previously, patients most likely to require operative intervention are those with the foreign body located in the sigmoid colon.[91] The use of grasping forceps should be avoided, as it may lead to rectal mucosal injury. If transanal extraction is unsuccessful, then a laparotomy should be performed to maneuver the foreign body into the rectum for transanal removal.[91] If this is unsuccessful, then a colotomy may be necessary for foreign body retrieval.

One recently described method of distal foreign body removal is both effective and minimally invasive. Under general anesthesia, one or more lubricated Foley catheters or similar tubes may be passed transanally past the foreign body (Figure 26-5). The balloons are safely inflated to provide traction. Air is injected into the distal port, proximal to the foreign body to prevent "suction," while the foreign body is advanced. Once the foreign body reaches the anus, it is grasped with a clamp and removed.[92] This approach has proven successful in multiple patients at the author's institution. Following removal, sigmoidoscopy should be performed to exlude a mucosal injury or perforation.
FIGURE 26-5. The "Blow as well as pull" technique for removal of rectal foreign body.

IBD: Diagnosis and Evaluation

Walter A. Koltun

History

In 1932, Crohn, Ginzburg, and Oppenheimer described 13 patients with "regional ileitis" included in a total of 52 cases of nonspecific granulomatous inflammation of the intestine.[1] Prior to their publication, numerous others had reported various cases of what were in retrospect, probably Crohn's disease (CD), as early as 1813,[2] but it was their published description that established the formal classification of the disease syndrome and association with noncaseating granulomas. The surgeon involved in the care of the majority of the patients, Dr. AA Berg, did not want his name included in the article. Because of the variable clinical and anatomic manifestations of the illness, "CD" has subsequently become as common a descriptor of this disease entity as the term "regional enteritis."

The difficulty in distinguishing the colonic form of CD and ulcerative colitis (UC) confused the diagnosis and treatment of these illnesses until their differences were clarified by classic publications by Brooke in 1959 and Lockart-Mummery in 1960.[3,4] These authors pointed out both the segmental and granulomatous nature of the colitis in CD. In addition, Brooke contributed significantly to the treatment of these inflammatory bowel diseases (IBD) by introducing pioneering surgical techniques in the 1950s that created a more functional ileostomy, which until that time was a miserable and disabling consequence of colectomy.[5] Truelove and Witts in 1959 reported on a double-blind, controlled study demonstrating the value of high-dose cortisone as treatment for severe colitis.[6] Other turning points in the management and treatment of CD include the demonstration of the therapeutic value of metronidazole[7], 6-mercaptopurine[8], and more recently, the tumor necrosis factor-alpha (TNF-α) antagonist, infliximab.[9]

Surgical management of UC has been a continuous evolution, starting with colectomy/ileostomy,[10,11] supplanted by the continent Koch ileostomy[12], and finally the definitive reconstruction procedure known as the ileal-pouch anal anastomosis (IPAA), first described by Parks and Nicholls in 1978 and subsequently refined by Utsunomiya.[13,14] The IPAA is now the standard of care for the surgical correction of UC.

Epidemiology

The causes of UC and CD remain unknown, and thus epidemiological data have been collected over many years in the hope of providing some clue to the etiologies of these illnesses. Much of this data must be viewed with caution, however. Variations in diagnostic criteria, definitions of disease, and biases resulting from surveys done in tertiary care specialty centers make universal conclusions difficult. However, some general statements can be made using such data that relate to disease prevalence and associated risk factors (Table 27-1).

The prevalence of IBD greatly varies throughout the world. Prevalence is the product of incidence and disease duration. Since IBD symptoms tend to wax and wane in severity, prevalence may be underestimated in some studies. IBD is found in the more temperate climates of North America and Europe. Studies from these regions show prevalence rates much higher than those in Asia, South America, or Africa. Prevalence rates as high as 300–400 per 100,000 population are found in Minnesota (USA), Manitoba (Canada), and UK. Conversely, prevalence rates of approximately 23/100,000 are found in Japan, 10/100,000 in Singapore, and 75–120/100,000 in Israel. The relative incidence of CD versus UC is, again, variable, with either being found greater than the other depending upon the geographic region studied.[15–19]

It is generally recognized that both CD and UC have been increasing in incidence to a remarkable degree over the past 20–30 years with two- to tenfold increases depending on the population and region studied.[18,20] These dramatic increases suggest an environmental effect, since a genetic factor would probably not influence disease rates so rapidly.

CD most commonly occurs in the third decade of life, while UC is more common in the fourth decade. There may

              ↓ UC
  Appendectomy ↓ ulcerative colitis
  NSAIDS – ↑ symptoms of IBD

ETOH alcohol; UC ulcerative colitis; CD Crohn's disease; NSAIDS nonsteroidal anti-inflammatory drugs.

be a bimodal distribution of disease incidence with a second peak in the sixth or seventh decade, but this pattern remains unclear and may simply be due to difficulty in differentiating it from other colitides such as diverticulitis or ischemic colitis.

Though originally thought to be relatively rare in blacks, more recent case–control studies in USA suggest a similar incidence to whites, although Africa itself has a very low incidence of IBD.[17] There is great variability in the incidence of IBD in Jews around the world, but nonetheless seems to be consistently higher than that found in the non-Jewish population in most countries studied.[21] IBD is more common in urban, "indoor" populations of individuals of middle to upper socioeconomic status, suggesting the "hygiene" hypothesis that relates the lack of early exposure to environmental antigens to the later development of disease.[15,19,22]

There is very little evidence that a specific dietary factor causes disease, although increased sugar consumption is associated with CD and alcohol intake is inversely related to UC.[23,24] Childhood diarrheal illness, and oral contraceptive and nonsteroidal anti-inflammatory drugs (NSAIDs) use are measurable risk factors for IBD, with NSAIDs reported as precipitating relapse in patients with inactive disease.[25]

Smoking has been clearly shown to worsen CD, with increased risk of developing the disease de novo and increased risk of recurrence after surgical resection. Conversely, smoking is protective for UC, as is prior appendectomy.[26,27]

Genetic Disease Determinants in IBD

Approximately 20% of patients with IBD will have a family member also afflicted, implying a genetic basis for the disease. The recent development of sophisticated genetic mapping techniques combined with the recruitment of large groups of clinically characterized IBD patients has led to genome-wide association studies (GWAS) identifying areas (loci) in the human genome that are associated with the various forms of IBD. Fine mapping of these loci has led to the identification of specific mutations [or so-called single nucleotide polymorphisms (SNPs)] affecting specific genes that predispose to the development of IBD. As of mid-2009, an excess of 32 loci (most containing several potential disease-causing genes) was found for CD alone. UC appears to have less of a genetic component to its pathobiology, but similarly has at least 15 loci associated with it (Figure 27-1).[28–32]

Such genetic work has allowed the identification of relevant genes and thus physiologic pathways that are altered in IBD. Patterns are emerging with some genes playing a role in both illnesses, while others are confined to playing a role in only CD or UC. Many of these genes, however, can be integrated into a mechanistic paradigm which suggests that IBD is the consequence of an altered host immune response to various environmental factors, most probably enteric or commensal bacteria within the gut. Other factors may also play a role, such as smoking or NSAID use that further alters the host immune system or affects its function (Figure 27-2).[33]

The bowel and its epithelium are in fact an interface between the host and a relatively hostile environment. This barrier is made up of the mucous layer, the epithelium itself (enterocytes, goblet cells, and mucin-secreting paneth cells), and the underlying immunologic apparatus that includes lamina propria dendritic cells, regulatory and effector lymphocytes, and an extracellular matrix that contains cytokines and surface receptors that help guide and regulate the host inflammatory process. Thus mutations in any of these components of either host immunity (innate or acquired) or the epithelial barrier can potentially result in an abnormal inflammatory response to enteric bacteria with resulting destruction of the relatively fragile intestinal mucosa.

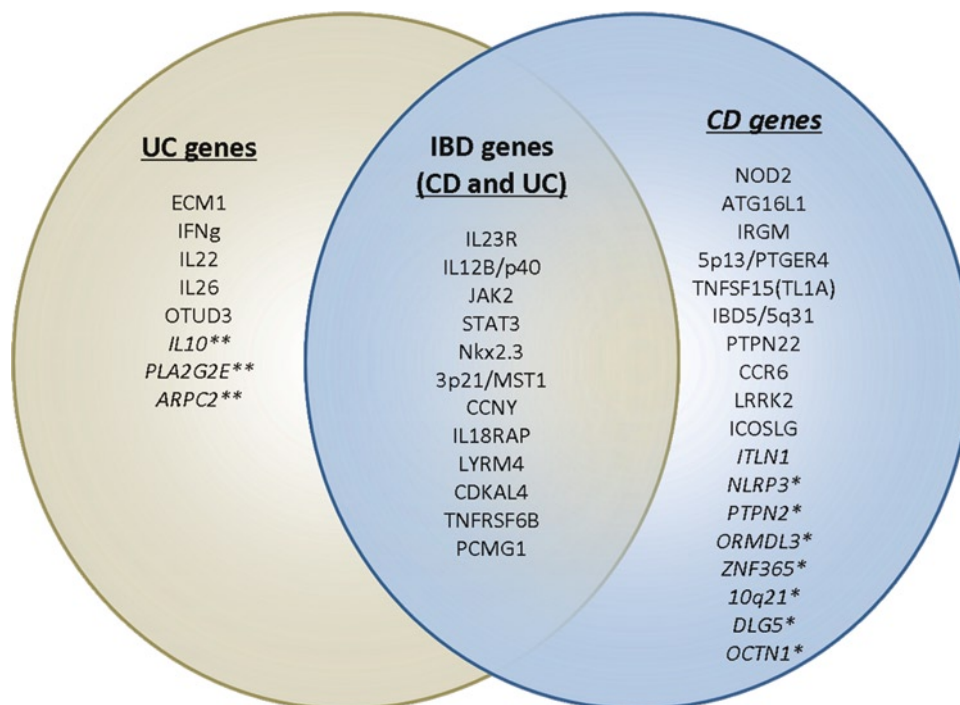
The first CD-associated genetic mutation was found in the NOD2/CARD 15 gene on chromosome 16.[34] This gene's protein product recognizes muramyl dipeptide, a component of bacterial cell walls, and activates NF-kappa B, a potent second messenger involved in immune regulatory mechanisms. Though a homozygous (double) mutation in this gene increases the risk of CD approximately 30-fold, any one patient with a mutation will still only have


FIGURE 27-1. Genes implicated in the pathogenesis of Crohn's disease and ulcerative colitis (as of late 2009). Some genes seem to play a role in both diseases. Not all genes have been confirmed by second investigators.
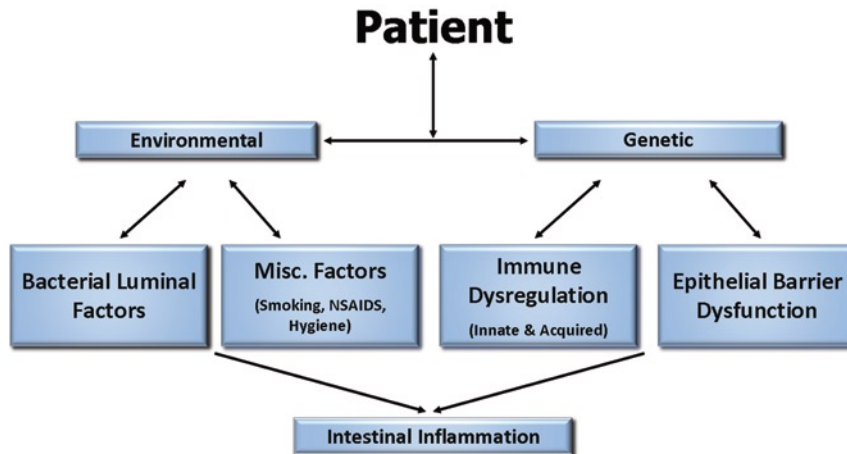

FIGURE 27-2. Pathogenesis of inflammatory bowel disease incorporating a genetic (predisposition) component and an environmental aspect, each of which may play a varying role in the individual patient.

a approximately 2.5% risk of developing CD, reflecting the role for other genetic determinants in the development of CD. Clinically, patients with this mutation tend to have earlier onset of disease in the ileocolic area.

The NOD2/CARD15 molecule is part of the innate immune system protecting the organism from invading enteric bacteria, but through the previously mentioned GWAS, several other genes affecting the innate immune system have been subsequently identified. Autophagy, i.e., the cell's ability to destroy and recycle defective cytoplasmic molecules including invading bacteria, is compromised by of mutations in the ATG16L1 and IRGM genes which have been associated with CD.[35] Similarly, mutations in the acquired immune system, especially those involving the IL-23 and IL-12 signaling

pathways, have been found. A mutation in the IL23R (receptor) gene has been shown to be *protective* against CD and UC.[29] Various alleles in other molecules found in the IL-23 pathway including JAK2, STAT3, and IL12B have also been linked with CD and UC. Experimentally, blockade of the IL-23 pathway has been shown to compromise bacterial clearance in some models, again reinforcing the concept that IBD is the consequence of an abnormal immune response to commensal gut bacteria.[36]

IBD-associated mutations have been found in many other genes, including DLG5 (coding for an epithelial cytoplasmic scaffolding protein), NKX2-3 (a developmental protein found in the lymphoid tissue of gut and involved in the expression of lymphocyte trafficking molecules), PTPN2 (involved in T-cell-dependant B-cell function), and IL-10R (receptor). Exactly how these mutations then lead to disease is often complex and not obvious. However, the relevancy of such genetic effects on the etiology of IBD is periodically validated by direct clinical discoveries. Such was the case for IL-10R where a clinical report described a severe early onset form of CD in two family pedigrees and several other children that were shown to be caused by homozygous mutations in IL10 receptor genes. This resulted in a hyperinflammatory immune response (increased secreted levels of TNF) associated with the clinical findings of proctitis with perianal fistulization, which was cured in one child by a bone marrow transplant from an IL-10R wild-type donor.[37]

The future of IBD management will likely depend on the reclassification of individual patients based on the genetic determinants of disease etiology. Both medical and surgical care will then be dictated not only by phenotype, but also by genotype. Improved responses to care interventions will be achieved by identifying which genetic determinants predict better results with specific therapies.

Signs and Symptoms

Gastrointestinal Symptoms

Crohn's Disease

CD can affect any portion of the gastrointestinal (GI) tract from the mouth to the anus. It is usually discontinuous, commonly involving several areas of the bowel at once, with sections of normal intestine interposed. The inflammation of CD involves the entire bowel wall, from mucosa to serosa and even into adjacent structures. These features are responsible for its presenting symptomatology.

The most common complaints of any patient with CD are abdominal pain and diarrhea, being found in over 75% of patients. Weight loss, fever, and bleeding are present in approximately 40–60% of patients, while anal symptoms of abscess and/or fistula occur in 10–20% of patients. Many classification systems for CD have been suggested, but the anatomic one has direct practical relevance in explaining

symptoms. CD is most frequently found in the ileo-cecal region, making up approximately 40% of patients. Abdominal pain most commonly correlates with disease in this region.[20] Colonic disease is found in approximately 30% of patients and most directly correlates with symptoms of diarrhea and bleeding. The remaining 30% of patients have disease confined to the small bowel proximal to the terminal ileum and correlates with abdominal pain, bloating, and a sense of postprandial nausea, especially if partial obstruction due to inflammation or stricture occurs. Anal disease is typically associated with patients having the terminal ileal and colonic distributions of disease.

The more recently developed Vienna classification of CD segregates patients into three categories based on behavior: inflammatory (B1), stricturing (B2), and fistulizing (B3).[38] This classification attempts to characterize disease biology but is imperfect. Patients will frequently change categories as disease progresses, since IBD commonly becomes stricturing or fistulizing disease. Louis et al.[39] over a 10-year period found that in 125 patients with CD, the B2 and B3 categories (stricturing and fistulizing) each increased from approximately 10% to approximately 30–40% with a compensatory decrease in the inflammatory, B1 category. Thus duration of disease plays a critical role in defining the category in this classification system.

Clinical severity of symptoms is widely variable, since CD typically has a waxing and waning course characterized by periods of disease activity interspersed with periods of remission. At any one time, approximately 50% of CD patients will be in clinical remission. The majority of patients (60–75%) will have alternating years of quiescence and disease activity. About 10–20% will have either a chronic, unremitting course or repetitive annual flaring of disease. Prolonged quiescence is found in about 10–15% of patients. The only useful predictor of future disease activity is past clinical behavior.

Ulcerative Colitis

The inflammation of UC characteristically starts in the rectum and extends proximally. The so-called backwash ileitis is the only possible area of the small bowel that can be affected in UC. If additional small bowel is involved, CD should be suspected. Clinical symptoms relate to the extent and location of disease. Thus rectal disease results in increased stool frequency, hematochezia, and tenesmus. Diarrhea is a frequent symptom and with tenesmus, it can result in incontinence, especially at night. In spite of severe rectal inflammation, constipation with a sense of incomplete evacuation can be a complaint in 20–25% of patients, but blood and mucous are nearly always present. With more proximal involvement, abdominal complaints increase including left lower quadrant pain and pain associated with peristalsis or stool evacuation. With increasing severity and extent of disease, nausea, vomiting, and weight loss ensue. Weight loss is due to both the loss of serum proteins through the diseased mucosa and the

reluctance of the patient to eat in order to avoid exacerbation of symptoms. The development of systemic signs of illness such as tachycardia, fever, and increasing fluid requirement bespeaks severe disease. High-dose steroids may disguise worsening abdominal complaints, including peritonitis, in such circumstances and should not divert the clinician from recognizing the gravity of the development of such symptoms and signs. The so-called toxic megacolon is a moniker that should be discarded, since severe life-threatening colitis may occur without colonic dilatation, and urgent surgical intervention should be based upon the triad of toxicity defined by tachycardia, fever, and elevated white blood cell count.

Extraintestinal Manifestations

Musculoskeletal

The most common non-GI complaints in IBD patients relate to the musculoskeletal system. Osteopenia and osteoporosis are very common, in part due to therapeutic steroid use, occurring in as many as 50 and 15% of IBD patients, respectively. Such bone density loss is now recognized as leading to significant comorbidity and complications in IBD patients. One study found a 40% increased risk of bone fractures in IBD patients.[40] The arthropathies associated with IBD are found in up to 30% of patients and are divided into two broad categories. Peripheral arthritis usually affects multiple small joints and has little relation to gastrointestinal disease activity. Axial arthritis (ankylosing spondylitis) is associated with certain HLA subtypes (B27) and is found in approximately 5% of both CD and UC patients. Its severity commonly parallels disease activity. Recently, anti-tumor necrosis factor (TNF) therapies have been shown to be effective in both CD and the arthropathy of IBD.[41,42]

Cutaneous

Pyoderma gangrenosum and erythema nodosum occur in approximately 0.5–5% of patients with IBD. These, as well as oral lesions such as aphthous stomatitis and pyostomatitis vegetans, are more commonly associated with CD than UC and commonly parallel underlying gastrointestinal disease activity. The new appearance of pyoderma gangrenosum around the ileostomy of an IBD patient after colectomy is unexplained but is a clear clinical phenomenon.[43] There is a reported increased rate of psoriasis and eczema in IBD patients that does not parallel disease activity. One-third to one-half of patients with pyoderma gangrenosum have IBD.[44]

Hepatobiliary

Primary sclerosing cholangitis (PSC) has a reported incidence of approximately 3% in both CD and UC patients. It may present independent of intestinal disease activity, and colectomy in UC patients does not affect the progression of liver disease. The presence of PSC in the UC patient increases the risk for malignant disease in both the colon and the hepatobiliary system.[45]

Several studies have suggested an increased incidence of gallstones in IBD, especially CD, although this is disputed. The mechanism is presumed to be due to an altered enterohepatic biliary circulation due to ileal disease.[46]

Ophthalmologic

Iritis, uveitis, and episcleritis can affect 2–8% of patients with UC and CD, respectively, and are generally unrelated to disease activity. Iritis and uveitis present as blurred vision, eye pain, and photophobia and requires prompt treatment to avoid scarring and even blindness. Episcleritis is typically less threatening and is characterized by scleral injection, burning, and tearing.

Coagulopathy

There is an identified increased risk of deep venous thrombosis (DVT), mesenteric thrombosis, and pulmonary embolism (PE) in IBD patients that are not explained simply by increased hospitalization and surgery. Decreased protein S and antithrombin III levels due to mucosal loss and increased levels of acute-phase reactants including factors V and VIII have been implicated. Mortality due to postoperative mesenteric thrombosis in the IBD patient has been reported to be as high as 50%, but probably occurs more frequently than previously recognized with an overall lower mortality and milder forms of morbidity.[47–49] Anticoagulation and work-up for coagulation disorders are usually recommended.

Disease Severity Assessment

Crohn's Disease

The CD activity index (CDAI) is the most commonly used method for quantification of disease severity in CD. It was developed by Best et al. using multiple regression analysis and includes a total of eight items that are measured, multiplied by respective weighting factors, and then summated to yield a score (Table 27-2). It is generally accepted that a total score less than 150 points indicates quiescent disease, whereas over 450 indicates severe, active disease. Relapses are defined as a score rising to over 150 or an increase of 100 points over baseline. The CDAI is most commonly used in longitudinal clinical studies to evaluate the results of experimental interventions. It suffers from many deficiencies including its reliance on subjective complaints and that it is time consuming, requiring the patient to keep a diary for 7-day periods defining symptomatology. Some measured symptoms, such as diarrhea and belly pain, may reflect short gut due to prior surgery or strictures that do not represent active IBD.[50] Other indices have been developed

TABLE 27-2. The Crohn's disease activity index (CDAI)

Item calculation	Data collected weighing factor	
No. of liquid stools	7-Day diary 2	Sum of 7 days
Abdominal pain	0–3 Scale, 7-day diary 5	Sum of score for each day
General well-being	0–4 Scale, 7-day diary 7	Sum of score for each day
Symptoms[a]	At clinic visit 20	Sum (6 total) possible
Lomotil use	7-Day diary 30	Yes = 1, No = 2
Abdominal mass	At clinic visit 10	None = 0, questionable = 2, definite = 5
HCT	At clinic visit 6	M: (47 subtract patient's HCT) F: (42 subtract patient's HCT)
Weight	At clinic visit 1	% below ideal weight

HCT hematocrit.
[a]Symptoms include presence or absence of each of arthritis/arthralgia, iritis/uveitis, erythema nodosum/pyoderma gangrenosum/aphthous stomatitis, anal fissure/fistula/abscess, other fistula, or temperature >100°F.

TABLE 27-3. Truelove and Witts ulcerative colitis activity index

	Mild	Severe

in an attempt to address these criticisms. The Harvey Bradshaw index (or modified CDAI) and the Van Hees Index, which relies entirely on nine objective factors such as ESR, albumin, temperature, and stool consistency, are two such measurement tools, but they are infrequently used, even in protocol settings.[51] The Vienna classification, discussed above, is an attempt to classify or categorize subsets of CD patients and is not used as a severity assessment tool.[38] A perianal CD activity index has also been described.[52]

Ulcerative Colitis

The benchmark study by Truelove and Witts in 1955 evaluating the effect of cortisone on UC also described the still most often used clinical assessment tool for severity assessment in UC (Table 27-3).[6] The simplicity and clinical relevancy of the factors in this index allow for its daily use as a clinical tool and also for clinical response in study protocols. Variations in its initial format have included the creation of a "moderate"

category for patients displaying features intermediate in value between the mild and severe categories. This index also does not take into account variability in the anatomic extent or observed severity of disease within the colon. Modern clinical studies requiring disease assessment will thus often use a variation in the Truelove and Witts classification, which will include additional criteria based on colonoscopic appearance and possibly pathologic severity as well.[53,54]

Evaluation

Radiology

The diagnosis of IBD depends on the triad of clinical presentation, radiologic work-up, and histopathology of tissue biopsy. Thus radiologic studies are critical in the evaluation of the patient with suspected or confirmed IBD.

Plain X-Rays

Conventional radiologic studies play a significant role in the work-up and management of IBD. Plain abdominal radiographs can show signs of obstruction, perforation (free air), and at times thickening of the bowel or loss of haustral markings. The initial presentation of any patient with abdominal pain and a known or suspected diagnosis of IBD will incorporate a plain and upright film to look for these features. On the plain film, air can act as a contrast medium and can allow the identification of the more subtle findings of nodularity of the mucosa, suggesting ulceration or pseudopolyp formation. Chronic colitis may result in an ahaustral, tube-like colon that can be seen with air contrast (Figure 27-3). Fulminant colitis may result in toxic dilatation (toxic megacolon) that mandates surgical intervention and the specific avoidance of colonoscopy or contrast enema studies that may result in perforation. Incidental discoveries of gallstones or renal calculi that occur with increased incidence in patients with IBD may also be made.

Contrast Radiologic Studies

Contrast studies will more frequently be used in patients with CD than in those with UC due to its predisposition for small bowel involvement. For the colitic patient, whether due to CD or UC, colonoscopy is usually the preferred study, frequently obviating the need for barium enema. However, a double-contrast barium enema may still be used to discover or delineate the extent of disease in patients with gastrointestinal symptoms, especially when due to CD. Colonic contrast studies in the patient with CD can reveal segmental disease, strictures, and fistuli. Reflux into the terminal ileum occurs in approximately 85% of patients and can more effectively reveal ileal disease than small-bowel follow-through due to

FIGURE 27-3. Plain radiographs of a patient with worsening symptoms of ulcerative colitis. Note the ahaustral left and transverse colon, signs of small bowel ileus and enlarged ("mega") transverse colon.

less interference by other intestinal loops. When fistuli or near obstructing strictures are suspected, a water-soluble dye such as Gastrografin is preferred. This contrast medium minimizes the complications associated with possible extravasation of the agent if a fistula or intestinal perforation is present or with subsequent impaction of barium proximal to a stricture. Frequently, in patients with CD, an unsuspected rectal fistula tracking to a diseased terminal ileum is found on rectal contrast study (Figure 27-4). Such a fistula can be easily overlooked during colonoscopy because it almost always originates with the diseased terminal ileum, while the rectum and sigmoid are normal.

The difficulty of reaching the small bowel using fiber-optic instruments necessitates the common use of small bowel contrast studies to assess the degree of CD involvement of the small bowel. A small bowel series can effectively show areas of stricturing and upstream dilatation but may be difficult to perform or interpret due to slow intestinal transit from strictures, overlying loops of bowel, and pain associated with compression spot views (Figure 27-5). Enteroclysis is preferred over simple small-bowel follow-through, although the need for the placement of a naso-intestinal tube makes patient cooperation and satisfaction with this study much less. High-density barium must be used as the contrast agent, since water-soluble dyes rapidly dilute in the small bowel, making detailed assessment of the intestinal mucosa difficult. After placement of the nasal tube beyond the pylorus, relatively small boluses of barium are injected that coat the walls of the intestine and then air is insufflated to distend the bowel, allowing detailed examination of the mucosa. Repetitive infusions of dye and air, with subsequent spot compression films, can result in remarkable detail being revealed but results are clearly dependent on operator expertise and patient cooperation.

FIGURE 27-4. Small-bowel follow-through contrast study showing terminal ileal stricturing disease, with displacement of adjacent bowel loops due to ileal thickening.

FIGURE 27-5. Colonic contrast study in Crohn's disease patient showing complex fistulizing disease. Contrast is present in the proximal, diseased ileum and air and contrast in the bladder due to fistulizing disease.

Gastrointestinal contrast studies surpass computed tomography (CT) for detecting enteroenteric and enterocolic fistuli.[55] The discovery of an enteric fistula can be made when orally consumed contrast material is seen in a distal portion of bowel without illuminating intervening intestine, such as can occur with ileal disease fistulizing into the rectum.

Sometimes the dye will directly illuminate the fistula or the involved organ, such as the bladder, as it tracks from the bowel irrespective of whether the contrast is given orally or rectally (Figure 27-4).

Sinography or fistulography can be used to delineate the path or origin of fistulous disease in patients with CD, whether involving the abdominal wall or the perineum. Such studies can also be done via the drainage catheter after percutaneous drainage of an abscess to document intestinal communication and should be done again with a water-soluble contrast agent. Such anatomic localization assists in directing subsequent surgical care (especially when fistulous disease involving the urinary tree is found) and assessing response to therapy.

Retrograde studies through a stoma, especially an ileostomy, can provide very good evaluation for disease. The effectively foreshortened intestine allows better delineation of disease with less overlapping bowel loops and better double-contrast definition.

Computed Tomography

Abdominal and pelvic CT is probably the most commonly obtained study in the acute evaluation of patients with IBD, especially CD. Such studies should be undertaken with orally ingested low-density barium or iodinated contrast material that has been allowed to traverse the entire GI tract. Due to strictures or slow transit time, rectal administration of contrast material will sometimes be necessary. CT scanning is especially useful for delineating enterovesical or colovesical fistuli, and scans should be obtained before administering intravenous contrast, as contrast originating from the bowel will be seen in the bladder defining the fistula. Air within the bladder without prior instrumentation is also a very sensitive sign defining the presence of a fistula.

The great advantage of CT is its ability to evaluate the entire thickness of the intestine and its adjacent structures. Thus, thickened intestine, phlegmon, abscess, air in extraintestinal structures, and fistula formation are signs of CD that can be found on CT scan (Figure 27-6). Percutaneous drainage of abscess collections done under CT guidance can also be performed. Though less commonly performed for UC, CT findings that can be seen include increased perirectal and presacral fat, inhomogenous areas of colonic thickening, target or "double halo" sign of the colon, and changes consistent with cancer development such as strictures or mass lesions.[55]

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is playing an increasing role in the evaluation of IBD patients. Intestinal CD can be identified simply by thickened bowel loops on conventional MRI. However, MRI differs from CT, in that the intensity of T2-weighted signals from areas of disease correlates with the severity of inflammation, especially after gadolinium

FIGURE 27-6. Computed tomography scan of Crohn's disease patient with severe terminal ileal thickening and early abscess formation under anterior abdominal wall.

administration. Such signal intensity in both the mesentery and bowel decreases with resolution of acute inflammation and may hold promise for monitoring the response of patients to medical therapy.[56,57]

The value of MRI in defining perineal disease in the CD patient approaches – and may exceed – that achieved with examination under anesthesia.[57,58] Endorectal coil placement may improve sensitivity but is infrequently necessary and sometimes impossible in the diseased anus. Intravenous injection of gadolinium highlights the fistula tract and combined with MRI's ability to define soft tissue anatomy accurately, it can result in remarkable delineation of disease.[59,60] MRI testing is expensive, however, and is probably unnecessary in the conventional perineal CD patient since examination under anesthesia performed by a competent surgeon is usually as accurate and can also aid in providing simultaneous treatment.[58] However, MRI is finding a role in re-assessing the failed patient for unrecognized pathology and, more recently, in defining whether medical treatment with infliximab has truly healed a patient's fistulous disease. Several studies using gadolinium-enhanced MRI have shown that many fistuli that respond to exclusive medical management are, in fact, still present but quiescent.[61,62]

Ultrasound

The role of ultrasound in IBD is presently very limited. European centers are more familiar with its use for assessing the GI tract in patients with IBD where it is sometimes used to assess a patient's response to therapy longitudinally. In the hands of an experienced operator, so-called transabdominal bowel sonography (TABS) can look for bowel wall thickening and fistula formation, and can even assess functional effects of strictures by observing bowel peristalsis and

distention in the vicinity of such pathology[63]. This method of noninvasive intestinal evaluation has not gained wide popularity in USA.

Intrarectal ultrasound can be used to document and map perianal fistula formation by injecting a solution of hydrogen peroxide into the external opening. The resulting bubbles are easily seen on ultrasound as they outline the path of the fistula tract. However, such uncomfortable and operator-dependent techniques of fistula assessment have been largely replaced by MRI scanning (see above).

Nuclear Medicine

The injection of radionuclide-labeled white cells allows subsequent scintigraphic imaging of the abdominal organs and is increasingly being used as a technique to visualize actively inflamed bowel. Most techniques use Indium[111] labeling of autologous leukocytes that are harvested from the patient, labeled, and then reinjected. Indium[111] has the advantage of a long half-life that allows scanning at 6, 12, and 24 h with any visualized bowel activity as being abnormal. A fixed area of activity suggests an abscess. Newer techniques using Technetium –99m-haxamethyl-propylamine-oxime (HMPAO) provide for better image quality due to its relatively selective labeling of granulocytes and also result in a lower radiation dose to the patient. Some studies using this tracer have shown very high sensitivity rates, but specificity is less due to its inability to differentiate between IBD and infectious causes of disease.[64] The advantage of such radionuclide scanning techniques relates mostly to their ability to differentiate between inflamed versus quiescent disease, and their use will probably increase as newer labeling agents are devised.

Endoscopy

Colonoscopy has strongly influenced the diagnosis and evaluation of the patient with IBD. It is the study of choice for the patient with suspected UC since it can directly visualize the entire extent of the disease process. It is similarly relevant for CD when involving the colon, and can also be used to intubate and evaluate the terminal ileum. Most significantly, colonoscopy provides biopsies, which allows a tissue diagnosis to be made by the pathologist. There are numerous indications for colonoscopy in the patient with IBD (Table 27-4) and as such, colonoscopy plays a significant role in the evaluation and management of these patients. The gross appearance of the colon as seen on colonoscopy can frequently differentiate between CD and UC (Table 27-5). Its use in the patient with severe disease is controversial. Although studies exist suggesting that it can be safely undertaken in the severely colitic patient, the risk of perforation due to insufflation, biopsy, or mechanical bending of the scope is generally acknowledged as being high and thus colonoscopy is generally avoided in the acute setting. However, such severely ill patients still need endoscopic evaluation to exclude concurrent diseases such as pseudomembranous or cytomegalovirus-induced colitis. Rigid or flexible proctoscopic evaluation is thus recommended, with biopsies done in the lower rectum below the peritoneal reflection in order to minimize the risk of free perforation.

The flexible sigmoidoscope is conveniently used for the evaluation of the unsedated, office patient, but is limited by its 65-cm length to visualize the colon up to approximately the splenic flexure. However, this evaluation can often be adequate and, in the case of UC, definitive. In the patient with typical presenting symptoms of bloody diarrhea and tenesmus, a flexible sigmoidoscopy with biopsies and stool culture for pathogens and ova/parasites may complete the work-up and make the diagnosis.

There is an increasing experience with through-the-scope (TTS) pneumatic dilatation of colonic or ileocolonic strictures in CD. The technique incorporates repetitive insufflation of the TTS balloon for 15–60-s periods, with the larger balloons (25 mm) being associated with more patient pain and

complications than the smaller ones (12 mm). In a prospective study of 55 patients, long-term success (mean follow-up of 34 months) with complete relief of obstructive symptoms was achieved in 62% of patients, while 19 (38%) patients required operation and six (11%) suffered a perforation.[65]

Upper endoscopy or esophagogastroduodenoscopy (EGD) will infrequently be used in the management of CD since gastroduodenal CD occurs in less than 5% of patients. However, when CD does affect the stomach or duodenum, strictures are common, and therapeutic dilatation and biopsies to evaluate for malignancy via EGD are necessary. More commonly, EGD is useful in the evaluation of the differential diagnosis of upper abdominal pain or dysphagia in the IBD patient. Esophageal candidiasis brought on by immunosuppression, duodenal or gastric ulcerative disease due to steroids, or reflux disease from downstream partial obstruction occurs with increased frequency in the IBD patient and is well evaluated by EGD. The so-called push enteroscopy using specially designed flexible scopes has been developed to improve access of the endoscopist to the jejunum, but its use is very limited. The preferred study for the evaluation of small bowel CD is still small-bowel contrast follow-through, enteroclysis, or CT enterography.

Wireless Capsule Endoscopy

Wireless capsule endoscopy (WCE) is a recent unique development for the visualization of the small bowel. An 11×26 mm capsule is swallowed that transmits two video images per second to a receiver worn on the belt. Over the 8-h battery life of the device, more than 50,000 images are transmitted and stored that are subsequently evaluated at 25 frames per second by dedicated software and the human eye. Subtle small bowel lesions, usually out of the reach of the colonoscope or upper endoscope, can be appreciated. Its role in CD is still being clarified, but criteria for its use include the recommendation for prior colonoscopy and intubation of the terminal ileum. Many studies using WCE have found CD in the most common regions that can be easily reached by a colonoscope, obviating the need for the more expensive WCE. In addition, a small-bowel contrast series is also necessary since the size of the capsule may cause it to impact at a stricture, precipitating acute bowel obstruction requiring surgery. Other problems include its limited battery life in patients with slow transit, the inability to biopsy, and its imperfect localization of identified lesions. Nonetheless, this technology provides an added and potentially more sensitive tool in the diagnosis and management of patients with CD.[57,66,67]

Pathology

Ulcerative Colitis

UC begins in the rectum and extends proximally to a variable distance, with the worst disease being distal and the least disease being proximal. The disease may be limited to the rectum (ulcerative proctitis), or extend to only the left colon or completely to the cecum (pancolitis). The terminal ileum may be inflamed in continuity with the cecum (backwash ileitis). The disease is in continuity, and segmental or "skip" disease does not occur, although the so-called rectal sparing or some degree of patchiness can be seen in the actively treated patient, especially when enema therapy has been given. The gross appearance of the inflammatory process depends on the severity and duration of the disease (Table 27-5). In early disease, inflammation is restricted to the mucosa but in its severest, toxic form, it can become transmural and indistinguishable grossly and histopathologically from CD, with deep ulcerations, pseudopolyp formation, and variable areas of thickened and thinned colonic wall.

The histopathologic features of UC are listed in Table 27-6. There are no pathognomonic features of UC and in its extreme form, it can resemble CD. However, typical UC is associated with inflammation limited to the mucosa or lamina propria, including relatively uniform crypt distortion and crypt abscesses. Goblet cell mucin depletion is common and the inflammatory infiltrate is usually neutrophilic, two features that distinguish UC from CD where mucin depletion is uncommon and the inflammation is usually mononuclear. More severe UC leads to the entire loss of the crypt, with deeper submucosal and transmural inflammation and ulceration. In the chronic, more quiescent phase, UC will have mucosal reconstitution but will still have crypt distortion, foreshortening, and branching. Inflammation will be variably reduced, or even absent, but when present, it will be relatively uniform in distribution. Dysplasia in long-standing UC is common but can be interpreted only in the setting of

TABLE 27-6. Histology of inflammatory bowel disease

	Ulcerative colitis	Crohn's disease
Early		
	Crypt distortion, branching	Patchy crypt distortion
	Goblet cell mucin depletion	Minimal goblet cell mucin depletion
	Vascular congestion (without inflammation)	Aphthoid ulcers
	Mucosal inflammation	
Intermediate		
	Uniform crypt abscesses	Focal crypt abscesses
	Loss of mucosa with retention of crypts	Vasculitis (20%)
	Noncaseating granulomas	
	Lamina propria neutrophils	(20–60%) Mononuclear cell infiltrate
Advanced/late		
	Crypt destruction	Transmural inflammation
	Neuronal hyperplasia uncommon	Neuronal hyperplasia common
	Deeper submucosa inflammation	Mucosal and submucosal
	Pseudopolyp, mucosal thickening bridging	Fibrosis and strictures
	Dysplasia common	Dysplasia uncommon

non-inflamed bowel, since many of its features are common with inflammation, namely, crypt distortion, increased mitotic index, and nuclear atypia.

Crohn's Disease

The gross features of CD include its ability to affect any portion of the GI tract, its transmural inflammation, and its propensity to create fistulas and strictures, including in the perianal area. Skip lesions are common, resulting in multiple areas of bowel affected simultaneously with intervening segments of normal intestine. Diseased bowel may fistulize into adjacent bowel that is otherwise unaffected, a type of bystander injury that only requires surgical removal of the offending segment of intestine with primary repair of the fistula in the remaining, healthy bowel. Serositis is common in CD, as is fat wrapping or creeping fat, all nonspecific responses to the observed transmural inflammation. On the mucosal surface, the earliest changes are aphthous ulcers, which are tiny white pinpoint lesions representing mucosal ulcerations in the vicinity of enlarged lymphoid follicles. These lesions are thought to then enlarge and coalesce into the larger, deeper longitudinal serpiginous ulcers commonly found in CD. These areas will have a deep, fissuring appearance and will extend ever deeper into the bowel wall, infrequently perforating freely, but instead recruiting an inflammatory response from adjacent organs that tend to wall off the inflamed bowel and that can then lead to fistulization. Healing is associated with granulation tissue and stricture formation, features not commonly found in UC.

Microscopically, the inflammatory infiltrate is commonly mononuclear and there is minimal goblet cell dropout in the mucosa. When crypt abscesses occur, they are nonuniform, affecting some crypts and not others. Vasculitis is sometimes seen (20%) and neuronal hyperplasia is common, both features that are rarely seen in UC. The classic noncaseating granuloma is found in 20–60% of patient biopsies and is composed of epithelioid and giant cells of the Langhans type. Granulomas probably wax and wane in their presence and can also be found in adjacent tissues affected in continuity, such as bladder, lymph nodes, ovaries, and perianal squamous epithelial skin tags. Their significance remains unclear, with some suggesting that they indicate a less aggressive form of CD.

Indeterminate Colitis

Approximately 10–15% of patients with colitis will have either clinical or pathologic features that do not allow a clear diagnosis of either CD or UC to be definitively made. This dilemma is often attributable to rapidly deteriorating, fulminant colitis, where even UC can have transmural or irregular mucosal involvement. Sometimes the gross anatomic appearance is complicated by incomplete response to various medications, especially when delivered transanally

as enemas, which can lead to relative "rectal sparing" and, therefore, suggest CD over UC. Frequently, the correct diagnosis involves the judgment of an experienced clinician who considers not only the histopathology, but also the clinical characteristics of the patient, the history of disease progression, and even more subtle data such as serum antineutrophil cytoplasmic antibody (ANCA) and ASCA testings (see Serum Tests for IBD). More than half of such indeterminate cases can usually be resolved with such consideration of the entire clinical picture. This is especially important in the patient who is a candidate for pelvic pouch reconstruction, where the results of such surgery are significantly worse in the misdiagnosed patient with CD.[68]

Serum Tests for IBD

Serum tests for IBD can be divided into several categories: acute phase reactants, nutritional parameters, and inflammatory markers. The prototypic acute phase reactant is the erythrocyte sedimentation rate (ESR), which is commonly used, especially in CD in spite of its imperfect correlation with disease activity. It is a necessary component to determine the CDAI (see section above). Some have suggested that ESR correlates better with colitis, either CD or UC, than with small bowel CD. This may be due to the fact that ESR may be normal in CD patients with noninflammatory disease who nonetheless may be very symptomatic due to the presence of "burned-out" fibrotic strictures.[69] Conversely, an acute abscess from a long-standing fistula in ano may elevate the ESR without any evidence for flaring of intestinal disease. Similar difficulties have been encountered in correlating disease status with other acute phase reactants, such as C-reactive protein (CRP), orosomucoid (alpha-1-acid glycoprotein), alpha-1-antitrypsin, and alpha-2-globulin.[70] The fecal excretion of alpha-1-antitrypsin when measured as a clearance ratio has some correlation to active intestinal disease, but difficulty with collection methodology makes this test rarely used. Presently, ESR and possibly CRP are the only two tests commonly used in the clinical arena.

Nutritional parameters are commonly used to assess the consequence of acute and subacute disease in IBD. Albumin, prealbumin, and iron (transferrin and serum iron) studies are reflective of the combined effects of decreased food intake (to minimize symptoms), compromised absorption (from inflammation or surgical shortening of the bowel), and increased losses (from loss of proteins and blood from mucosal ulceration). B12 is commonly decreased in CD patients with ileal disease or after surgical resection. Such nutritional tests are nonspecific, but extremely valuable in clinical decision making from either a surgical or a medical perspective. Other relevant serum studies include liver function testing that may reveal subclinical primary sclerosing cholangitis.

Research into the immune regulatory pathways that play a role in the inflammation seen in IBD has resulted in the

identification of numerous chemokines that are altered in IBD.[45] Many of these, including IL-1, IL-2, IL-6, IL-8, TNF, CD45, soluble IL-2, and interferon-gamma, have not been used beyond investigative protocols for a number of reasons. Frequently, serum levels of these cytokines do not correlate with the abnormal levels found in the affected tissues, thus obviating their use as serum tests. A possible exception may be the soluble IL-2 receptor (sIL-2r). Increased serum levels of sIL-2r seem to correlate with mucosal inflammatory activity. Levels drop with response to therapy in parallel with the CDAI, and high levels have been predictive of clinical relapse.[71]

Perinuclear antineutrophil cytoplasmic antibody (pANCA) is an autoantibody found in the serum of approximately 50–70% of UC patients, but only in 20–30% of CD patients.[72] It does not correlate with disease activity, but is thought to indicate a more aggressive disease type, due to its association with patients who are relatively resistant to medical management and also with patients who commonly suffer pouchitis after IPAA.[73,74] Another serum antibody, to a common yeast, *Saccharomyces cerevisiae* (ASCA), has been shown to be present in 50–70% of CD patients but only in 10–15% of UC patients. Thus, the measurement of both ANCA and ASCA is increasingly being used to try to differentiate between CD and UC when the disease is limited to the colon and confusing features, such as rectal sparing, exist.

Recently, a number of genetic mutations have been discovered which are associated with Crohn's disease. The presence of these mutations can be assayed using the DNA of leukocytes harvested by peripheral blood draw. Three mutations affecting the CARD15/NOD 2 gene on the short arm of chromosome 16 have been identified as being associated with CD.[34,75] The NOD2/CARD15 gene codes for an intracellular protein that has high binding affinity for bacterial peptidoglycan and may play a role in innate immunoresponsiveness to enteric bacteria. Mutations in this gene are found in approximately 10–30% of CD patients versus 8–15% of healthy controls. The relative risk of developing CD if mutations are carried in both copies of this gene is 10–40 times that in the general population. The presence of this mutation in a patient with CD is associated with ileal disease, earlier age of onset, and possibly fibrostenosing characteristics.[76,77] Mutations can be easily assayed by polymerase chain reaction (PCR) techniques, and hold promise for possibly predicting responsiveness to medical or surgical therapies.

Evaluation of the Acute Patient with Acute Exacerbation of IBD

The clinical and laboratory evaluation of the patient presenting with IBD will depend on many factors. Obviously, a good history and physical examination will focus the clinical caregiver

in one or another area that will then direct subsequent testing and care. Many of the testing regimens described previously in this chapter apply to a greater or lesser degree based on clinical circumstances. There is no one good test for IBD, so the clinical judgment, experience, and acumen of the physician are key in patient management. Nonetheless, there are some basic and fundamental testing regimens that should at least be considered, if not repetitively performed, whenever IBD is considered the possible diagnosis. A basic outline of evaluation of the acutely presenting IBD patient is found in Table 27-7. It is important to remember that the patient with a known diagnosis of IBD will frequently still require such a basic evaluation whenever the disease flares. This need is in part due to the recognition that these patients are at significant risk for the development of a superimposed secondary diagnosis not infrequently related to iatrogenic causes. These associated problems might include pseudomembranous or cytomegalovirus colitis, stress or steroid-induced gastric ulceration, fungal sepsis, or neutropenia. In addition, a patient known to have IBD who presents with worsening symptoms may have progression of the disease or the development of a directly related complication, such as an intraabdominal abscess, bowel obstruction, toxic colitis, or colovesical fistula. Thus the studies outlined in Table 27-7 should be regularly considered for the patient presenting with an acute exacerbation of IBD, tempered by the good clinical judgment of the caring physician.

TABLE 27-7. Evaluation of the patient with inflammatory bowel disease

	Test	Purpose
Serum labs	CBC	r/o anemia, leukocytosis
	Electrolytes, renal function	r/o electrolyte disturbance 2° diarrhea, dehydration
	ESR, +/– CRP	↑ in systemic disease
	LFT's, albumin	r/o PSC, nutritional compromise
Stool studies	C. difficile	r/o infectious causes
	O&P	r/o infectious causes
	Pathogens	r/o infectious causes
X-rays	Plain abdominal X-rays	r/o free air, toxic colitis, stones, obstruction
	SBFT/enteroclysis	For small bowel disease
	Barium/Gastrografin enema	For fistuli, strictures, and distribution of disease
	CT scan	For abscess, obstruction, fistuli, and adjacent organ involvement
Endoscopy	Flexible/rigid scope	For biopsy to r/o CMV, granulomas, pseudomembranes
	Colonoscopy	For biopsy, visualize extent and severity of disease

SBFT small-bowel follow-through; *r/o* rule out; *CMV* cytomegalovirus; *LFTs* liver function tests; *CT* computed tomography; *O&P* ova and parasites; *ESR* erythrocyte sedimentation rate; *CRP* C-reactive protein; *CBC* complete blood cell count; *PSC* primary sclerosing cholangitis.

IBD: Medical Management

Bruce E. Sands

Introduction

Crohn's disease (CD) and ulcerative colitis (UC) are inflammatory conditions characterized by periods of symptomatic relapse and remission. The cause of inflammatory bowel disease (IBD) is unknown but it is believed to be caused by a combination of environmental, genetic, and immunological factors in which an uncontrolled immune response within the intestinal mucosa leads to inflammation in genetically predisposed individuals. Multifactorial evidence suggests that a defect of innate immune response to microbial agents, as well as abnormalities in adaptive immunity and epithelial barrier function are involved in IBD.[1]

The goals of therapy for IBD include controlling symptoms, improving quality of life and minimizing short-term and long-term complications of disease and treatment. Therapy is guided by the anatomic extent of inflammation, the severity of clinical symptoms, patient response to treatment, adverse outcomes related to treatment and the occurrence of disease complications. There are two phases of treatment: (1) inducing remission in active disease and (2) maintaining remission. Surgery is usually reserved for treating medically refractory disease or for specific complications; however, appropriate timing for surgery requires considerable judgment about the anticipated risks, benefits, and outcomes of surgery.

Crohn's Disease: Medical Management

CD is a chronic inflammatory condition that can affect any area of the gastrointestinal tract from the mouth to the anus. The disease most commonly affects the ileum and colon. Inflammation in CD disease tends to be focal, asymmetric, transmural, and occasionally granulomatous. In addition, CD may be complicated further by penetrating (fistula, abscess) or cicatrizing (stricture) complications. Such complications are variable in their rate of occurrence, with some individuals presenting early with complicated disease behavior, and others never developing such complications over long periods of observation. Recurrent disease tends to manifest with the same complications. Therefore, a patient who requires a resection for ileal stricture is at increased risk for a second surgery for the same complication, and patients who demonstrate fistulizing disease behavior are likely to have recurrent fistulas. It is also possible to find both sorts of complications in the same individual. In particular, enteroenteric or enterocolonic fistulas may arise behind high grade strictures.

Given the variability of disease location and complications, symptoms and their severity are highly variable among individuals. Characteristic symptoms of CD include diarrhea, sometimes including nocturnal diarrhea, abdominal pain, and fatigue. Rectal bleeding may occur in CD but is less common than in UC. Clinical signs include fever, weight loss, pallor, an abdominal mass or tenderness, and perianal conditions, including fissure, fistula, or abscess. Extraintestinal manifestations are also common. These include arthralgias or frank arthritis; inflammatory conditions of the eye, including scleritis, iritis, or uveitis; skin conditions such as erythema nodosum or pyoderma gangrenosum; and mouth sores.

Mild-to-Moderate Crohn's Disease

Individuals with mild to moderate disease have fewer than four stools daily, are ambulatory, and able to tolerate solid foods and liquids. Often these individuals do not experience abdominal tenderness and do not have an abdominal mass. Severe complications such as intestinal obstruction are lacking, as are signs of systemic toxicity (fever, tachycardia, anemia, elevated erythrocyte sedimentation rate). Aminosalicylates and antibiotics are often used to treat mild-to-moderate Crohn's disease, although the topically acting steroid, budesonide, is increasingly used as a drug of choice for mild to moderate disease of the terminal ileum or proximal colon, with minimal steroid side effects.

Sulfasalazine and 5-Aminosalicylates

Sulfasalazine (SSZ) and 5-aminosalicylates (5-ASA) are often used as first-line therapy for the treatment of mild to moderate CD, despite thin evidence in support of their efficacy. The National Cooperative Crohn's Disease Study (NCCDS) and the European Cooperative Crohn's Disease Study (ECCDS) were large controlled clinical trials evaluating the efficacy of SSZ for the induction and maintenance of remission in patients with active CD.[2,3] The results of NCCDS demonstrated the benefits of SSZ 6 g/day over placebo for up to 16 weeks in patients with active ileocolonic and colonic CD.[2] In contrast, SSZ did not induce remission at 3 g/day as monotherapy but was shown to be beneficial in combination with methylprednisolone in the ECCDS.[3] Most studies have shown that SSZ is not consistently effective for patients with active disease limited to the small intestine.[3–5]

Mesalamine (5-ASA), an aminosalicylate without the sulfa component found in SSZ, was developed to increase tolerance and decrease the occurrence of side effects. Depending on the delivery system, 5-ASA is formulated to release at certain pH values or in a time-dependent manner in specific areas of the small and/or large intestine. Delayed-release formulations of mesalamine include Eudragit-S coated mesalamine (Asacol®) that releases 5-ASA in the terminal ileum and cecum at pH 7, and Eudragit-L coated mesalamine formulations (Salofalk®, Mesasal®, and Claversal®) that release in the mid-ileum at pH 6. Pentasa®, (a sustained-release formulation of mesalamine microgranules enclosed within a semipermeable membrane of ethylcellulose), is designed for controlled release throughout the small and large intestine, beginning in the duodenum. Newer azo-bonded formulations designed for release in the colon include the 5-ASA dimer, olsalazine (Dipentum®), and balsalazide (Colazal®), which are composed of 5-ASA molecules azo-bonded to the inert carrier molecule 4-aminobenzoyl-β alanine. Lialda® is a delayed-release tablet containing mesalamine that allows for once-daily dosing and releases at a pH 7 or above, normally in the terminal ileum. Apriso®, also a mesalamine compound, is an extended release capsule that is taken once daily and dissolves at a pH 6 starting in the small intestine and continuing throughout the colon.

Although commonly prescribed for the treatment of CD in clinical practice, 5-ASA has not consistently demonstrated efficacy in controlled clinical trials.[6] Table 28-1 describes dosing guidelines for SSZ and 5-ASA. Response to therapy should be evaluated after 6–12 weeks. Though occasionally used for disease limited to the rectum and left colon, topically delivered preparations of 5-ASA (suppositories, enemas) have not been evaluated in controlled trials in patients with distal colonic CD. SSZ and 5-ASA are not recommended for maintenance of remission.

Treatment-limiting adverse events occur frequently with SSZ. Headache and gastrointestinal upset are common dose-dependent side effects of SSZ. Patients who are slow-acetylators are at an increased risk of developing these side effects.[7] Rare side effects include hypersensitivity reactions, fever, rash, pneumonitis, hepatitis, pancreatitis, hemolytic anemia, and bone marrow suppression. SSZ depletes folate and should therefore be given with a folate supplement. Young men wishing to conceive should be alerted to the fact that SSZ may cause reversible sperm abnormalities, leading to relative infertility that reverses within 3 months of stopping the drug.

5-ASA preparations are well tolerated, and hypersensitivity reactions are rare. The majority of patients who cannot tolerate SSZ can tolerate a 5-ASA. Common side effects include headache, diarrhea, flatulence, nausea, and abdominal pain. Patients taking olsalazine may experience worsening of diarrhea resulting from increased ileal fluid secretion. This dose-dependent phenomenon usually improves with time.

Antibiotics

Antibiotics are used as alternative agents to SSZ or 5-ASA in CD. In addition to treating mild-to-moderate CD, antibiotics are valuable in treating perianal or perforating complications of CD. The two most commonly prescribed antibiotics are metronidazole and ciprofloxacin. The majority of studies demonstrate improvement with antibiotics when disease is limited to the colon.[8–11]

Clinical response is seen in patients taking up to 20 mg/kg of body weight daily of metronidazole.[8,9] Side effects occur in up to 50% of patients who take metronidazole short-term and include gastrointestinal intolerance, metallic taste, and

TABLE 28-1. Sulfasalazine and 5-aminosalicylates

Generic	Brand	Daily dose	Site of action
Sulfasalazine	Azulfidine	4–6 g daily in divided doses	Colon
	Azulfidine EN-Tabs	4–6 g daily in divided doses	Colon
Mesalamine	Canasa (suppositories)	500–1,000 mg daily QHS	Rectum
	Rowasa (enemas)	1–4 g daily QHS	Rectum/distal colon
	Asacol	2.4–4.8 g daily in divided doses	Terminal ileum/colon
	Pentasa	2–4 g daily in divided doses	Distal small bowel/colon
	Lialda	2.4–4.8 g daily in a single dose	Colon
	Apriso	1.5 g daily in a single dose QAM	Colon
Olsalazine	Dipentum	1.5–3 g daily	Colon
Balsalazide	Colazal	6.75 g daily	Colon

reaction to alcohol. Peripheral neuropathy, possibly irreversible, may occur with long-term use and patients should be counseled about this potential complication.

Ciprofloxacin, a quinolone antibiotic, has a suppressive effect on a variety of intestinal bacteria. Ciprofloxacin was shown in one study to be as effective as 5-ASA for achieving remission in mild-to-moderate active disease.[12] Combination treatment with metronidazole and ciprofloxacin may be an alternative to steroid treatment in mild-to-moderate active CD.[13] Ciprofloxacin is generally prescribed at a dose of 500 mg twice daily. Side effects include gastrointestinal upset, skin reactions, and an increase in transaminase levels. In addition, ciprofloxacin has been associated with rare cases of tendonitis and Achilles tendon rupture.

Rifaximin, a broad spectrum antibiotic with negligible intestinal absorption, was shown to be efficacious in an open-label study in patients with active CD.[14] A dose of 200–400 mg three times daily is usually prescribed. Described side effects include flatulence, headache, abdominal pain, tenesmus, and fecal urgency.

Budesonide

Enteric coated preparations of budesonide deliver corticosteroid topically with minimal systemic exposure. Multiple randomized controlled trials have demonstrated the efficacy of budesonide over placebo for the induction of remission in patients with mild to moderately active ileal or ileo-right colonic disease.[15–17] Budesonide has also been shown to be a more effective treatment than 5-ASA for patients with the correct disease locations.[18] Several studies have compared budesonide with prednisone and found that rates of clinical remission were similar in each group and the occurrence of corticosteroid-related side effects was considerably less.[19–22]

Approximately 90% of budesonide undergoes first-pass metabolism, which accounts for lower systemic exposure than traditional corticosteroids and minimizes adverse events. A course of therapy is initiated at 9 mg/day. After clinical response is achieved, usually in 4–8 weeks, the dose is tapered by 3 mg every 2 weeks. Budesonide, 6 mg/day, can delay clinical relapse rates for 3–6 months[23–26] but not at 1 year;[27] therefore, it is not recommended as a long-term maintenance agent.

Moderate-to-Severe Crohn's Disease

Patients with moderate-to-severe CD are considered to have failed treatment for mild-to-moderate disease, or have prominent symptoms of fever, significant weight loss of >10%, abdominal pain or tenderness, intermittent nausea or vomiting (without obstructive findings), or significant anemia. The treatment options for these patients include corticosteroids, biologic agents, and the early addition of immunomodulator therapy with azathioprine (AZA), 6-mercaptopurine (6-MP), or methotrexate (MTX) as an adjunct or a bridge to maintenance therapy.

Oral Corticosteroids

Oral corticosteroids are effective for the induction of remission in patients with moderate to severe CD. Approximately 60% of patients treated with prednisone in the NCCDS were in clinical remission at 17 weeks compared to 30% on placebo.[2] During the ECCDS, 80% of patients treated with methylprednisolone achieved clinical remission at 18 weeks compared to <40% of placebo patients.[3]

Prednisone doses of 40–60 mg daily are often prescribed for 2–6 weeks to induce remission, although no appropriate dose-ranging studies have been performed to date. Approximately 50–70% of patients will achieve remission at these doses.[2] Higher doses of prednisone (1 mg/kg) or methylprednisolone (1 mg/kg) have had somewhat higher response rates of 80–90%; however, there is an increased incidence of side effects.[3] Generally, prednisone doses are tapered by 5–10 mg/week until 20 mg and then by 2.5–5 mg weekly from 15 or 20 mg until discontinuation of therapy; however, taper schedules vary by clinician and according to patient response. The majority of patients treated with corticosteroids are unlikely to remain well over 1 year without specific effective maintenance therapy with other agents.[28,29] Corticosteroids are not recommended as maintenance agents.

Dependency and resistance are major concerns when treating patients with corticosteroids. On average, 50% of patients treated for active symptoms with a corticosteroid will become "steroid dependent" or "steroid resistant."[28,29] Studies suggest that younger patients, smokers, and/or those with colonic disease have the highest risk of becoming corticosteroid dependent.[30]

The occurrence and severity of most side effects associated with corticosteroids are related to the dose and duration of treatment. Common findings include insomnia, fluid retention, acne, moon face, abdominal striae, weight gain, hypertension, hyperglycemia, glaucoma, cataracts, and mood disturbances. Musculoskeletal complications, such as osteoporosis, osteonecrosis, and myopathy, are important side effects. In addition, adrenal suppression can arise in the course of treatment and contribute to physiologic dependence.

Immunomodulators

AZA and 6-MP are effective for maintaining a corticosteroid-induced remission and are beneficial as steroid sparing agents in steroid-dependent and steroid-refractory CD.[31,32] In clinical practice, AZA 2.0–2.5 mg/kg and 6-MP 1.0–1.5 mg/kg are used for maintenance therapy. Clinical benefit may not be evident for 3–4 months after initiation[31,32] but may be durable.

Adverse events include leukopenia, liver function abnormalities, pancreatitis (3–7%) and lymphoma.[33] Pancreatitis typically presents during the first 8 weeks of therapy. Reintroduction of either agent should be avoided if pancreatitis occurs as it will invariably reoccur. Routine monitoring of

complete blood counts, initially every 1–2 weeks, then, at least every 3 months is recommended to avoid the risk of acute or delayed bone marrow suppression. Rare hypersensitivity reactions, including high fever, rash, liver function test abnormalities, may occur. Non-melanoma skin cancers and cervical cancer may also occur more frequently. There is a slightly increased risk of lymphoma estimated at nine cases in 10,000 patient-years of exposure.[34] Genetic polymorphisms of thiopurine methyltransferase (TPMT), the primary enzyme metabolizing 6-MP, have been identified and drug metabolite levels may be measured. Such clinical assays allow practitioners to more accurately monitor and dose these medications according to measurements of the metabolites 6-thioguanine and 6-methylmercaptopurine.[35] The value of therapeutic monitoring has not been adequately assessed in a prospective fashion. Prior to starting AZA or 6-MP, TPMT enzyme activity or genotype should be determined for each patient whenever possible. AZA and 6-MP should be avoided in patients deficient in TPMT. Patients with heterozygous genotype of intermediate activity should initiate therapy at reduced doses, generally, AZA 1.0–1.25 mg/kg or 6-MP 0.5–0.75 mg/kg daily. If TPMT activity or genotype cannot be assayed in advance of starting therapy, these drugs should be dosed with caution initially, with careful monitoring for leukopenia.

Methotrexate

MTX may be used to induce remission and as a steroid sparing agent in patients with corticosteroid-refractory or dependent CD.[36–40] MTX 25 mg administered once weekly subcutaneously (SC) or intramuscularly (IM) is the preferred dose. Folic acid 1 mg daily is routinely given as well. After remission has been achieved, a dose of 15 mg weekly may be effective. Oral doses ≤15 mg/week are sometimes used to prevent development of antibodies to anti-TNF agents, a regimen adapted from rheumatology practice but never validated in IBD. MTX is an alternative agent to AZA and 6-MP for maintenance of remission.[39,41,42]

The most frequent side effects reported with MTX are nausea, vomiting, stomatitis, and, less often than with AZA or 6-MP, leukopenia. Ondansetron (Zofran®) and other antiemetic agents may improve tolerance. Rare complications of therapy include hepatic fibrosis and hypersensitivity pneumonitis. MTX is contraindicated in pregnancy as it is teratogenic and abortifacient.

Biologic Therapy

Historically, biologic therapies (primarily anti-tumor necrosis factor antibodies) have been considered when CD is moderately to severely active despite therapy with aminosalicylates, corticosteroids, and/or immunomodulators, or if corticosteroids or immunomodulators are contraindicated, not tolerated, or ineffective. Biologic therapy may also be indicated if patients are corticosteroid dependent or refractory,

or treatment with previous biologics was ineffective. Patients with complications such as draining fistulas or extraintestinal manifestations may derive particular benefit from biologic therapy.

Infliximab (chimeric monoclonal antibody) has been shown to effectively induce remission in patients with moderate to severe CD and to maintain remission in those patients.[43,44] Initial response to infliximab was seen in 58% of patients enrolled in the ACCENT I trial.[44] During long-term follow-up, 51% of patients receiving infliximab experienced a clinical response compared to 27% of patients taking placebo. In this same study, remission was achieved in 39% of patients receiving infliximab compared to 27% in the placebo group.[44]

Infliximab is also useful for treating patients with corticosteroid-dependent and fistulizing disease.[44,45] Patients treated with infliximab experience fewer hospitalizations and surgeries related to CD.[46] The occurrence of extraintestinal manifestations, such as spondyloarthropathy, arthralgias, and pyoderma gangrenosum may be reduced with infliximab.[47–49]

Approximately 30% of patients have no response to infliximab and not all responders have a complete response.[44,50,51] Elevated C-reactive protein (CRP), nonstricturing and pure colonic disease subtypes, and concomitant use of immunomodulators have been described as positive predictors for response to infliximab.[52] AZA and 6-MP are most commonly used as concomitant suppression. Methotrexate (MTX) may also be used.[53]

Adalimumab (human anti-TNF antibody) and certolizumab pegol (pegylated humanized anti-TNF Fab) are effective for inducing and maintaining remission in patients with moderate to severe CD who are naïve to anti-TNF agents or who have been exposed to infliximab, and for healing intestinal mucosa.[51,54–64] Adalimumab is also effective as a steroid sparing agent and in treating fistulas.[51,65,66]

Initial response rates to adalimumab and certolizumab pegol were 58% (CHARM) and 64% (PRECiSE 2), respectively.[51,67] During long-term follow up of over 1 year, adalimumab achieved a clinical response in 52% of patients compared to 27% patients taking placebo among patients who initially responded. Remission was achieved in 40% of those taking adalimumab compared with only 17% in the placebo group.[51]

During the PRECiSE 2 study 62.8% of patients receiving certolizumab pegol experienced a clinical response compared to only 36.2% of those assigned to placebo among patients who initially responded to induction therapy with certolizumab pegol. Remission was achieved in 47.9% of patients assigned to certolizumab pegol compared to only 28.6% of those receiving placebo.[67]

Newer treatment paradigms, referred to as "top-down therapy," have been investigated, with the suggestion that anti-TNF therapy may be more effective when given earlier in the course of disease, and when given in combination with an immunomodulator such as AZA. A landmark study from

Belgium and the Netherlands randomized patients with active CD, no history of complicated disease behavior, and no prior exposure to corticosteroids, immunomodulators or anti-TNF antibodies to receive either "step-up" therapy or early aggressive therapy. In the step-up arm, patients were given a steroid taper. If this proved unsuccessful in controlling symptoms, or if symptoms reoccurred upon taper, a second steroid taper was given. Failing this, patients received an immunomodulator (AZA, or MTX if AZA was not tolerated). Finally, patients refractory to each of these steps were given an infusion of infliximab. This arm of randomization represents the prevailing paradigm of treatment, where therapy is dictated by control of symptoms as trial and error escalation through therapies of increasing immune suppression. The second arm of randomization incorporated induction dosing with infliximab 5 mg/kg at weeks 0, 2, and 6, and simultaneous initiation of an immunomodulator. If the patient flared despite this regimen, an additional dose of infliximab could be given, and failing this, a tapering course of oral corticosteroids. The primary outcome measures were remission without corticosteroids and without bowel resection at weeks 26 and 52. At week 26, 60% of patients in the combined immunosuppression group were in remission without corticosteroids and without surgical resection compared to only 35.9% in the "step-up" group (absolute difference 24.1%, CI 7.3–40.8, $p=0.0062$). Similar benefits were seen at week 52, 61.5% receiving early immunosuppression achieved the clinical endpoints of corticosteroid-free remission and prevention of surgical resection compared to 42.2% taking corticosteroids (absolute difference 19.3%, 95% CI 2.4–36.3, $p=0.028$). The occurrence of serious adverse events was comparable in each group. The authors concluded that combined immunosuppression was more effective than conventional management for induction of remission and reduction of corticosteroid use in patients who had been recently diagnosed with CD. Initiation of more intensive treatment early in the course of disease may result in better outcomes.[68]

In a second randomized controlled trial, the benefits of monotherapy with an immunomodulator or anti-TNF antibody was compared to the combination of both in patients with relatively early and uncomplicated disease. The SONIC study was conducted to compare azathioprine monotherapy, infliximab monotherapy, and the combination of both agents in patients with CD naïve to immunomodulators and biologic therapy.[69] The primary endpoint of the study was corticosteroid-free clinical remission at 26 weeks. In the study, significantly more patients treated with infliximab alone or the combination of infliximab and azathioprine had relief of symptoms than patients treated with azathioprine alone. Approximately 31% of patients taking azathioprine alone significantly achieved corticosteroid-free clinical remission compared with 44.4% of patients on infliximab monotherapy and 56.8% of patients on combination therapy.[69] Patients with the highest levels of C-reactive protein and/or with endoscopic evidence of ulcers did better with infliximab alone or

with combination therapy. Mucosal healing was seen in 44% of patients receiving infliximab combination therapy and 30% receiving infliximab monotherapy compared with 17% of patients receiving azathioprine alone.[69] Patients with CD who are naïve to immunomodulators and biologic agents are more likely to have enhanced mucosal healing when they are treated with infliximab and AZA, and attain a corticosteroid-free clinical remission. Adverse events were similar in all three arms of the study. There was no trend toward an increased risk of serious infections with infliximab alone or in combination with azathioprine.[69]

Additional data to support the "top-down" approach has shown that response to anti-TNF agents decreases with longer duration of disease. In the CHARM study 59% of patients diagnosed with CD for <2 years responded significantly to treatment with adalimumab compared to only 41% of patients having CD for ≥5 years.[70] Similar results were seen in the PRECiSE trial. Sixty-eight percent of patients with CD for <1 year responded to treatment with certolizumab pegol compared to only 44% of patients with a disease duration >5 years.[67]

Natalizumab is a humanized monoclonal antibody that targets human α_4 integrin, thereby interfering with trafficking of leukocytes into the mucosa. Natalizumab is indicated for the induction and maintenance of response or remission in patients with moderate to severely active CD with documented inflammation, such as an elevated serum CRP concentration. Natalizumab should only be used in patients who are refractory or intolerant to immunomodulators and anti-TNF therapy and for whom surgery is not an acceptable option. In addition, because of the risk of progressive multifocal leukoencephalopathy (PML), natalizumab should not be used concomitantly with immunomodulators or anti-TNF agents, and corticosteroids should be tapered off by 12 weeks from initiation of therapy with this agent.[71–74] See Table 28-2 for specific indications and Table 28-3 for dosing guidelines for biologic therapies.

Anti-TNF agents and natalizumab have been shown in randomized placebo-controlled trials to be effective for maintenance of remission in patients with moderate to severe CD.[44,51,67,73]

Loss of Response to Anti-TNF Agents

One-third of patients who initially respond to an anti-TNF agent will subsequently lose response over the course of 6–12 months.[44,51,67] Loss of response is attributed to the development of antibodies to therapy or loss of response to the mechanism of action of the TNF agent. The development of antibodies against biologic therapies can decrease the degree and duration of therapeutic response, and increase the likelihood of infusion reactions in the case of infliximab. Forty-eight percent of patients receiving infliximab in ACCENT I, 46% of patients taking adalimumab in CHARM and 37% of patients receiving certolizumab pegol in PRECiSE 2 no longer responded to treatment at 6 months.[44,51,67]

X[1] Must have also failed anti-TNF therapy and have evidence of inflammation.

TABLE 28-3. Dosing guidelines for biologic therapy

Biologic agent	Induction regimen	Maintenance dose	Attenuated response	Discontinue therapy
Infliximab	5 mg/kg IV at weeks 0, 2, and 6	5 mg/kg IV every 8 weeks beginning at week 14	10 mg/kg at 8-week intervals, or 5 mg/kg every 4 weeks	No response after 2 doses or infusions are required more frequently than every 4 weeks
Adalimumab	160 mg SC on day 1 of week 0, then 80 mg SC on day 1 of week 2	40 mg SC every other week	40 mg SC weekly or 80 mg every other week	No response to induction therapy or duration of response decreases to less than 1 week
Certolizumab	400 mg SC at weeks 0, 2, and 4	400 mg SC every 4 weeks	Extra dose of 400 mg SC 2 weeks after last dose	No response to induction therapy or when the duration of response decreases to 2 weeks
Natalizumab	300 mg IV at weeks 0, 4, and 8	300 mg IV every 4 weeks	Other dosing regimens have not been adequately evaluated	Lack of response or inability to discontinue steroids by week 12

Human anti-chimeric antibody (HACA) is produced in response to treatment with infliximab. It is associated with a shorter duration of response and increases risk of infusion reactions.[75] Patients who develop HACA will often be switched to an alternate anti-TNF agent. In a recent study, 92% of patients with loss of response to infliximab with detectable HACA had a clinical response to an alternative anti-TNF agent compared with only 17% of patients who underwent an alternative strategy of increasing the dose of infliximab. In contrast, those patients with detectable HACA and subtherapeutic serum concentrations of infliximab responded significantly better to increased doses of Infliximab (86%) rather than an alternative anti-TNF agent (40%).[76] Therefore, a reasonable approach to loss of response to infliximab is to test for HACA and levels of infliximab. Patients with detectable HACA (normal <1.69 mcg/ml, levels ≥8 mcg/ml associated with loss of response) should be changed to an alternative anti-TNF agent or, less desirably, the dose could be increased. Those patients with subtherapeutic levels of infliximab (levels ≥12.0 mcg/ml at 4 weeks postinfusion correlate with a longer duration of response) may benefit from an increase in dose or frequency of dosing. An alternative option for these patients is changing to a different anti-TNF agent.[75,76]

A recent study evaluated the use of adalimumab in patients with CD who had responded to infliximab initially then either lost that response or became intolerant to therapy. Patients were randomly assigned to receive induction doses of adalimumab, 160 and 80 mg, at weeks 0 and 2, respectively, or placebo at the same time points. The primary endpoint was induction of remission at week 4. Twenty-one percent of patients in the adalimumab group versus 7% of those in the placebo group significantly achieved remission at week 4. The absolute difference in clinical remission rates was 14.2%. Adalimumab induced remission more frequently than placebo in adult patients with CD who could not tolerate infliximab or had symptoms despite receiving infliximab therapy.[77]

Concomitant immune suppression with AZA, 6-MP, or MTX reduces the development of antibodies. Antibodies to infliximab (ATI) were found in 38% of patients receiving episodic doses of infliximab without an immunomodulator compared to only 16% receiving both episodic doses of infliximab and an immunomodulator during the ACCENT I study.[78] Maintenance doses of anti-TNF agents in combination with an immunomodulator have been shown to limit the development of ATIs.

Adverse Events Associated with Biologics

Anti-TNF agents share similar adverse events including infusion or injection site reactions, autoimmunity (positive ANA, anti-double-stranded DNA antibodies; rare lupus-like reactions), activation of latent tuberculosis and development

of opportunistic infections. Fungal infections caused by *Histoplasma capsulatum* have been reported in 240 patients taking an anti-TNF agent, of which 12 deaths have occurred.[79] Given the risk of reactivation of latent tuberculosis, all patients should be screened for tuberculosis with tuberculin skin testing (and chest X-ray if skin testing is positive) prior to initiating therapy with infliximab. Hematologic complications may also occur, including such as leukopenia, neutropenia, thrombocytopenia, or pancytopenia. Rarely, liver toxicity may occur and present as acute liver failure, jaundice, hepatitis, and cholestasis. Neurologic disorders including optic neuritis, seizures, and new onset or exacerbation of central nervous system demyelinating disorders, including multiple sclerosis, have been reported with the use of anti-TNF agents.

Rare cases of hepatosplenic T-cell lymphoma, a lethal form of non-Hodgkin's lymphoma, have been reported in patients receiving infliximab and AZA/6-MP.[80] Cases of hepatosplenic T-cell lymphoma have been described almost exclusively in young males, and non-Hodgkin's lymphoma is more common among men in general. There is a slightly increased risk of non-Hodgkin's lymphoma estimated at 6.1 cases in 10,000 patient-years of exposure to anti-TNF agents in combination with immunomodulators, as compared to the general population risk of 1.9 per 10,000 patient-years.[81] An age-and gender-adjusted standardized incidence ratio is 3.23 per 10,000 patient years (95% CI 1.5–6.9).[81]

Natalizumab may cause headache or rare infusion reactions. Among patients receiving natalizumab for multiple sclerosis or CD, the risk of developing PML is approximately 1 in 1,000 patients for patients treated for at least 1 year.[82] Immunomodulators are contraindicated with natalizumab due to increased risk of PML. There are also rare reports of liver toxicity with natalizumab.[83]

Contraindications to Biologic Therapies

Contraindications to anti-TNF agents are consistent across the class and include the following:

1. Known hypersensitivity to agent, if severe
2. Active infection
3. Untreated latent tuberculosis
4. Preexisting demyelinating disorder
5. Moderate to severe congestive heart failure
6. Current or recent malignancy, without advice from an oncologist
7. Further treatment with infliximab is contraindicated when the patient presents with uncontrolled infusion reactions

Contraindications to natalizumab include

1. Known hypersensitivity to agent, if severe
2. Active infection
3. Current or past PML
4. Liver disease
5. Continued treatment with an immune modulator or anti-TNF antibody

Tacrolimus

Data on the use of tacrolimus in CD are limited and the drug is infrequently used to treat patients with significant disease and no other options. Various small studies have shown a trend toward clinical benefit especially in fistulizing disease.[84–90] Oral therapy is usually started with 0.1–0.2 mg/kg/day as a twice daily divided dose. Adverse effects of tacrolimus include renal insufficiency, liver function abnormalities, infection, hyperglycemia, hypertension, and myelosuppression. Drug levels, blood counts, liver enzymes, renal function, glucose level, and blood pressure need to be monitored on a regular basis in patients taking tacrolimus. Laboratory tests should be performed weekly initially and then less often after stable dosing is achieved. Trough drug levels should be maintained between 5 and 15 ng/mL.

Severe Crohn's Disease

Patients with severe to fulminant CD have ongoing symptoms despite treatment with oral corticosteroids or an anti-TNF agent. Symptoms include high fever, frequent vomiting, evidence of intestinal obstruction, rebound tenderness, cachexia, or evidence of an abscess. These patients often require hospitalization and resuscitative therapy with fluid and electrolytes for dehydration. Surgical evaluation is warranted for patients with intestinal obstruction or who have a tender abdominal mass suggestive of an abscess.

Severe disease may be treated with high-dose intravenous corticosteroids. Doses of hydrocortisone 100 mg IV three times daily or methylprednisolone up to 60 mg IV daily may be used to induce remission. AZA or 6-MP should be initiated in patients who respond to IV corticosteroids.[86] A patient who does not respond after 5–7 days of therapy may benefit from infliximab or intravenous (IV) cyclosporine (CSA). Failure to respond to medical therapy or worsening symptoms are indications for surgery.

Indications for Surgery in Crohn's Disease

Unlike UC, CD is not surgically curable. Approximately two-thirds of patients with CD will require surgery at some point during their disease course. Surgery is often performed to avoid medication side effects or to treat complications of disease such as hemorrhage, perforation, obstruction, or abscess. While surgical resection is most commonly done, the disease predictably recurs at the anastomotic site, and stricturoplasty is a reasonable surgical alternative if previous small bowel resections place the patient at risk of short bowel syndrome. Any patient who fails to respond to 7–10 days of intensive inpatient management should be strongly considered for surgery.

The indications for emergency surgery include primary free perforation or secondary rupture of an abscess into the

peritoneal cavity and massive, uncontrollable hemorrhage. Urgent surgical procedures (performed within a few days after the diagnosis of a complication) are required for fulminant Crohn's colitis with or without toxic megacolon and severe perianal sepsis. Elective procedures (performed within weeks after the decision for surgery) are an option for definitive treatment of intra-abdominal abscesses, complete or incomplete obstruction of the bowel, or an intractable course of disease (including steroid-dependent or steroid-resistance) and neoplastic or pre-neoplastic lesions.[91]

Crohn's Disease: Maintenance Therapy After Medical Induction of Remission

The goal of maintenance therapy is to reduce hospitalizations, prevent surgery, and improve patients' quality of life. Although often given in clinical practice, randomized controlled trials investigating the use of SSZ[2,3] or 5-ASA[92] have not demonstrated significant maintenance benefits in CD. In particular, 5-ASA (at a dose of 4 g daily) has not been efficacious in preventing relapse after corticosteroid-induced remissions.[93] Immunomodulators, including AZA, 6-MP, and MTX, as well as anti-TNF agents and natalizumab may be effective maintenance agents, particularly among those patients who have initially responded to these agents.

Postoperative Reoccurrence of Crohn's Disease and Prophylaxis

Factors associated with an increased risk of early postoperative recurrence include smoking, absence of prophylactic postoperative therapy and extent of disease greater than 100 cm.[94] Many patients with long-standing strictures have a relatively good postoperative prognosis, whereas patients with rapid progression of perforating complications and smokers have a worse prognosis.

Despite multiple studies, the best postoperative prophylactic therapy remains uncertain. 5-ASA and, to a lesser extent, SSZ are often used in clinical practice to prevent postoperative reoccurrence of CD because of their well-known safety profile. SSZ has not been statistically superior to placebo in preventing postoperative relapse.[95] A meta-analysis of 15 randomized controlled studies of 5-ASA as a maintenance medication in CD found a modest pooled risk reduction of 13% for those patients with surgically induced remissions.[96] Some authors believe that 5-ASA may be more effective in preventing postoperative recurrence in patients with isolated small bowel disease.[97]

Data supporting the use of AZA and 6-MP for prevention of postoperative recurrence are limited; however, the data suggest possible efficacy.[98–100] Preliminary reports propose that infliximab may be used as a postoperative prophylactic agent.[101] It has been shown to prevent postoperative clinical and endoscopic recurrence after ileocecal resection.[102]

Imidazole antibiotics, including metronidazole, decrease short-term, but not long-term endoscopic recurrence and are limited by side effects.[103] Corticosteroids do not prevent postoperative relapse. At the moment, there is insufficient evidence to support the use of probiotics in preventing postoperative recurrence of CD. Overall, there are no consistent recommendations regarding medical therapy after surgical resection for Crohn's disease.

Perianal Crohn's Disease

Perianal disease may precede the onset of bowel symptoms in CD. Perianal complications include skin tags, anal fissures, fistulas, abscesses, and anal stenosis. The most common acute complication is a fistula-related abscess. An abscess requires surgical drainage with or without the placement of setons.

Perianal fistulae occur in up to 43% of patients.[104] Treatment often combines medication and surgery. Medications commonly used for the treatment of perianal fistulae include antibiotics, immunomodulators, and anti-TNF agents. There is no role for the use of 5-ASA or corticosteroids in the treatment of perianal fistulas.

Perianal fistulae typically respond to metronidazole alone[105–107] or in combination with ciprofloxacin; however, continuous therapy may be necessary to prevent recurrent drainage. Simple, superficial fistulae may respond completely to fistulotomy and antibiotics. However, patients with complex fistulae may respond best to combined medical/surgical approaches. Some patients may require chronic maintenance therapy with AZA or 6-MP. MTX has not been prospectively evaluated in perianal fistulizing CD, but several uncontrolled studies suggest a possible benefit.[108] Two pivotal studies have demonstrated that infliximab is effective at acutely closing fistula[45] and maintaining closure with maintenance dosing.[50]

Ulcerative Colitis: Medical Management

Ulcerative colitis is a chronic inflammatory condition that results in ulceration of the mucosal lining of the large intestine. Inflammation is diffuse and continuous, and uniformly affects the rectum but may extend proximally to involve part or all of the large intestine. Common symptoms of UC include frequent bloody bowel movements, diarrhea, urgency, and tenesmus.

Proctitis

Proctitis refers to inflammation of the rectum. This area can be effectively treated with topical therapies such as enemas or suppositories. Oral agents can also be effective

if patients fail, cannot tolerate, or refuse topical therapies. Topical formulations of 5-ASA are considered first-line therapy for the treatment of proctitis. These agents are considered more effective than rectal steroids and have been shown to be more effective than oral 5-ASA.[109] Suppositories are preferred over enemas because they are more easily administered and are more viscous than enemas so leakage is less. Canasa (1.0–1.5 g daily) in the evening or in divided doses is highly effective for proctitis up to 20 cm.[109] The proportion of patients achieving remission increases with the duration of treatment and is not dose dependent. Response is usually seen within 2–3 weeks with increased response rates (63–79%) at 4–6 weeks.[110] For patients not responding to rectal 5-ASA alone, combination treatment with topical corticosteroids (foam or enema) is better than either therapy alone.[111] As an alternative, oral 5-ASA can be used with topical therapy for active proctitis.[109,112]

Distal Ulcerative Colitis

Patients with distal colitis can be treated with topical 5-ASA (suppositories, enemas) topical corticosteroids (suppositories, enemas), oral 5-ASA, or a combination of these agents. Rectal therapies may have a more rapid effect than oral therapies.[110] Rectal 5-ASA is considered superior to rectal corticosteroids for inducing remission,[113] however, combination therapy with a topical corticosteroid may be more effective than monotherapy.[3,111] Therapy with a combination of oral and rectal 5-ASA achieves higher remission rates than either therapy alone.[112] Remission rates for topical therapy increase with duration of treatment (63–72% after 4 weeks) and are independent of dose. There are no advantages to prescribing doses greater than 1 g daily of a topical 5-ASA.[110]

A small proportion of patients have a hypersensitivity to 5-ASA either given orally or rectally. It may present as worsening of rectal bleeding and urgency usually within 3–5 days of administration. 5-ASA should be discontinued and improvement should be seen within 72 h. Treatment with a topical corticosteroid is usually effective in achieving remission in this group.

Extensive Ulcerative Colitis

Extensive UC refers to inflammation which extends proximal to the splenic flexure and requires systemic medications. Supplementary topical medications are often beneficial to treat prominent rectal symptoms of urgency or tenesmus. Activity is defined as mild to moderate, moderate to severe, or severe to fulminant. Treatment is based on clinical activity.

Mild-to-Moderate Extensive Ulcerative Colitis

Signs and symptoms of mild disease include <4 stools daily with or without blood, no systemic signs of toxicity and normal erythrocyte sedimentation rate (ESR). Patients with moderate disease will experience somewhat more serious symptoms but are not yet considered to have severe UC by virtue of toxic features. Inflammation extends proximal to the splenic flexure and beyond the reach of topical therapy. Oral therapy is required for extensive disease.

Sulfasalazine and 5-Aminosalicylates

SSZ and oral 5-ASA are considered first-line agents for induction of remission in mild to moderate UC. The efficacy of SSZ has been well-established.[2] SSZ achieves remission in 64–80% of patients at doses of 2–6 g daily.[2] There is a dose–response for SSZ; the higher the doses the higher the rate of remission. However, 30–40% of patients are unable to tolerate increased doses due to systemic absorption of the sulfapyridine component.[114]

Clinical response can be achieved in up to 84% of patients taking a 5-ASA.[115] All formulations of 5-ASA work topically and have similar pharmacokinetic profiles. The dose of 5-ASA should be increased in patients who do not begin to improve within 2 weeks of starting therapy. Combining oral 5-ASA with topical 5-ASA preparations has been shown to be well tolerated and more efficacious in patients with extensive UC.[116]

Corticosteroids

Patients who do not respond to optimal doses of oral 5-ASA can be given an oral corticosteroid. Oral corticosteroids successfully induce remission in the majority of patients. Doses of prednisone 20–60 mg/day are often used, but doses greater than 60 mg/day have no additional benefit. There is no difference between once-daily and divided dosing. Once remission is achieved prednisone is tapered by 5–10 mg weekly until 15–20 mg then taper by 2.5–5 mg weekly while attempting to maintain remission with a 5-ASA. Budesonide is released in the distal ileum and proximal colon limiting its effectiveness in UC. Topical corticosteroids in addition to oral and/or rectal 5-ASA may be beneficial for relieving rectal symptoms associated with extensive UC.

Severe and Fulminant Extensive Ulcerative Colitis

Severe disease is defined as ≥6 bloody stools daily, abdominal tenderness with signs of systemic toxicity including fever (>37.5°C), tachycardia (>90 bpm), anemia (<75% of normal value), and increased ESR (>30 mm/h).[117] Fulminant disease is defined as >10 bloody stools per day, anemia requiring a transfusion, signs of systemic toxicity, abdominal distention and tenderness, fever and leukocytosis.

Intravenous Corticosteroids

Approximately 60% of patients with severe/fulminant colitis treated with IV corticosteroids respond fully.[117] Doses of

hydrocortisone 100 mg IV three times daily or methylprednisolone 60 mg IV daily are used to induce remission. Continuous infusion of corticosteroids is not more efficacious than bolus dosing. Patients who fail to improve within 3–7 days (depending on severity of illness) should be considered for colectomy or rescue therapy with CSA or infliximab.

Azathioprine/6-Mercaptopurine

In patients with persistently active, steroid-dependent, or steroid-refractory UC, immunomodulators (AZA or 6-MP) should be considered.[118–120] AZA or 6-MP can induce a clinical remission or response in 30–50% of patients, improve overall symptoms, and allow the dose of steroids to be reduced or discontinued.[119,120] Induction of remission may take as long as 3–4 months to achieve. Doses of 2.5 mg/kg for AZA and 1.5 mg/kg for 6-MP are often used. Infliximab is an alternative agent for refractory disease.

Cyclosporine

Intravenous CSA is used as rescue therapy for severe corticosteroid-refractory UC. Patients failing to respond to 7 days of IV corticosteroids may benefit from IV CSA. Several studies report response rates between 70 and 80% in patients with this type of UC.[121–123]

CSA is initiated as a continuous infusion while continuing IV corticosteroids. Doses of 2–4 mg/kg daily are used clinically. General improvement is seen within 4–5 days of initiating treatment. If a response is noted the patient is transitioned to oral CSA 5 mg/kg/day divided BID and AZA is usually started as maintenance therapy. If no improvement is noted within 7 days or the condition deteriorates during treatment with CSA surgery should be considered. CSA is discontinued generally after 3–4 months if treatment proves effective.

Symptoms of CSA toxicity include infection, paresthesia, nausea, tremors, headache hypertension, and permanent or temporary renal toxicity. Patients who are noncompliant, have a history of uncontrolled seizures or active infection should not receive CSA. Patients with low cholesterol (serum cholesterol < 120 mg/dl) and low serum magnesium levels (serum magnesium < 1.5 mg/dl) are at increased risk of seizures. CSA is contraindicated in patients with multiple organ dysfunction.

Tacrolimus

One randomized controlled trial and multiple open-label trials of tacrolimus for the treatment of refractory UC have reported favorable results.[85,124,125] In the randomized controlled trial, patients with refractory active UC were assigned to one of three groups: (1) high trough concentration (10–15 ng/ml), (2) low trough concentration (5–10 ng/ml), or (3) placebo group ($n = 20$). Initially, each patient was prescribed a dose of 0.05 mg/kg tacrolimus or placebo twice daily. Improvement

was seen in 68.4% of cases in the high trough group compared with 10.0% in the placebo group ($p < 0.001$). In the high trough group, 20.0% of patients had clinical remission and 78.9% had mucosal healing. Tacrolimus was shown to be a steroid sparing agent during the open-label portion of the study. The mean dose of prednisolone was reduced from 19.7 to 7.8 mg/day at week 10. The incidence of side effects was significantly increased in the high trough group compared to the placebo group. The most common event was mild finger tremor. The optimal target range appears to be 10–15 ng/ml in terms of efficacy with 2-week therapy.[125]

Infliximab

Infliximab is the only anti-TNF agent approved for use in UC. It has been shown to successfully induce and maintain remission in patients with moderate to severe and corticosteroid-dependent UC.[126] In ACT 1 and ACT 2, a clinical response was seen in ≥60% of patients receiving infliximab compared to ~30% of patients in the placebo group. In those same studies clinical remission was achieved in ≥30% of patients assigned to infliximab as compared to only 14.9% receiving placebo.[126] Infliximab is also used as a steroid sparing agent in patients with corticosteroid dependent or refractory UC. Infliximab appears to decrease the rate of colectomy at 3 months and 1 year.[117,127]

Ulcerative Colitis: Maintenance Therapy After Medical Induction of Remission

Remission is achieved when diarrhea, tenesmus, bleeding, urgency, and passage of mucopus have resolved. Rectal and oral 5-ASA are effective for maintaining remission of distal UC and proctitis[128] even when used on an intermittent basis.[129] Up to 90% of patients with extensive colitis can be maintained in remission using oral once-daily 5-ASA therapy.[130,131] AZA and 6-MP are useful as corticosteroid sparing agents,[132] for maintaining remission[133] in patients not adequately controlled by 5-ASA alone, and for maintaining CSA-induced remission.[134] Maintenance benefits have been shown for up to 2 years[135] but endure much longer for most patients. Infliximab was able to maintain remission in patients with UC for up to 54 weeks in a large randomized controlled trial.[126] The role of MTX in the treatment of UC is still controversial.

Indications for Surgery in Ulcerative Colitis

The goal of medical therapy has been to reduce the need for colectomy while avoiding fatal complications. Between 20 and 30% of UC patients will eventually require surgery. Indications for emergency surgery include massive

hemorrhage, toxic megacolon, perforation and severe colitis unresponsive to medical therapy. Elective surgery may be performed for cancer/dysplasia, failure of therapy, adverse events resulting from medial therapy, malnutrition, growth retardation in children and control of certain extraintestinal manifestations.[117]

Preoperative Treatment Effect on Postsurgical Complications

Many patients with inflammatory bowel disease will require surgery during the course of their disease. For most patients requiring surgery, medical options have been exhausted. Preoperative treatment with corticosteroids, immunomodulators and biologic agents raises concerns about potential postoperative complications.

Studies have shown that corticosteroid use prior to surgery increases the risk of postoperative infectious complications.[136–138] Patients taking corticosteroids preoperatively may have double the risk of infectious complications compared to those not taking corticosteroids.[139] A meta-analysis was performed to estimate the risk of postoperative complications (infectious and noninfectious) in patients receiving corticosteroids prior to abdominal surgery. Patient taking corticosteroids preoperatively were more likely to experience postoperative complications including infections (all postoperative complications OR 1.41, 95% CI 1.07–1.87, infectious complications OR 1.68, 95% CI 1.24–2.28). Patients taking >40 mg had a considerably higher risk of developing postoperative complications (OR 2.04, 95% CI 0.28–3.26).[140] The risk of postoperative infections may be related to corticosteroid doses >10 mg/day and duration of treatment >1 month.[138,141]

Although the data are limited, most studies have shown that treatment with AZA or 6-MP prior to surgery is not a risk factor for postoperative complications.[136,137,142] The effect of preoperative infliximab on postsurgical complications is controversial. Two retrospective studies in patients with CD suggest that infliximab infused within 8–12 weeks before abdominal surgery is not associated with an increased rate of postoperative complications.[142,143] In contrast, analysis of a third retrospective series found that infliximab use within 3 months prior to surgery is associated with increased rates of postoperative sepsis, abscess, and hospital readmission in patients with CD.[144]

The data regarding postsurgical complications in UC patients receiving infliximab prior to surgery are limited. A retrospective review was conducted in patients with chronic UC treated with and without infliximab before IPAA to compare postoperative complications. Infliximab use prior to surgery was shown to be associated with an increased risk of pouch failure and infectious complications related to the pouch. The authors suggest that the pouch should be constructed as a three-stage procedure in this population.[145]

Pouchitis

Pouchitis is the most common long-term complication of ileal-pouch anal anastomosis (IPAA) for UC. Most often patients respond to 2 weeks of ciprofloxacin at 500 mg twice daily or metronidazole 750–1,200 mg/day.[146] Over 60% of those patients, however, will go on to develop a second episode and approximately 20% of patients will have refractory or relapsing symptoms.[147,148] These patients require a prolonged course of the same antibiotic or with a combined antibiotic regimen. If patients relapse at least three times within 1 year, chronic maintenance therapy with lower doses of antibiotics is recommended.[147,148]

Approximately 20% of patients develop chronic refractory pouchitis.[147] Longer courses of antibiotics are required for these patients and each new antibiotic should be tried for at least 1 month prior to making any changes. Combination antibiotic therapy may be the most effective.[149] Rifaximin alone or in combination with ciprofloxacin is an effective treatment for patients with active chronic, refractory pouchitis.[149–151]

Budesonide and infliximab may be used as alternative treatments.[152,153] Maintenance with VSL #3, a probiotic, is an option.[154] Patients who are refractory to all forms of medical treatment should be referred to a surgeon for a pouch revision or excision.

Irritable Pouch Syndrome

Irritable pouch syndrome (IPS) is often misdiagnosed as pouchitis because of its similar presentation. The major differentiating factor between IPS and pouchitis is that with pouchitis, mucosal inflammation is evident.[147] Treatment with anti-diarrheals such as diphenoxylate and loperamide, or anti-spasmodics, such as dicyclomine and hyoscyamine, may help to control symptoms.

Crohn's Disease of the Pouch

CD of the pouch is one of the most common long-term inflammatory complications of IPAA and one of the leading causes of pouch failure. It can occur weeks to years after an IPAA for UC. CD of the pouch may be treated with topical and oral 5-ASA, oral or topical corticosteroids, antibiotics, and immunomodulators. In patients whose disease is refractory to these agents, particularly when they have concurrent extraintestinal symptoms, biological agents such as infliximab and adalimumab can be used.[155,156]

Conclusion

Treating patients with IBD poses a significant challenge. Often it is a balancing act between controlling symptoms, improving quality of life, and minimizing complications of disease and treatment. Aminosalicylates are first-line agents for the treatment of mild to moderate disease and for maintaining

remission; however, in the case of CD, evidence of efficacy is sparse. Antibiotics are somewhat effective in colonic CD but are not considered useful as treatment for UC, although efficacious for the treatment of pouchitis. Corticosteroids are effective for inducing remission in more severe disease but are associated with multiple side effects. Corticosteroids are not recommended as maintenance therapy. The immunomodulators, AZA, 6-MP, and MTX, are best employed as maintenance agents and, in the case of AZA and 6-MP, require approximately 3–4 months to be effective.

Recently, biologic agents have become the focus for treatment of moderate to severe CD. These agents are effective for inducing and maintaining remission and healing fistulas, as steroid sparing agents, and for the treatment of certain extraintestinal manifestations. Infliximab is the only anti-TNF agent approved for use in UC, thus far.

Ulcerative Colitis: Surgical Management

Zuri Murrell and Phillip Fleshner

Ulcerative colitis (UC) is a diffuse inflammatory disease of the mucosal lining of the colon and rectum that manifests clinically as diarrhea, abdominal pain, fever, weight loss, and rectal bleeding. Since removal of the affected organ is curative, surgery has assumed a pivotal position in the management of these patients. Although removal of the entire colon and rectum with a permanent ileostomy had been the standard operation for decades, increased experience with anal sphincter preservation has demonstrated the feasibility of performing surgical procedures which spare sphincter function while still removing all disease. This chapter considers the surgical alternatives, decision making, and techniques surrounding these procedures.

Indications for Surgery

Approximately 10% of UC patients will undergo surgery for very specific reasons, including: an acute flare unresponsive to medical measures, development of a life-threatening complication such as toxic colitis, perforation, or hemorrhage, medical intractability, risk of malignancy, disabling extracolonic disease, and growth retardation in children. During an acute exacerbation of colitis, the patient should be aggressively treated with intravenous steroids and bowel rest. The role of parenteral hyperalimentation in this situation is controversial. Encouraging results have been reported with the use of either cyclosporine[1] or infliximab[2] in the acute setting, yet long-term effectiveness of these treatment modalities remains undefined. While there is no reported increase in the incidence of perioperative complications after subtotal colectomy in patients treated before surgery with cyclosporine,[3,4] there is some controversy as to whether infliximab increases the perioperative complication rate after restorative proctocolectomy as these patients usually have more advanced active disease than do the patients who are not receiving active infliximab treatment.[5,6] The *combined* use of cyclosporine and infliximab is not advised as there

may be a higher incidence of infectious complications in patients who ultimately require colectomy.[5]

Patients with life-threatening complications are generally easy to recognize and define. Nevertheless, these patients are frequently taking large doses of steroids and may appear deceptively well; consequently, appreciation of the severity of the disease and the timing of operation are of paramount importance. Medical intractability is the most common indication for operation and may seem difficult to define. In fact, there is probably no strict definition that a physician can uniformly apply. It is important to recognize that medical intractability is a problem that the patient identifies in conjunction with the physician. Although a physician may feel that 12 months of steroids or other immunosuppressive management without complete resolution of symptoms is an adequate medical trial, the patient must be convinced that surgery is indicated. Only the patient can decide that he or she feels fatigued, has missed too much work or school, or is unable to do things he or she would like to do because of the systemic effects of active colitis and/or its medical treatment. If the surgeon waits until the patient has arrived at the conclusion that the disease is not satisfactorily controlled medically, the patient will graciously accept alternatives the surgeon has to offer. We feel this is a particularly important strategy for the surgeon to employ if the patient is to be satisfied.

Patients with UC are also prone to the development of colorectal cancer. The risk of cancer is relatively low for the first 10 years after disease onset, but then begins to increase so that by the time the patients has had the disease for 20 years, the cumulative risk of colorectal cancer may be as high as 10%. The overall prevalence of colorectal cancer in any UC patient is approximately 4%.[7] The question of timing of surgery for cancer prophylaxis remains undefined. Certainly, surgical treatment of carcinoma is mandatory. More controversial, however, is the management of patients with dysplasia. Most surgeons contend that during a surveillance biopsy program identification of dysplasia of any grade by an experienced pathologist, especially in the absence of severe inflammation,

is an indication for colectomy. The management of patients with UC who are found to have a sporadic adenoma (by definition a dysplastic lesion) is also contentious, as the simultaneous discovery of both lesions is not uncommon. If the lesion is detected in an area of colonic mucosa unaffected by UC, such a lesion may be reliably diagnosed as a sporadic adenoma. Alternatively, dysplastic mass lesions detected within should be viewed with a high degree of suspicion for malignant potential.[8]

Elective colectomy may be indicated for some categories of severe extraintestinal manifestations of the disease. Persistent or recurrent monoarticular arthritis, uveitis, or iritis all respond favorably to colectomy. However, primary sclerosing cholangitis, ankylosing spondylitis, and sacroiliitis are not improved by colectomy. The response of pyoderma gangrenosum to colectomy is unpredictable.

Growth retardation is a common feature in children with UC. Contrary to popular belief, steroid therapy cannot be entirely blamed for delayed growth. Inadequate protein intake and excess loss in the colon are also contributory.[9] A rapid growth spurt is often observed after definitive surgery.

Emergency Versus Elective Procedures

Operative management of UC largely depends on whether the surgery is elective or emergent. Under elective conditions, the four available surgical options are: (1) total proctocolectomy and Brooke ileostomy, (2) total proctocolectomy and continent ileostomy, (3) abdominal colectomy with ileorectal anastomosis (IRA), and (4) ileal pouch–anal anastomosis (IPAA). Total proctocolectomy and Brooke ileostomy has been traditionally regarded as the optimal surgical approach and remains the operation with which alternative procedures should be compared. The technique has been well described, and the immediate and late results are very satisfactory. Furthermore, patients avoid any risk for cancer, steroid medications are eliminated, and physician visits and reoperations are kept to a minimum. Although quality-of-life studies[10] have demonstrated excellent results, the loss of fecal continence and its attendant physical and psychological sequelae continue to be significant drawbacks of the procedure. In addition, problems with nonhealing of the perineal wound, and the high incidence of small bowel obstruction (SBO) and ileostomy revision, are not to be minimized,

Total proctocolectomy and continent ileostomy couples the benefit of complete large bowel excision with a reduction in some of the untoward aspects of an ileostomy, since no external appliance is needed and the stoma can be placed in a less conspicuous position on the abdominal wall. Continent ileostomy can be performed at anytime in UC patients having previously undergone total proctocolectomy and Brooke ileostomy if they find a standard ileostomy unsatisfactory. Due to increased surgical experience and improved surgical techniques, the morbidity associated with the continent

pouch has decreased since its initial clinical description. Most patients are ultimately happy with the results of the operation.[11] Nonetheless, troublesome complications leading to incontinence continue to plague the postoperative course of a substantial number of patients.[11,12] The continent ileostomy may also be a viable treatment option in selected patients who have failed an IPAA.[13]

There are many attractive features of total colectomy and IRA. The procedure avoids the perineal complications of total proctocolectomy, the risk of sexual dysfunction is minimal, is technically easy to perform, may provide perfect control of feces and flatus, and is well accepted by most patients. However, unlike the three other surgical options, ileorectostomy does not achieve total excision of colorectal mucosa. Many surgeons have not used this operation for patients with UC, arguing that in excess of 25% patients will require subsequent rectal excision for persistent proctitis, a small percentage of patients will develop cancer in the rectal remnant, and only one-half of the patients have satisfactory long-term functional results. While we concur that this operation should not be advised in most patients with UC, IRA does have a role in certain clinical situations. For example, an elderly patient with a long history of UC who develops a transverse colon cancer may be well served with an IRA in lieu of total proctocolectomy. An IRA may also be offered to females of childbearing age to preserve fertility.[14] Decisions must be made on an individualized basis, taking into account the compliance of the rectum and the integrity of the sphincter mechanism.

Ileal pouch–anal anastomosis has the attractive features of complete excision of the colorectal mucosa, avoidance of a permanent intestinal stoma, continence via a normal route of defecation, and no prospect for a troublesome nonhealing perineal wound. Continence is usually preserved and the frequency of defecation is diminished with incorporation of a pelvic pouch into the operative procedure. Although the operation is associated with minimal mortality, the morbidity of this complex procedure is relatively high, and problems such as small bowel obstruction and pouchitis continue to be a cause for concern.

Under emergent conditions, surgical alternatives are limited. If the patient is septic, the diseased or perforated bowel should be removed. If the colon is bleeding, the colon should be removed. Traditionally, it has been taught that the rectum should also be removed. However, with currently available sphincter-saving alternatives, careful preoperative proctoscopic evaluation to exclude a rectal etiology for the bleeding and a subsequent abdominal colectomy with end ileostomy can be safely performed. A subsequent procedure can then restore intestinal continuity. Similarly, with toxic colitis, it is seldom necessary to perform a proctectomy at the time of colectomy. In general, concerns over healing of the perineal wound in these frequently malnourished patients receiving high-dose steroids should deter surgeons from undertaking proctectomy in the emergent setting. Many surgeons have

not found it necessary to use the blow-hole technique of Turnbull, but this alternative is a philosophically acceptable approach in that it does not preclude subsequent continence-preserving alternatives.

A few technical issues regarding subtotal colectomy in these patients must be stressed. Mesenteric dissection in the vicinity of the ileocecal valve should be flush with the colon in order to preserve ileal branches of the ileocolic artery and vein. These branches are necessary to facilitate subsequent construction of an ileal pouch. Distally, it is unnecessary to mobilize the rectum within the pelvis. In fact, dissection of the sigmoid to the sacral promontory, without violation of presacral planes, and a Hartmann procedure are recommended. This precaution has shown to decrease the incidence of pelvic sepsis and facilitate subsequent pelvic surgery. A transanal rectal drain may prevent leakage from the diseased Hartmann pouch closure site. Laparoscopic-assisted or hand-assisted subtotal colectomy is both feasible and safe in these patients.[15]

There is a trend to avoid subjecting patients to multiple surgical procedures and to perform a definitive procedure at the time of emergent surgery. Although an IPAA can be successfully performed in patients undergoing surgery for emergent complications, this approach is generally not safe. These patients are usually on high doses of steroids and are nutritionally depleted. Patients with UC receiving high-dose steroids (more than 40 mg/day) have a significantly greater risk of developing pouch-related complications after colectomy than patients with UC receiving 1–40 mg/day and patients with UC who are not receiving corticosteroids.[16] From a practical standpoint, surgical options are limited in emergent situations. Salvage of the patient should be the primary concern. Abdominal colectomy is safe in these very ill, nutritionally depleted patients[17] and the procedure does not preclude the future of any of the other surgical alternatives. Additionally, the patient is able to live with an ileostomy and assess its impact on his or her life, thus allowing for an informed decision regarding subsequent continence-restoring surgery.

Brooke Ileostomy

The preoperative period should include effective patient education. A patient must be fully informed of the effects of an ileostomy on his or her quality of life. An ileostomy visitor, preferably age and sex matched and who has completely recovered from surgery, is invaluable during this period. Resistance to a permanent ileostomy can be tempered by stressing the beneficial aspects of this operation such as curing the disease. It is also essential, when possible, to select the stoma site preoperatively with the help of an enterostomal therapist. As discussed in Chap. 31 the stoma should be placed in a flat area away from bony prominences, scars, and significant skin creases. Attention to these details will ensure a well-functioning ileostomy.

Operative Technique

A colectomy is performed in the standard fashion with the patient in a modified lithotomy-Trendelenburg position. A minimally invasive approach is often preferred.[18] The proctectomy phase of the procedure is remarkable for keeping the dissection close to the rectal wall, especially anteriorly in the area of Denonvilliers' fascia. Meticulous dissection to minimize the risk of injury to pelvic autonomic nerves is essential. Perineal dissection should be performed in the intersphincteric plane. After the colorectum is removed, a 2-cm circular piece of skin is excised at the marked stoma site and a two finger-wide aperture is made through the lateral one-third of the rectus muscle. It is most important that this opening be of correct size to avoid chronic stomal obstruction or parastomal hernia. The mesentery of the ileum should be well mobilized to allow at least 5–6 cm of the ileum to protrude through the abdominal wall defect. The ileum may be anchored to the abdominal wall fascia with nonabsorbable sutures to prevent retraction of the stoma in the postoperative period. These sutures may also help prevent parastomal herniation, but there is no controlled study demonstrating that they are effective in preventing this complication. After the bowel is brought through the abdominal wall, a defect remains lateral to the small bowel mesentery. It is unclear whether this defect needs to be routinely closed. This area can be closed either by eliminating the defect laterally or by suturing the mesentery to the anterior abdominal wall. If the stoma is thought to be temporary, closing this mesenteric defect could possibly complicate subsequent small bowel mobilization.

The technical contribution of Brooke[19] was primary maturation of the ileostomy. Previously, the immature protruding ileostomy was left to protrude from the abdominal wall. Exposure of the serosa resulted in ileitis characterized by symptoms of small bowel obstruction. By folding the ileum back on itself, one covers the serosa and minimizes these symptoms. The stoma is routinely matured by removing 3–5 cm of mesentery from the end of the ileum and folding the edge of the bowel upon itself (see Chap. 31). To anchor the edge of the bowel, we use the "three-bite" suture that includes the full thickness of the bowel, seromuscular layer of the bowel, and the dermis of the skin. It is important to avoid placing a suture through the epidermis, in which mucosal cells can be implanted and cause difficulty with appliance security. An appliance is then placed over the stoma. Bowel function is expected in 1–3 days.

In some situations, the end of the ileum does not reach far enough through the abdominal wall to allow primary maturation. In these situations, the mesentery is usually a limiting factor and selection of a more proximal site in the bowel may allow better mobilization. Alternatively, a loop ileostomy rather than an end ileostomy may reach more easily. In these unusual situations, a segment of intact bowel is brought through the abdominal wall defect. Some surgeons prefer to suture the bowel to the fascia with nonabsorbable sutures rather than to use a rod to support the bowel in place.

Regardless of how the bowel is secured, the stoma should be primarily matured. This step is done by dividing the bowel distally through 85% of its circumference. The bowel is then folded back upon the proximal bowel and primarily sutured with the three-bite technique already described.

Postoperative Complications

Brooke ileostomy is a safe procedure with a predictable long-term outcome. It is, however, not entirely free of complications. Delayed healing of the perineal wound is not uncommon and can be quite problematic.[20] Failure of the wound to close should prompt investigation to exclude the presence of retained mucosa, foreign material, or Crohn's disease (CD). Sexual complications of proctocolectomy in men are much less common than in patients having a radical resection for cancer, yet permanent impotence or retrograde ejaculation can occur. Almost 30% of women complain of dyspareunia after this operation, presumably due to perineal scarring.[21] Intestinal obstruction is a troublesome complication that can be managed conservatively in most patients. Gentle irrigation of the stoma is an important therapeutic maneuver. Prolonged nonoperative treatment should not be pursued for fear of infarction. Although problems from the ileostomy have diminished markedly with the use of modern appliances and the Brooke modification, skin irritation, stomal stenosis, prolapse, and herniation remain significant causes of postoperative morbidity. Treatment of these problems can be as simple as reeducating a patient about the proper maintenance of the ileostomy. However, up to one-third of these patients ultimately require operative revision.[22] Despite the fact that these patients have undergone major abdominal surgery and have a permanent stoma, their quality of life as measured by validated questionnaires is very good and similar to that of the general population.[10] Over 90% of patients are happy with their current lifestyle. However, significant problems do remain. Almost 25% of patients are restricted in their social and recreation activities, and nearly 15% of patients who are knowledgeable of alternative procedures would consider conversion. In short, the Brooke ileostomy is generally well accepted, although a number of patients experience significant psychosocial and mechanical difficulties. This procedure is commonly performed using minimally invasive techniques. Current indications for the procedure include elderly patients, individuals with distal rectal cancer, patients with severely compromised anal function, and patients who choose this operation after appropriate education.

Continent Ileostomy

Physicians involved with patients requiring an ileostomy should be aware of the continent ileostomy. Although this procedure is less commonly performed today, it remains a viable alternative in patients who have discrete problems with an appliance. The surgeon should not primarily advise this procedure after a proctocolectomy. The continent ileostomy should be reserved for patients who have failed Brooke ileostomy or those individuals who are candidates for an IPAA, but cannot have a pouch because of rectal cancer, perianal fistulas, poor anal sphincter function, or occupations that may preclude frequent visits to the toilet.

Preoperatively, exclusion of CD using barium examination of the stomach and small intestine and/or CT-enterography and/or capsule endoscopy is important. Suspicion of CD contraindicates construction of a continent ileostomy, since the risk of recurrent disease in the pouch is increased; this could necessitate resection of 45 cm of valuable small bowel and render the patient unable to maintain nutrition. Obesity and age over 40 years are associated with an increased risk of pouch dysfunction and represent relative contraindications to the continent ileostomy.[23]

The period before surgery must also include an open discussion with the patient, stressing that although continence is likely, major complications often occur. These setbacks generally must be corrected surgically, sometimes leading to pouch excision and creation of a standard Brooke ileostomy. The patient must comprehend that by learning to care for and intubate the reservoir; he or she plays an important role in its functional outcome. Only highly motivated, emotionally stable individuals should consider this procedure.

Operative Technique

Patients undergoing combined total proctocolectomy/continent ileostomy have a proctocolectomy performed in the usual fashion. Excision of a very short segment of terminal ileum and a diligent search for CD during the procedure are essential. In patients with a standard ileostomy undergoing conversion to continent ileostomy, the stoma is mobilized from the abdominal wall. Construction of the reservoir in these two patient groups is then performed in an identical fashion.

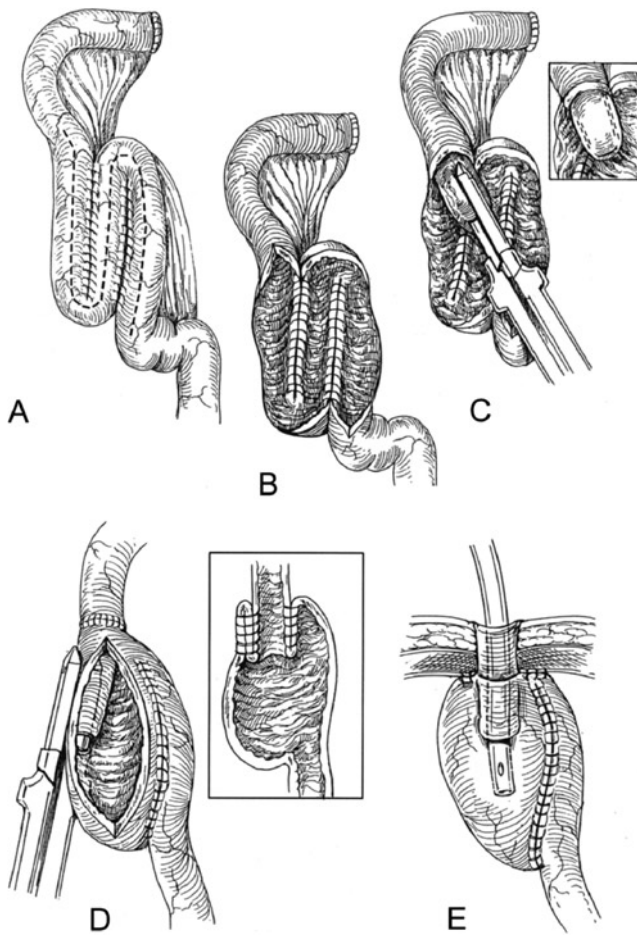
The technique of constructing a continent ileostomy is conceptually difficult (Figure 29-1). Using the terminal 45 cm of the ileum, an aperistaltic reservoir is created by making an S pouch or a pouch originally described by Kock.[23] In the classic technique, two 15-cm limbs ileum are sutured together with continuous absorbable sutures to form a pouch. The antimesenteric border is incised and then folded over to form a reservoir. The ileum immediately distal to the reservoir is then scarified with electrocautery and 5 cm of adjacent mesentery is removed and intussusception of this terminal 15 cm of ileum into the pouch is performed. The intussusception is secured with multiple nonabsorbable sutures and staples. The end of the ileum is then brought


FIGURE 29-1. Continent ileostomy. **A** Three limbs of small bowel are measured and the bowel wall is sutured together. **B** After opening the bowel (see the *dotted lines* in **A**), the edges are sewn together to form a two-layered closure. **C** A Valve is created by intussuscepting the efferent limb into the pouch and fixing it in place with a linear noncutting stapler. (*Inset*: staples in place on valve.) **D** The valve is attached to the pouch sidewall with the linear noncutting stapler (a cross section of the finished pouch is shown). **E** After closure of the last suture line, the pouch is attached to the abdominal wall and a catheter is inserted to keep the pouch decompressed during healing.

through the abdominal wall at the preoperatively identified site just above the escutcheon. The stoma is sutured flush with the skin and the pouch firmly anchored to the posterior rectus sheath. A wide plastic tube with large openings is placed into the pouch to allow gravity drainage of the pouch in the early postoperative period. This tube is occluded for progressively longer periods beginning 10 days after surgery until it can be removed for 8 h without distress. At this point, the pouch is significantly expanded, the tube is removed, and drainage is achieved by intubating the pouch three times a day. A 6-week period of the indwelling catheter is not uncommon.

Postoperative Complications

Postoperative complications that frequently occur are nipple valve slippage, pouchitis, intestinal obstruction, and fistula. Nipple valve slippage[24,25] occurs because of the tendency of the intussuscepted segment to slide and extrude on its mesenteric aspect. Difficult pouch catheterization, chronic outflow tract obstruction, and incontinence ensue. Because of the frequency of this problem, many techniques other than simple surgical stapling have been described to stabilize the valve. Wrapping the valve with prosthetic materials does prevent valve slippage, but also is accompanied by a potentially unacceptably high incidence of parastomal abscess and fistula formation.[12] Despite these technical modifications, nipple valve slippage remains the most common complication after continent ileostomy, occurring in almost 30% of patients.[12,24,25] Although nonoperative approaches have been attempted to correct this problem, surgical correction is virtually inevitable. Repair of the existing malfunctioning valve or creation of a new valve from the afferent ileal limb is performed.

Pouchitis is recognized in 25% of patients, making this the second most common postoperative complication after continent ileostomy.[12,24,25] Pouchitis refers to nonspecific inflammation that develops in the reservoir, and is thought to result from stasis and overgrowth of anaerobic bacteria. Patients present with a combination of increased ileostomy output, fever, weight loss, and stomal bleeding. The diagnosis is made by history and confirmed by pouch endoscopy. Pouchitis usually responds to a course of antibiotics and continuous pouch drainage.

Other complications include an incidence of intestinal obstruction after continent ileostomy of about 5%. Surgical intervention is mandatory when nonoperative therapy has been unsuccessful. The incidence of fistulas after creation of a continent ileostomy is approximately 10%. Fistulas most commonly originate in the pouch itself or at the base of the nipple valve. Pouch fistulas results from dehiscence of suture lines or, rarely ileostomy tube erosion. These tracts may close with bowel rest, parenteral nutrition, and continuous pouch drainage. Fistulas from the base of the valve lead to incontinence, since ileal contents bypass the high-pressure zone of the nipple valve. These fistulas commonly arise with tearing of the sutures anchoring the pouch to the anterior abdominal wall. Valve fistulas rarely heal without operation. At laparotomy, the valve is excised, the pouch rotated, and a new continent valve constructed from the afferent tract.

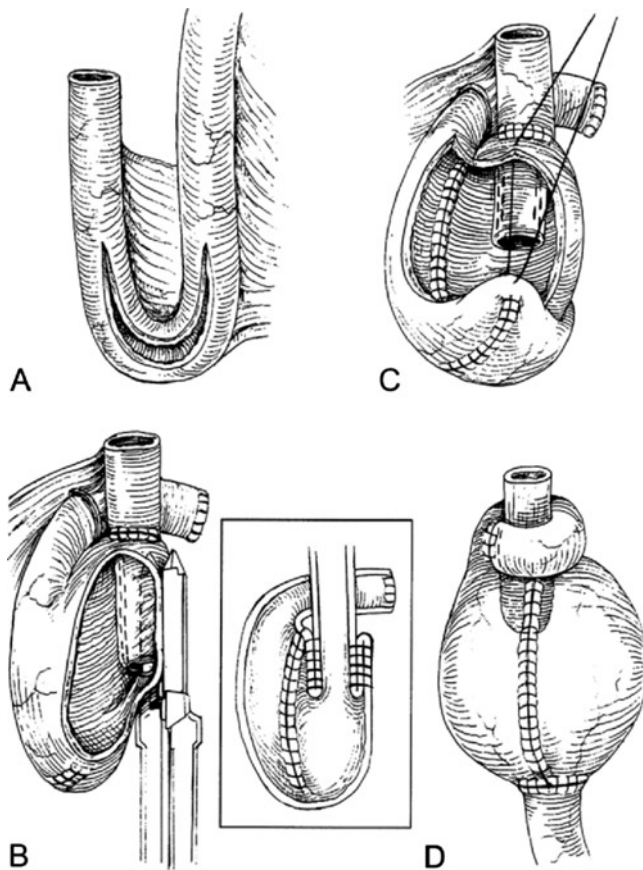
Patient satisfaction with a continent ileostomy has been reported by some authors as being very high.[11,26] Most patients note a marked improvement in their lifestyle, and almost all patients work and participate in social and recreational activities without restriction.[11,24] These observations are understandable in that 90% of patients eventually have total continence after one or more procedures. Conversely, their enthusiasm is surprising considering that complications


FIGURE 29-2. Barnet continent ileostomy reservoir (BCIR). **A** Two limbs of small intestine are sewn together and opened. **B** The afferent limb in intussuscepted to form a valve and the valve is stapled and stapled to the side of the reservoir. **C** The pouch is folded back and sutured closed. *Inset* shows cross section of pouch. **D** Completed BCIR. The afferent limb of bowel has been divided and reattached to the apex of the pouch and the efferent limb is wrapped around the valve to form a collar.

are quite frequent and often require major surgical intervention.[11,26] The often advertised Barnett modification of the Kock pouch (Figure 29-2) uses the afferent limb of small bowel to construct the nipple valve and wraps a portion of the residual efferent limb around the nipple valve.[27] Although designed to reduce the incidence of valve slippage and fistula formation, there are no controlled data to suggest that this modification is any better than the standard procedure most centers are using.

Ileorectal Anastomosis

Before the advent of IPAA, abdominal colectomy with IRA was performed in UC patients who might otherwise have been offered a permanent ileostomy. Currently, IRA is mainly considered in patients with indeterminate colitis (IC), in high-risk or older patients who are not good candidates for IPAA, or if

there is mild rectal disease where rectal compliance remains adequate. The use of the operation may also be indicated in the teenager or young adult in order to rapidly regain good health, avoid a stoma and return to school or work quickly. In addition, it can also be considered in young females in an attempt to preserve fertility.[14] Functional results depend on the level of the anastomosis as well as the state of the rectum. Contraindications to IRA include a very diseased and non-compliant rectum, dysplasia or nonmetastatic cancer, perianal disease, and a severely compromised anal sphincter.

Postoperative Complications

Ileorectal anastomosis is a safe operation; mortality is low, particularly when it is performed as an elective procedure. The early morbidity of IRA is low, with the incidence of anastomotic leak being less than 10%, and major sepsis is very uncommon. Sexual function is well preserved. The overall complication rate is much lower than that of an IPAA.[28] Although the frequency of defecation after IRA is variable, most patients pass between two and four semi-liquid stools a day. Nocturnal defecation is quite common, but true incontinence is rare.[29]

The main concerns surrounding IRA for UC are the long-term issues regarding cancer risk in the retained rectum and the incidence of persistent rectal inflammation. The overall risk of cancer developing in the rectum after IRA approximates 6%, but this depends on the duration of follow up.[30] Few of these cancers develop less than 10 years after operation, with most cancers appearing 15–20 years after operation. Rectal cancer following IRA produces few symptoms and early lesions are not always easily identified at sigmoidoscopy. Patients being offered IRA must realize the need for semi-annual sigmoidoscopy with multiple biopsies to detect dysplasia, polyps, or invasive cancer. This recommendation is particularly important in young adults or children since these patients have the highest risk of developing cancer and are much more likely to be lost to follow up.

The rectal stump may be the site of recurrent or persistent inflammation in 20–45% of patients. Clinical features include severe diarrhea, tenesmus, bleeding and urgency. Rectal excision is needed in those cases that do not respond to topical or systemic therapies. About one-quarter of patients require proctectomy after IRA for severe proctitis.[28,30] The only clinical factor which predicts a successful outcome is the degree of inflammation in the rectum preoperatively, minimal proctitis being associated with an excellent prognosis.[28] A great advantage of the IRA is that should a failure occur, other options remain. Conversion from an IRA to an IPAA may be required when there is a poor functional outcome because of poor rectal compliance, persistent and disabling proctitis, and with development of an upper rectal cancer. If conversion to IPAA is required, it can be performed safely, although poorer bowel function may be expected. However, quality of life is similar before and after conversion in these patients.[31]

Ileal-Pouch Anal Anastomosis

The most attractive of the continence-preserving alternatives is the IPAA, which consists of near total proctocolectomy, creation of an ileal reservoir, and preservation of the anal sphincter complex. The original operation as described by Sir Alan Parks included a complete stripping of the anal mucosa of the anal canal.[32] In an attempt to improve functional outcome, some surgeons[33,34] preserve the anal transition zone and perform a stapled anastomosis between the ileal pouch and the anal canal immediately cephalad to the dentate line (double-staple technique). Both of these techniques remove the colorectum without creating a perianal wound, preserve innervation to the anus, bladder, and genitals, and retain the usual pathway for defecation. Preoperatively, the rectum should be evaluated sigmoidoscopically. Active rectal disease requires topical 5-aminosalicylic acid or steroid enemas to minimize rectal inflammation and facilitate mucosectomy. The anorectal sphincter mechanism must be intact to prevent leakage of watery ileal contents. Use of this procedure in patients with poor sphincter function or fecal incontinence must be carefully individualized. Preoperative evaluation also allows the surgeon to be certain that patients undergoing this operation are highly motivated and willing to cope with potential postoperative complications.

Recent surgical advances have allowed both laparoscopic and hand-assisted proctocolectomy and IPAA. Laparoscopic ileal pouch surgery is associated with longer operating time and less blood loss, but may have short term benefits such as diminished postoperative pain, reduced narcotic requirements, and shorter hospital stay compared to open surgery.[35,36] A prospective randomized controlled trial of hand-assisted laparoscopic colonic mobilization and open rectal dissection (via an 8-cm Pfannenstiel incision) versus open surgery through the midline showed no difference in postoperative quality-of-life measurements.[36]

Operative Technique

The patient is brought to the operating room and placed in the modified lithotomy position. A midline incision is made and the abdomen explored to rule out evidence of CD. The colon is mobilized in the usual fashion. A few technical points should be stressed. Omentectomy may be inappropriate, since there is a lower incidence of postoperative sepsis when the omentum is preserved.[37] Stapling of the distal ileum flush with the cecum is very important, as is preservation of the ileal branches of the ileocolic artery and vein. These vessels provide perfusion of the pouch after mesenteric division. The pelvic peritoneum is incised and rectal mobilization begun. Dissection is carried ventrally to the level of the prostate in men and the mid-portion of the vagina in women. Posteriorly, the dissection is carried past the end of the coccyx. Mobilization of the rectum should be flush with the fascia propria to minimize damage to nearby autonomic nerves traveling to urinary bladder and sexual organs.

Laparoscopic-assisted IPAA is performed using four to five trocars and a 4-cm to 5-cm periumbilical, Pfannenstiel, or lower midline incision with the patient in low modified lithotomy position. The lateral attachments are divided, and most commonly the mesenteric vessels are divided with a bipolar vessel sealing and cutting device. If a temporary diverting ileostomy is planned, a disc of skin and subcutaneous fat can be excised from the chosen stoma site for the placement of the trocar in the right lower quadrant. Exteriorization of the mobilized colon and rectum can be achieved through a 4-cm to 5-cm incision placed at the umbilicus, or in the suprapubic region as either a Pfannenstiel or a short vertical suprapubic incision. Resection and pouch construction is performed extracorporeally similar to the open procedure or in a laparoscopic intracorporeal manner. The pouch is then returned to the abdomen and under laparoscopic control anastomosed to the anal canal. A diverting loop ileostomy is constructed in the right lower quadrant.

Hand-assisted laparoscopic (HAL) colectomy begins with an 8-cm Pfannenstiel or lower midline incision after which the hand device is positioned into the incision (Figure 29-3).
FIGURE 29-3. Hand-assisted colectomy begins with 8 cm Pfannenstiel or lower midline incision. Note how positioning of towels from the root of penis or top of the introitus to the anterior superior iliac spine creates a right angled triangle, assuring a straight transverse incision.
FIGURE 29-4. Technical maneuvers during hand-assisted laparoscopic total colectomy. **A** Traction of the ileocolic fat pad with traction towards the right lower quadrant will facilitate identification and preservation of the ileocolic artery. The omentum and transverse colon mesentery are divided either together **B** or separately after entry into the lesser sac **C**.

FIGURE 29-5. Typical wound appearance at completion of surgery.

FIGURE 29-6. Lone Star™ retractor.

A 12-mm trocar is inserted just below the umbilicus for the laparoscope and pneumoperitoneum. Additional 5-mm or 10-mm trocars are inserted as needed to facilitate the dissection. The surgeon's left hand is placed into the peritoneal cavity and the following procedures assisted. The greater omentum is dissected, the hepatocolic and splenocolic ligaments are taken down to mobilize the transverse colon, and the mesocolon is divided using a vessel sealing device (Figure 29-4). Although some authors advocate HAL rectal mobilization, the chapter authors advocate continuing the surgery open directly through the hand-device. The remainder of the procedure is continued akin to the open approach. This procedure provides the patient with a cosmetically acceptable outcome (Figure 29-5).

If desired, mucosal stripping is performed from a perineal approach. The use of a Lone Star™ (Lone Star Medical Products, Stafford, TX) retractor facilitates exposure and minimizes damage to the sphincter mechanism (Figure 29-6). A solution of dilute epinephrine is injected into the submucosal plane to facilitate mucosectomy and minimize bleeding

(Figure 29-7). The excised mucosa and remaining proximal rectum are removed, leaving a short cuff of denuded rectal muscle distally for about 4 cm above the dentate line. Attention is then directed towards creation of the ileal reservoir. The terminal ileum is aligned in a J configuration and the pouch constructed with either a continuous absorbable suture or stapling device (Figures 29-8 to 29-11). Both limbs of the J are approximately 15–25 cm in length, the exact length guided by where the pouch reaches deepest into the pelvis. The prospective apex of the pouch must reach beyond
FIGURE 29-7. Mucosectomy. In **A**, a spinal needle is used to inject saline solution with epinephrine (1:200,000) into the submucosa from the dentate line to the levators. A circumferential incision through the mucosa is made at the dentate line. A sleeve of mucosa is dissected free from the internal sphincter using sharp dissection **B**.

the symphysis pubis in order to accomplish a tension-free ileoanal anastomosis. Selective division of mesenteric vessels to the apex of a proposed J-pouch will allow for more length (Figure 29-12). Superficial incision on the anterior and posterior aspects of the small bowel mesentery along the course of the superior mesenteric artery, and mobilization of the small bowel mesentery up to and anterior to the duodenum,

are two additional important lengthening maneuvers. The pouch is then pulled into the pelvis and the anastomosis carried out between the apex of the pouch and the dentate line, approximating full-thickness of the pouch wall to the internal sphincter and anal mucosa (Figure 29-13). A proximal defunctioning loop ileostomy is created. One or two suction drains can be placed in the presacral space and brought
FIGURE 29-11. Ileal J-Pouch. Intraoperative photograph showing the completed J-Pouch.

FIGURE 29-12. Ileal J-pouch. The peritoneum is scored to lengthen the mesentery. Selective division of mesenteric arcades is used to produce additional length (From Veidenheimer MC. Mucosal proctectomy, ileal J-reservoir, and ileoanal anastomosis. In: Braasch JW, Sedgwick CE, Veidenheimer MC, Ellis FH Jr., editors. Atlas of abdominal surgery. Philadelphia: WB Saunders; 1991).

out through the lower abdominal quadrant. Placement of an anti-adhesion barrier around the stoma and underneath the incision should be considered to reduce the incidence and severity of postoperative abdominal adhesions.[38]

In the double-stapled technique, the anorectum is divided by the abdominal operator approximately 2 cm above the dentate line using a right-angle linear stapler (Figure 29-14). After the pouch is created, the anvil of the mid-sized circular stapler device is tied in to the apex of the ileal pouch. Before proceeding with the anastomosis, integrity of the rectal staple line is tested using air insufflation. The stapler is placed transanally and the trocar advanced through the transverse staple line. The stapler is then closed as the abdominal surgeon ensures that no extraneous tissues are trapped within the stapling device.

Postoperative management is similar to that in patients who have had a low anterior resection. Ileostomy output can be quite high, since the stoma is more proximal than a traditional Brooke ileostomy. Patients should be encouraged to keep themselves well hydrated. In some instances, antidiarrheal medication is prescribed.

Patients are usually discharged after 7–10 days in the hospital and return 6–8 weeks later to have the temporary ileostomy closed. Before closure, however, the pouch is thoroughly investigated. Digital rectal examination is used to assess anal sphincter tone and detect anastomotic strictures or defects. The pouch is examined endoscopically
FIGURE 29-13. Handsewn ileoanal anastomosis. After the pouch is gently pulled through the anal canal by the perineal surgeon, four sutures incorporating full thickness of the pouch and a generous bite of the internal sphincter are placed at right angles to anchor the efferent limb within the anal canal **A**. The anastomosis is completed by placing sutures between each anchoring suture **B**. Completed anastomosis **C**.

to ensure that the suture lines are healed, and a contrast study is performed to detect pouch leaks, fistulas and sinus tracts. Only after confirmation that pouch abnormalities are
FIGURE 29-14. Double-stapled J pouch anastomosis. The anvil of a mid-sized circular stapler is tied into the apex of the J pouch **A**. The anorectum is divided with a stapler within the levator muscles about 1–2 cm above the dentate line. Adjacent tissue such as the bladder or vagina must be excluded from incorporation in the staple line. The integrity of the staple line should be tested with air insufflation through an anoscope **B**. The perineal operator advances the mid-sized circular stapler against the anorectal transaction site and advances the trocar through the transverse staple line **C**. The anvil mechanism is positioned onto the rod of the circular stapler. Before completing the anastomosis, the abdominal operator must prevent extraneous tissue from being trapped into the stapling device **D**.

not present is the ileostomy closed. Sphincter strengthening exercises should be encouraged in the period leading up to ileostomy closure, since they appear to improve functional results. In over 90% of patients, the ileostomy can be closed through a peristomal incision. However, in the remainder the midline abdominal incision must be reopened.

Postoperative Complications

Performing an IPAA is safe, with reported mortality rates ranging 0–1%.[39] In distinct contrast to mortality, however, morbidity after IPAA remains considerable. Small bowel obstruction occurs in 20% of patients and results from adhesion formation to the large number of raw surfaces after colectomy and from kinking at the ileostomy site. Most of the obstructive episodes occur in the immediate period after either procedure. Although an initial trial of nonoperative therapy is appropriate, surgical intervention may ultimately be required.[40] Several strategies have been devised to prevent adhesion formation. Intraoperative application of a bioresorbable adhesion barrier may reduce the incidence of clinical adhesive SBO.[41]. It is also anticipated that the incidence of adhesive SBO will be reduced with the increasing use of laparoscopic IPAA.

Although the incidence has steadily decreased with increasing surgical experience, pelvic sepsis still occurs in 5% of patients after IPAA. Septic complications result from anastomotic dehiscence or an infected pelvic hematoma. Pelvic sepsis may present in the immediate postoperative period or it may be delayed, manifesting as abscess formation (usually presacral) or a perineal fustula. The symptoms suggestive of early pelvic sepsis are fever, anal pain, tenesmus, and discharge of pus or secondary hemorrhage through the anus. Diagnosis is confirmed using computed tomography (CT) or magnetic resonance imaging (MRI), which demonstrates the presence of an abscess or of edematous tissues. As patients who develop sepsis in the early postoperative period have a higher likelihood of subsequent pouch failure,[42] an aggressive therapeutic approach should be adopted in these patients. Although most patients respond to intravenous antibiotics within 24–36 h, patients with ongoing sepsis and an organized abscess should undergo early operative endoanal or imaging-guided percutaneous drainage. If drainage of the cavity is unsatisfactory, an attempt should be made to deroof the abscess and curette the cavity through the anus, creating a large communication between the abscess and the reservoir. A catheter should be placed into the cavity to promote drainage and irrigation. Sometimes several local procedures are needed to eradicate sepsis. Although relaparotomy is reserved for cases in which CT-guided drainage or minor surgery has failed to control sepsis and also for patients who deteriorate quickly with signs of generalized peritonitis, this approach is rarely needed.

The reported incidence of ileoanal anastomotic stricture has varied between 5 and 38%,[43–46] and depends in part on the definition of stricture used by different authors. For some, a stricture is a narrowing of the anastomosis that requires at least two dilations[44,45] whereas for others, a stricture is narrowing associated with pouch-outlet obstruction and poor evacuation that requires repeated dilations. The etiology is usually anastomotic tension that also predisposes to infection from leakage. Full mobilization of the mesentery and avoidance of traction on the reservoir are key technical maneuvers to avoid stricture formation. Anchoring the pouch to surrounding tissues may prevent direct tension on the anastomosis itself. Avoidance of sepsis is paramount to a successful outcome. An apparent stricture may be noted when digital examination is carried out for the first time after the operation. These asymptomatic web-like strictures can be easily disrupted by gentle passage of the finger. More fibrotic strictures can usually be fractured digitally, but occasionally the insertion of graded dilators under anesthesia is necessary. Operative management usually requires repeated dilatations yet reasonable function can be expected in over 50% of patients.[44,45,47] Rarely, a transanal approach involving excision of the stricture and pouch advancement distally is necessary.[48]

Anastomotic separation is seen in approximately 10% of patients. If this complication is recognized during

preileostomy closure contrast studies or as a defect on digital examination, ileostomy closure should be delayed until complete clinical and radiographic evidence of healing. Local drainage procedures for an associated abscess or a direct repair of the separation are sometimes necessary.[49] This aggressive approach will almost always be successful, allowing ileostomy closure.

The reported incidence of pouch-vaginal fistula ranges from 3 to 16%.[50–53] The patient complains of a vaginal discharge and clinical examination usually demonstrates the fistula. Occasionally, it is only detected by radiological contrast enema (pouchogram). It is important to exclude a pouch-vaginal fistula by careful operative examination of the vagina as well as the anal canal before closing the defunctioning ileostomy. The fistula may present before ileostomy closure or after stoma closure.[50] The internal opening is usually located at the ileoanal anastomosis, but less often it may arise at the dentate line, perhaps as a form of cryptoglandular sepsis. Causative factors may include injury to the vagina or rectovaginal septum during the rectal dissection or anastomotic dehiscence with pelvic sepsis. The latter is probably the major predisposing factor as pelvic sepsis rates are significantly higher in patients with pouch–vaginal fistula than in those without.[54] CD has been reported to be more common in patients with pouch–vaginal fistula, yet is difficult to prove in the majority of cases. Management depends on the severity of symptoms. When these are minimal and acceptable to the patient, no action or the placement of a seton may be all that is necessary.[52] In those with a clinically significant degree of incontinence, a diverting ileostomy should be established if not already present. The defunctioning, sepsis is drained with or without placement of a seton suture and, once it has settled, repair is indicated. Simple defunctioning alone does not often lead to fistula closure.[55] Medical therapy is not indicated in managing these fistulas, although one recent series showed efficacy of infliximab.[56] Surgical options are divided into abdominal and local procedures. The former includes abdominal revision with advancement of the ileoanal anastomosis, and the latter fistulectomy with or without sphincter repair, endoanal advancement flap repair, and endovaginal or transvaginal repair. The height of the ileoanal anastomosis is the essential feature that influences the choice of operative approach. Pouch–vaginal fistula from an anastomosis at or above the anorectal junction should be approached abdominally with pouch dissection, repair of the vaginal defect, and creation of a new ileoanal anstomosis. Several reports have reported an approximately 80% success rate using this approach.[55,57,58] A fistula arising from an anastomosis within the anal canal should not be treated with an abdominal procedure as there is not sufficient distal anal canal length to be clear of the fistula. A local procedure is necessary in such circumstances and most surgeons have used either an endoanal ileal advancement flap procedure[50,51,53,54] or a transvaginal technique.[59] Although both approaches result in fistula closure in 50–60% of cases, the

transvaginal repair may have an advantage over the endoanal technique as it allows a direct approach to the fistula without the possibility of sphincter damage. Another alternative is the use of a gracilis muscle interposition.[60]

The most frequent long-term complication after IPAA for UC is a nonspecific inflammation of the ileal pouch commonly known as pouchitis.[61–63] There are two clinical forms of pouchitis. Acute pouchitis responds rapidly to oral antibiotic treatment. In a smaller number of patients, chronic pouchitis can develop, a condition requiring long-term therapy with antibiotics or other agents.[64] Clinical factors associated with acute pouchitis include the use of steroids before colectomy and smoking. Factors directly related to chronic pouchitis are the presence of extraintestinal disease such as primary sclerosing cholangitis, elevated platelet count, and length of follow-up after IPAA. Smoking appears to protect against the development of chronic pouchitis.[65,66] Expression of the serologic factors, perinuclear antineutrophil cytoplasmic antibody (pANCA) and CBir1, before colectomy predict the development of acute and chronic pouchitis after IPAA.[67,68] The etiology of this nonspecific inflammation is unclear, but as with the continent ileostomy may be due to an overgrowth of anaerobic bacteria. Presenting symptoms include abdominal cramps, fever, pelvic pain, and sudden increase in stool frequency. Treatment of pelvic reservoir pouchitis relies primarily on the use of antibiotics such as metronidazole and ciprofloxacin.[69,70] A mixture of probiotics is useful in most IPAA patients after resolution of the acute symptoms to prevent recurrence of pouchitis.[71] Although these regimens are almost always successful, occasionally steroid enemas or 5-aminosalicylates will be necessary. Uncommonly, an ileostomy with or without pouch excision is required for severe refractory pouchitis.

The number of bowel movements after successful ileoanal pouch procedures averages six per 24 h. Most patients are not particularly concerned with how often they defecate since most can postpone defecation to accommodate social and recreational activities. Major incontinence is very unusual, although minor incontinence to mucus or stool, particularly at night, is observed in approximately 30% of patients. These patients are managed effectively with good perianal hygiene and the occasional use of a perineal pad. Although continence is clearly altered after pelvic pouch surgery, quality of life is extremely well preserved.[72] Quality-of-life studies have disclosed that more than 95% of patients are satisfied with their pouch[73] and would not go back to an ileostomy. In order to obtain these results, however, approximately one half of patients regularly take a bulking agent or antidiarrheal medication to help regulate their bowels. Many patients also tend to eat less in the evening than at midday in order to minimize bowel movements when they are going out or while sleeping. Total failure, defined as removal of the pouch, occurs in only 5–8% of cases and is usually caused by pelvic sepsis, undiagnosed CD, or an unacceptable functional outcome.

Issues related to fertility, pregnancy, and the preferred method of delivery are of great importance in the female IPAA patient, many of whom are young and within their reproductive years. Two large studies showed a significant decrease in postoperative fertility.[74,75] Results of a recent systematic review were more promising, revealing an infertility rate of 12% before restorative proctocolectomy and only 26% after surgery based on 7 studies and 945 evaluable patients.[76] The decrease in postoperative fertility was attributed to probable tubal occlusion from adhesions, a phenomenon observed in another study.[77] However, physician recommendations against conception and patient concerns about having children affected with UC could not be discounted.[74] There are a number of strategies to improve fertility in these patients. Application of an anti-adhesion membrane around the fallopian tubes and ovaries during surgery is recommended. Surgeons may also consider delaying proctectomy until a family has been established. Finally, since laparoscopy appears to reduce the number of peritubal adhesions after IPAA,[78] minimally invasive surgery should be strongly considered in all young females.

The optimal method of delivery remains controversial. Cesarean section decreases the risk of incontinence resulting from damage to the anal sphincters and yet is associated with complications inherent to abdominal surgery, including injury to the pelvic pouch and adhesion formation. Vaginal delivery may damage the pudendal nerve and the anal sphincter mechanism, but it reduces the problems associated with abdominal surgery and recovery is more rapid. Recent reports show a higher incidence of an anterior sphincter defects and lower mean squeeze anal pressures following vaginal delivery compared with cesarean delivery in women with an IPAA.[79] In the short-term, vaginal delivery does not seem substantially to influence pouch function or quality of life.[76,80] However, vaginal delivery has been shown to cause occult sphincter damage[81] and injury to the innervation of the pelvic floor in normal females.[82] These factors could lead to an increased risk of fecal incontinence with age, which would be particularly devastating in a patient with a pelvic pouch.

Controversies

In approximately 10% of colitis patients, there are inadequate diagnostic criteria to make a definite distinction between UC and CD, especially in the setting of fulminant colitis.[83,84] Although some studies have found higher rates of perineal complications, development of CD, and eventual pouch loss in IC patients,[85] other papers have suggested that IC patients have outcomes comparable to UC patients.[86,87] These conflicting results in part arise from the retrospective design, small patient number, suboptimal patient follow-up and referral center bias typical of these studies. The disparate results also arise from widespread confusion over the precise diagnosis of IC. Even though the term IC was initially applied to resection specimens,[83] it has in recent years been also used in patients having atypical preoperative radiographic or endoscopic features, including biopsy specimens. This had resulted in many studies including patients with indeterminate features preoperatively, postoperatively, or both. Recently published World Congress of Gastroenterology recommendations recommend that the diagnosis of IC should be made only after colectomy, and that the term inflammatory bowel disease-unclassified (IBDU) be used in all other cases where definitive features of CD and UC are absent.[88] A large, prospective study recently reported the incidence of acute pouchitis, chronic pouchitis, and de novo CD after ileal pouch–anal anastomosis do not differ significantly between patients with UC, IBDU, or IC.[86] Patients with IBDU and IC can undergo ileal pouch–anal anastomosis and expect a long-term outcome equivalent to patients with UC.

Another debated issue is whether IPAA should be offered to elderly patients. Two reasons to avoid these procedures in older patients relate to the higher incidence of anal sphincter dysfunction with increasing age and the morbidity of reoperations in these potentially medically compromised patients. However operations for rectal cancer with anastomosis to the anal sphincter are regularly undertaken in patients in their seventh and eighth decades, and thus many surgeons contend that an IPAA should also be made available. Many groups have demonstrated that IPAA in the elderly patient is safe and feasible.[89,90] It appears that chronologic age should not itself be used as an exclusion criterion. Pouch procedures are feasible in suitably motivated elderly individuals who understand the risks and problems of this procedure. Although bowel frequency remains constant in the first decade after the surgical procedure,[91,92] it is unclear what will occur as the patient continues to age. Perhaps the use of a double-stapled technique with preservation of the anal transition zone might improve function over time, but this remains unproven.

Another controversy relates to the use of the IPAA in UC patients who have an established colorectal cancer. The presence of distant metastatic disease is generally a contraindication to IPAA. These unfortunate patients should be managed with segmental colectomy or abdominal colectomy with IRA to facilitate early discharge and allow them to spend the rest of their lives relatively free of complications. Patients with middle and low rectal tumors, in accordance with basic principles of cancer surgery, may not be eligible for this procedure. Radiation therapy, if indicated, should be performed preoperatively; a pelvic pouch should not be subjected to radiation because of a high incidence of pouch loss. UC patients with cecal cancers represent another unique subgroup of patients. The sacrifice of a long segment of adjacent distal ileum with its mesenteric vessels may limit positioning of the reservoir into the pelvis. If a tension-free anastomosis cannot be ensured, a Brooke ileostomy may be necessary.

Studies examining the use of the ileoanal pouch in patients with locally invasive cancers of the colon and upper rectum have been conflicting. In one series,[93] UC patients with a carcinoma had postoperative complications and functional results identical to UC patients without cancer. Metastatic disease developed in a small number of patients. In contrast, another study revealed that almost 20% of UC patients with cancer who had an IPAA died of metastatic disease.[94] Since both of these patients had T3 cancers at surgery, it is unclear that their course was adversely influenced by performing IPAA. This conservative management approach is also encouraged by surgeons at the Lahey Clinic,[95] where UC patients with a T3 cancer initially undergo an abdominal colectomy with ileostomy. An observation period of at least 12 months is recommended to ensure that no recurrent disease develops. Another reason to postpone IPAA in these patients is to allow adjuvant chemoradiation therapy to proceed unhindered without any added morbidity from a pouch–anal anastomosis and a relatively proximal ileostomy.

A number of innovations of the IPAA operation spurred by a desire to decrease complications and improve function have led to a series of technical controversies. Some authors feel that the entire rectal mucosa does not need to be removed. They favor leaving 1–2 cm of distal mucosa behind, transecting the rectum just above the puborectalis muscle and stapling the pouch to the rectal remnant. The potential advantages of the double-stapled approach include technical ease as it avoids a mucosectomy and the perineal phase of the operation, less tension on the anastomotic line, and improved functional results because sphincter injury is minimized and the anal transition zone with its abundant supply of sensory nerve endings is preserved.[96] On the other hand, surgeons who oppose this operative approach not only contend that residual diseased mucosa is at risk of malignancy, but are also concerned about the potential for continuing proctitis in the residual mucosa (i.e., cuffitis). A recent review of cases of adenocarcinoma occurring after IPAA suggested that cancer can occur when either a mucosectomy or a double-staple technique was used, whether there was dysplasia preoperatively, or whether the rectum was initially involved.[97] Although inflammation in the rectal cuff after double-stapled IPAA is commonly seen, only about 10% of these patients are symptomatic.[98] One small, uncontrolled study with significant patient dropout suggested that mesalamine suppositories might be an effective treatment for symptomatic cuffitis.[99] In an effort to resolve the handsewn versus stapled controversy, three small prospective randomized trials and one meta-analysis of those three trials failed to demonstrate any significant differences in perioperative complications or functional results in those patients where a mucosectomy was done versus those patients where the distal rectal mucosa was preserved.[100–103] It is important that the surgeon performing an IPAA be familiar with both techniques in the event of failure or inability to use the stapler or when a handsewn anastomosis is contemplated but where
FIGURE 29-15. Different ileal pouch configurations.

anastomotic tension is excessive. It must be stressed that if a stapled technique is used, care should be taken to create an ileal pouch to anal anastomosis and not an ileal-to-rectum anastomosis. In addition, the patient must also be made aware of the need for long-term surveillance of the cuff, particularly if surgery was performed for carcinoma or dysplasia.[104] Alternatively, if mucosectomy is selected, the patients must understand that a cancer or colitis can occur in the isolated viable mucosal islands inside of the muscular cuff, but outside of the pouch serosa. Therefore these areas cannot be visualized or biopsied.

Another technical controversial issue is the shape and size of the reservoir. Although the initial ileal reservoir created by Parks in the late 1970s was a triple-loop S pouch,[32] other pouch configurations have been described in an attempt to reduce pouch complications and improve functional outcome (Figure 29-15). Three other configurations that have been described are the double-loop J pouch, the quadruple-loop W pouch, and the lateral isoperistaltic H pouch.[105–107] S pouches were initially plagued with evacuation problems associated with a long (5-cm or more) exit conduit, frequently requiring pouch catheterization.[32] With shortening of the exit conduit to 2 cm or less, mandatory catheterization has been substantially reduced.[108] The long outlet tract formed in the H pouch was also associated with pouch distention, stasis and pouchitis.[109] The W pouch has been favored by some surgeons[107] because its theoretically greater capacity may lead to fewer daily bowel movements. However, two randomized trials comparing the W and J pouch did not confirm this hypothesis.[110,111] In one study,[110] the median number of stools per day was the same in patients with a J or W pouch, and there was no difference in functional outcome between the two reservoirs in rates of incontinence, urgency, soiling, and the use of antidiarrheal agents. Johnston and coworkers[111] also demonstrated similar functional results between J and W pouches 1-year after surgery. At present, most centers perform a J pouch since it is easier and faster to construct.[110,112] An S pouch can provide additional length (2–4 cm) compared with the J pouch and can be useful in minimizing

anastomotic tension. However, the 2-cm exit conduit of the S pouch may lengthen over time and obstructive defecation may develop.

A controversy that merits discussion relates to the routine use of a diverting loop ileostomy. Proponents of routine fecal diversion[113,114] contend that postoperative septic complications are minimized. Loop ileostomy also obviates the problem of immediate severe diarrhea through an edematous ileal pouch and a sphincter that has been damaged surgically by mucosectomy or double-stapling. On the other hand, many surgeons believe that the loop ileostomy is counterproductive.[115,116] Notwithstanding the additional operation and increased hospitalization associated with its closure, the morbidity of ileostomy closure is not insignificant, as small bowel obstruction and anastomosis leaks can occur. In addition, these ileostomies may be proximal in the small bowel and thus represent high-output stomas that can cause clinical dehydration. Some surgeons contend that omission of the ileostomy is safe when the anastomosis appears intact and under no tension, the procedure is not complicated by excessive bleeding or other technical difficulties, the terminal ileum is not affected by backwash ileitis, and the patients are not on high steroid doses prior to surgery. These criteria, however, have not been clearly studied in a prospective randomized fashion. It should be stressed that problems associated with the ileostomy or its closure such as dehydration, anastomotic leak, or bowel obstruction are easily managed with medical or surgical means. The development of a pouch specific complication in those patients without an ileostomy is a particularly morbid event requiring repeat laparotomy and fecal diversion in a septic patient. Clearly, more work is needed to further resolve the issue of whether an ileostomy should be routinely used in this procedure. It is clear that although associated with more skin irritation and stomal nursing care, a loop ileostomy is preferred over an end ileostomy for temporary fecal diversion after IPAA because of the ease of loop stoma closure.[117]

Many of the pelvic complications of the ileal pouch can be effectively managed by a perineal procedure. In some cases, however, these local procedures are not successful. The role of abdominal salvage surgery aimed at avoiding pouch excision or indefinite fecal diversion in patients with refractory pelvic sepsis, poor pouch function or inflammation of retained rectal mucosa remains to be defined. Successful outcomes after salvage surgery have been reported in up to 90% of UC patients.[118–121] Others, however, have reported poorer results.[42,47,122] This great variability in success rates may be explained by variation in the severity of sepsis and its location in relation to the anastomosis.[42] The duration of follow-up is also an important factor, as failure after salvage continues steadily with time.[42,47] Various factors need to be considered when advising an abdominal salvage procedure, including feasibility of success, magnitude of operation, overall duration of treatment, and the patient's wishes. Counselling is essential and the patient must be given a realistic appraisal of the prospect of a successful outcome. The potential morbidity of removal of the reservoir resulting in a permanent ileostomy should also be discussed, including the possibility of a high-output ileostomy, pelvic nerve damage, and an unhealed perineal wound.

Conclusion

The approach to the patient with UC who requires surgical intervention must begin with an honest and thorough discussion concerning the pros and cons of each procedure. Surgeons should individualize treatment based on the patients' desires, fears, and expectations. In general, those patients desiring a minimum of complications without regard for continence should undergo total proctocolectomy with Brooke ileostomy. Those patients wanting to preserve fecal incontinence, but also willing to accept a number of potential postoperative complications that in some cases may necessitate a stoma should consider an IPAA. The risk of complications and the unknown long-term effects of continence-preserving surgery require that patients be willing to undergo careful and regular follow-up. Patients not expected to comply with or take care of a continent ileostomy or IPAA should not be offered these procedures. The Standards Practice Task Force of the American Society of Colon and Rectal Surgeons has published practice parameters for the surgical treatment of UC.[123]

Crohn's Disease: Surgical Management

Scott A. Strong

Introduction

Crohn's disease is a chronic, unremitting inflammatory condition of uncertain etiology that can affect the entirety of the alimentary tract. Appropriate diagnosis and management of the disease requires collaboration among physicians, radiologists, pathologists, and surgeons who work to safely maintain a satisfactory quality of life in patients who suffer from this incurable disorder. Depending upon the patient age, disease location, disease behavior, and other clinical parameters, the surgeon uses intestinal bypass, strictureplasty, and/or bowel resection to manage disease that is confounded by complications or refractory to conventional medical therapy. Particular care must be taken during surgery to address all areas of symptomatic disease while minimizing the risk for future complications arising from recurrent disease.

Prevalence

Increasing trends in the worldwide prevalence of Crohn's disease have been observed with a broad north–south gradient still prevailing in Europe.[1] The highest incidence areas are still seen in distinct regions of Canada, France, New Zealand, Netherlands, Scandinavia, and Scotland. While affluence and an industrialized status are common associations between endemic areas, an etiological role cannot be clearly supported based upon the current evidence.

Crohn's disease is recognized to demonstrate a bimodal age distribution with the first peak occurring between the ages of 15 and 30 years and the second between 60 and 80 years. However, most patients experience the onset of disease symptoms before 30 years of age. The disorder is more common in whites than in blacks, Hispanics, or Asians, and a two to fourfold increase in the prevalence has been found among the Jewish population in the USA, Europe, and South Africa compared to other ethnic groups.[2,3]

In a sample of nine million Americans, Kappelman and colleagues[4] recently reported the prevalence of Crohn's disease in patients aged younger and older than 20 years to be 43 and 201 per 100,000, respectively. A slight male predominance was seen in the pediatric population and a converse female predominance was noted in adulthood. Overall, only subtle regional differences in the prevalence were seen with the lowest prevalence observed in the South. However, the amount of geographic variation was less than that seen reported in Canada and Europe.

Etiopathology

The development of Crohn's disease likely involves host genetics, an environmental trigger, and altered immune responses. A recent review[5] of eight genome-wide association studies performed in Crohn's disease have identified several loci influencing disease susceptibility and a meta-analysis[6] implicated another 20–30 loci. Many of the new findings in Crohn's disease segregate into particular biological pathways and functions. Two particular pathways have generated significant interest.[7] The first of these involves autophagy, which is responsible for the recycling of cellular organelles and long-lived proteins, and plays an important role in tissue homeostasis as well as intracellular bacteria processing. The second is the IL-23/Th17 pathway. IL-23 stimulates the Th17 cell population to produce IL-17 and other pro-inflammatory cytokines involved in intestinal inflammation.

Environmental triggers of Crohn's disease have been long sought and research is based upon epidemiological, clinical, and experimental studies. To date, three hypotheses associate environmental factors with the etiopathology of Crohn's disease and they include the hygiene, infection, and cold chain hypotheses. Although the role of smoking as a risk factor has been reasonably well established,[8] many other environmental factors have been investigated, including diet, drugs, infectious agents, social status, and stress. Among these other factors, antibiotics, oral contraceptives, and selected microbes could potentially play a role in the triggering of Crohn's disease.[9–11]

In normal intestine, the immunologic character is typified by suppression or tolerance of immune responses against nonpathogens present within the gut lumen. These nonpathogens include both commensal flora and dietary antigens. Conversely, this tolerant state, at least to specific components of the flora, is lost in patients with Crohn's disease. Tolerance is mediated by regulatory cells that control immune responses, and these cells may be ineffectively activated or maintained in Crohn's disease. Although the cellular constituents are responsible for the inflammation, the cellular products and their effect on other local cell populations lead to the actual disease manifestations and the particular disease behavior is likely dictated by the distinct pathway involved in the abnormally regulated inflammatory response. Mounting evidence also suggests that the inflammatory mediators may transition over time because of the natural disease course or in response to medical therapy.[7]

Therefore, Crohn's disease likely arises in a genetically susceptible individual exposed to an ordinarily harmless trigger that initiates a dysregulated inflammatory response causing an aggressive and persistent inflammatory response that becomes progressively resistant to medical therapy during the patient's lifetime.

Classification

The original classification of Crohn's disease was described nearly four decades ago,[12] but inaccuracies associated with this and subsequent systems led to the development of the Vienna classification[13] and its modification, the Montreal classification.[14] The Vienna schema was generated by a World Congress of Gastroenterology Working Party that prospectively designed a simple phenotypic classification system based on objective and reproducible clinical variables that include age at disease diagnosis (A), anatomic location of disease (L), and disease behavior (B).

The ability of experts to independently agree on disease phenotype using the Vienna classification in controlled trials ranged from poor to fair.[15] Accordingly, the Montreal classification was introduced. The new schema did not alter the three principal categories, but modifications within each of the variables were introduced (Table 30-1).[14]

With respect to age of onset, the Montreal classification introduced a subgroup for patients with early onset of disease because several studies have demonstrated that specific serotypes or genotypes are more frequently found in early onset Crohn's disease.

Regarding disease location, the major limitation of the Vienna classification was that the four locations were mutually exclusive, and experience suggests that upper gastrointestinal disease can commonly coexist with more distal disease. Therefore, the upper gastrointestinal disease description is now used alone or as a modifier of the ileal, colonic, or ileocolonic subgroups. Ileal disease is defined as disease limited

TABLE 30-1. Montreal classification system of Crohn's disease[14]

Age of diagnosis	A1 <16 years
	A2 17–40 years
	A3 >40 years
Location	L1 Ileal
	L2 Colonic
	L3 Ileo-colic
	L4 Isolated upper
Behavior	B1 nonstricturing nonpenetrating
	B2 Stricturing
	B3 Penetrating
	P Perianal disease

to the lower third of the small bowel (terminal ileum) with or without cecal involvement. Colonic disease is any colon involvement between the cecum and rectum without terminal ileal disease. Ileocolonic disease is disease of the terminal ileum with colon involvement noted between the cecum and rectum. Lastly, upper gastrointestinal disease is defined as any disease location proximal to the terminal ileum.

The behavior variable was edited because several reports indicate that perianal fistulizing disease is not inevitably associated with penetrating intestinal disease, and it was convincingly argued that perianal disease alone required a separate subclassification.

Initial application of the Vienna classification to clinical practice demonstrated that the Crohn's disease phenotype markedly changes for a given patient over time.[16] While only 15% of patients experience an alteration in anatomic location, nearly 80% of individuals with inflammatory disease ultimately demonstrate stricturing or penetrating behavior. It is unclear whether the various classification systems fail because of the heterogeneity of the disease or the inherent shortcomings of the schema itself. Although these failings may limit the utility of the Montreal classification in clinical trials and disease management, advances in determining the genetic linkages associated with Crohn's disease will eventually lead to a classification system that combines genotype and phenotype characteristics. In order to improve clinical utility, a classification system specific for perianal Crohn's disease has been described and is shown in Table 30-2.[17]

Symptoms and Signs

The symptoms and signs of patients suffering from Crohn's disease can vary depending upon multiple factors that include the anatomic location and behavior of the disease. Chronic diarrhea is the most common presenting symptom and is defined as a decrease in fecal consistency for more than 6 weeks to adequately differentiate this from self-limited infectious diarrhea. Abdominal pain and weight loss are seen in about 70% and 60% of patients before diagnosis, respectively. Blood or mucus in the stool can be seen in 40–50% of patients with Crohn's disease of the colon, but is unusual in patients with ileal or isolated upper gastrointestinal disease.

TABLE 30-2. Perianal Crohn's disease activity index[17]

Feature	Score
Abscess	
None *or*	0
First occurrence, single abscess *or*	1
First occurrence, multiple abscesses *or*	3
First recurrence, single or multiple abscesses *or*	4
Multiple recurrence, single or multiple abscesses	5
Maximum abscess score	8
Fistula	
None	0
Short-term (<30 days) fistula *or*	1
Long-term (>30 days) fistula *or*	2
Persistent postsurgery fistula *or*	3
Recurrent fistula	3
Multiple fistulas	3
Rectovaginal/rectourethral fistula *or*	4
Recurrent rectovaginal/rectourethral fistula	6
Maximum fistula score	14
Ulcer and fissure	
None	0
Short-term (<30 days) ulcer/fissure *or*	1
Long-term (>30 days) ulcer/fissure *or*	2
Single ulcer/fissure *or*	1
Multiple ulcers/fissures	2
Maximum ulcer/fissure score	4
Stenosis	
None	0
Short-term (<30 days) stenosis *or*	1
Long-term (>30 days) stenosis	2
Recurrent stenosis	4
Maximum stenosis score	6
Incontinence score	
No incontinence *or*	0
Incontinence score of 1–6 *or*	1
Incontinence score of 7–14 *or*	3
Incontinence score >14	5
Maximum incontinence score	5
Concomitant disease[a]	
None *or*	0, 0, 0
Moderate *or*	3, 2, 1
Severe	4, 3, 2
Active fistula	4, 3, 2
Maximum concomitant disease score	18

[a]Scores are for rectal, colonic, and small-bowel disease, respectively.

The most common of the recognized extra-intestinal manifestations, are abnormalities involving the axial and peripheral joints of the musculoskeletal system, which are most frequently seen when Crohn's disease affects the colon.[18]

Diagnosis

The initial diagnosis of Crohn's disease is based on an amalgamation of clinical, laboratory, imaging, endoscopic, and histologic findings. Although no single diagnostic test provides an unequivocal verdict, differing studies used in varying combinations can usually provide the information required to diagnose Crohn's disease. Accordingly, the current view is that the diagnosis is established by a defined combination of findings from clinical presentation, radiology, endoscopy, surgery, histology, and perhaps serology. Lennard-Jones and colleagues[19] were among the first to define macroscopic and microscopic criteria required to establish the diagnosis.

With evolving therapies that now allow physicians and surgeons to effectively treat nearly all forms of Crohn's disease, the success of these treatments depends upon the clinician's ability to recognize the extent and nature of disease. Therefore, the investigative studies must not only correctly identify the diagnosis of Crohn's disease, but also accurately assess its location, behavior, and severity. This knowledge is especially important in many scenarios such as distinguishing colonic Crohn's disease from ulcerative colitis and other colitides, inflammatory sites of narrowing from fibrotic strictures, intra-abdominal abscesses from phlegmons, and complex fistulas from simple fistulas.

A thorough history and physical examination might suggest the form of disease as earlier suggested, but laboratory testing can help identify patients with complicating disorders, such as anemia, inflammation, or malnutrition, or monitor response to therapy. Anemia and thrombocytosis represent the most common changes in the complete blood count in patients with Crohn's disease.[18] The C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) are standard laboratory surrogates of the acute phase response to inflammation. CRP broadly correlates with disease severity as assessed by standard indices, and the CRP level can be monitored to measure serial changes in inflammatory activity because of its relatively short half-life of 19 hours.[20,21] The ESR less accurately measures intestinal inflammation because it reflects changes in both plasma protein concentration and packed cell volume. Although the ESR level parallels disease activity, it better correlates with colonic than with ileal disease.[22]

The usage of imaging studies has greatly expanded in recent years with the advent of computed tomographic (CT) enterography and enteroclysis. These modalities differ from standard CT imaging of the abdomen and pelvis by using intraluminal bowel distention with neutral enteric contrast, mutidetector CT with narrow slice thickness and reconstruction interval, and intravenous contrast administration followed by delayed scans that optimize bowel wall enhancement (Figure 30-1). CT enterography has largely supplanted barium examinations because the CT study is more sensitive and allows improved visualization of small bowel loops within the pelvis.[23] Contrast-enhanced magnetic resonance imaging (MRI) enterography and enteroclysis also accurately display bowel wall changes in early Crohn's disease and appear to provide results comparable to those seen with CT studies without the risk of exposure to ionizing radiation.[23] Similar to the advances seen with imaging studies, endoscopic evaluation techniques have evolved from traditional ileocolonoscopy and esophagogastroduodenoscopy to now include capsule endoscopy and double-balloon

FIGURE 30-1. CT enterography.

enteroscopy, which allow visualization of small bowel that was previously impossible to view.

Microscopic features can be only partly judged on mucosal biopsy, but completely assessed on an operative specimen. The diagnosis of Crohn's disease typically depends on the finding of discontinuous and often granulomatous intestinal inflammation. The European Crohn's and Colitis Organization recently offered a consensus statement detailing the microscopic features required for the histologic diagnosis of Crohn's disease based upon findings associated with endoscopic biopsies and surgical specimens.[18]

Natural History

A recent comprehensive review of the natural history of Crohn's disease revealed that patients' initial presentations are equally distributed among ileitis, colitis, and ileocolitis, and the disease location remained relatively stable over time as earlier discussed.[24] Conversely, the majority of patients have nonstricturing, nonpenetrating disease at the time of diagnosis, but tend to evolve into a stricturing or penetrating phenotype over their lifetime.

Prior to the wide-spread usage of immunomodulators and introduction of biologic agents, approximately 1% of patients suffered continually active disease, 10% enjoyed prolonged remission, and one-half experienced a full year of remission within 3 years of diagnosis, but surgery was commonly required to achieve remission.[24] It is too early to accurately understand how advancements in medical therapy have impacted long-term disease activity and relapse rates.

Before the current medication era, steroids were prescribed to nearly one-half of patients at some time during the course of their disease. Nonresponders, sustained responders, and steroid-dependent responders comprised approximately one-fifth, one-third, and one-third of the patients receiving steroids, respectively, and one-third of patients required surgery despite treatment with steroids.[24] However, it is important to

recognize that, the cumulative risk for surgery within 10 years of diagnosis is 40–55% and the risk of a second operation has been estimated to be 16%, 28%, and 35% at 5, 10, and 15 years following the initial procedure, respectively.[25]

Among unselected patients with Crohn's disease in a systematic review and meta-analysis of population-based studies focused on overall and cause-specific standardized mortality rates, overall mortality was slightly but significantly higher than that seen in the general population.[26] Regarding the cause-specific mortality, a significantly increased risk of cancer death, especially pulmonary cancer, was observed. Moreover, chronic obstructive pulmonary disease, gastrointestinal diseases, and genitourinary diseases were more commonly implicated as a cause of death in this cohort of patients.

Operative Indications

The indications for operative management of Crohn's disease include acute disease complications, chronic disease complications, and failed medical therapy. The acute complications are hemorrhage, perforation, and severe colitis with or without associated megacolon, whereas the chronic disease complications include extra-intestinal manifestations, growth retardation, and neoplasia. Failed medical therapy can take several forms, including unresponsive disease, incomplete response, medication-related complications, and noncompliance with medication.

Hemorrhage

Crohn's disease may be responsible for life-threatening lower gastrointestinal hemorrhage and even exsanguination, but fortunately this complication infrequent.[28] More commonly, entities unrelated to disease involvement, including peptic ulcer disease and gastritis, may precipitate intestinal bleeding. Accordingly, gastric aspiration and possibly esophagogastroduodenoscopy are required to exclude sources of hemorrhage indirectly associated with Crohn's disease. The principal management of disease-related hemorrhage is determined by the severity and persistence of bleeding as well as the risk for recurrence. Localization of the bleeding site is essential regardless the planned therapy.[27] In a stable patient with colonic disease, endoscopic evaluation is preferred because this approach allows for disease assessment and therapeutic attempts at control of the identified bleeding site. However, indiscriminate usage of colonoscopy for bleeding colitis should be discouraged because this form of hemorrhage typically accompanies severe colitis, and colectomy with ileostomy is advised in this instance, regardless of the endoscopic findings.

A patient who requires ongoing resuscitation to maintain hemodynamic stability or in whom a small bowel source of active bleeding is suspected should undergo emergent

mesenteric angiography to localize the source of hemorrhage and arrest ongoing bleeding through superselective angiographic embolization.[28] If the hemorrhage is localized but cannot be controlled by this interventional modality, the catheter is left in position and intra-operative angiography is performed to accurately identify the bleeding site and guide a limited bowel resection.[29] Otherwise, wide resection might be unnecessarily performed to manage hemorrhage from a small ulcerated area within an extensive segment of diseased bowel.

An operation is warranted if the patient's hemodynamic state cannot be sustained, bleeding persists despite 6 units of transfused blood, hemorrhage recurs, or another indication for surgery exists. Resection with or without anastomosis is usually required for ongoing hemorrhage, whereas intra-operative enteroscopy with endoscopic therapy might be employed in less emergent settings.

Perforation

Free perforation of the small bowel is unusual and typically occurs at or immediately proximal to a stricture site.[30] The most appropriate treatment is resection of the involved bowel with or without anastomosis. A primary anastomosis without proximal diversion should be typically avoided, especially in the setting of delayed treatment, malnutrition, significant comorbidity, or severe sepsis. Instead, resection and proximal ileostomy with or without anastomosis is often recommended because it has an associated mortality rate of 4% compared to 41% with simple suture closure alone.[31] Perforation of the colon is also rare and typically requires subtotal colectomy for optimal management as these cases often occur in the setting of severe colitis or steroid usage.[32]

Severe Colitis

Severe colitis occurs in 4–6% of patients with colonic Crohn's disease and is a potentially fatal complication particularly if accompanied by megacolon. While several methods exist to accurately identify severe colitis, one reasonably simple schema employs a definition that includes a disease flare accompanied by at least six or more bloody stools per day with evidence of systemic toxicity as demonstrated by anemia (<10.5 g/dL), elevated ESR (>30 mm/h), fever (>37.8°C), or tachycardia (>90 beats/min). Use of this relatively objective definition may aid in the diagnosis and care of these patients whose severe condition can be underappreciated because of high dosages of corticosteroids, immunomodulators, or biologic agents.

Initial management in this setting is directed at reversing physiologic deficits with intravenous hydration, correction of electrolyte imbalances, and blood product transfusions. Free perforation, increasing colonic dilatation, massive hemorrhage, peritonitis, and septic shock are indications for emergent operation after the patient has been adequately resuscitated.

In the absence of these features, stool studies are performed to exclude routine pathogens and *Clostridium difficile* as the cause of the acute flare. Gentle endoscopy can be used to judge the severity of disease, which potentially predicts the likelihood of treatment response. Furthermore, cautious endoscopic biopsies and serum studies are used to exclude cytomegalovirus as a cause of the fulminant symptoms.

For a presumed diagnosis of severe colonic Crohn's disease, medical therapy is initiated with high dosages of intravenous corticosteroids, immunomodulators, and/or biologic agents.[33] Broad spectrum antibiotics directed against intestinal flora are prescribed to minimize the risk of sepsis secondary to transmural inflammation or micro-perforation. Anticholinergics, antidiarrheals, and narcotics are avoided as they may worsen already impaired colonic motility or conceal ominous symptoms. The patient is closely observed with serial examinations and abdominal roentgenograms. Any worsening of the clinical course over the ensuing 24–72 h mandates urgent operation. Early surgical intervention before the occurrence of perforation typically avoids the onset of multiple organ dysfunction syndrome. Moreover, this approach reduces operative mortality rates to 2–8% compared to rates that approach 40% if perforation has occurred.[34]

If the patient minimally improves after approximately 5 days of conventional therapy, the medical therapy should be altered and hyperalimentation started if the patient is otherwise unable to maintain adequate nutritional requirements or surgery should be advised. No controlled data exists related to treatment with ciclosporin, tacrolimus, infliximab, or adalimumab in this setting.[35] Therefore, the clinician should be candid when counseling the patient about the potential risks and benefits associated with medication versus surgery. The medication's associated risk of treatment failure and serious opportunistic infections should be carefully weighed against the likelihood of operative complications or requiring a permanent ileostomy.[36] If medical therapy is pursued, patients not responding within 5–7 days should be referred for surgery, patients who do respond should be closely monitored for infections.

The principal operative options in patients with severe or fulminant colitis complicating Crohn's disease include subtotal colectomy with end ileostomy, total proctocolectomy with end ileostomy, and loop ileostomy with decompressive blowhole colostomy. Subtotal colectomy with end ileostomy is the most widely practiced of these options. The most difficult aspect of the surgery is managing the distal bowel stump. The distal limb may be closed with sutures or staples and left in the pelvis. Alternatively, if left sufficiently long, it can be delivered to the anterior abdominal wall where it can lie without tension in the subcutaneous fat of the lower midline wound. With this approach, dehiscence of the closure during the postoperative period results in a mucous fistula instead of a pelvic abscess as encountered when the closed stump is left within the peritoneal cavity. If the bowel wall is too friable to hold sutures or staples, a mucous fistula is

primarily created. Rarely, instead of creating the fistula, the rectosigmoid stump must be exteriorized and wrapped in gauze to prevent retraction with a mucous fistula safely fashioned in 7–10 days.

Postoperatively, the patient typically improves over the ensuing few days and can be typically discharged within a week of the operation. An ileoproctostomy can be recommended 6 months later in selected persons who demonstrate minimal mucosal inflammation, adequate rectal compliance, absence of significant perianal disease, and sufficient sphincter strength. Otherwise, the diseased rectum is left in place and the patient is counseled about the risk of neoplasia and the need for appropriate surveillance endoscopy.[37] In these individuals, proctectomy is usually recommended if disease-related symptoms prove to be too bothersome, neoplasia is identified, surveillance is limited because of stricturing, or abdominal surgery is warranted for other reasons. Disease-related symptoms are likely to occur in patients with prior perianal disease and proctectomy is often required within the first few postoperative years.[36,38]

Proctocolectomy with end ileostomy is rarely performed in the severely ill patient with severe colitis because of the excessive rates of morbidity and mortality.[39,40] Proctectomy increases the difficulty of the procedure and risks pelvic bleeding as well as autonomic nerve damage. In rare instances of profuse colorectal hemorrhage or rectal perforation, or in the less severely ill patient who would not be a candidate for future ileoproctostomy, proctocolectomy may be a viable option. The surgeon must be cautioned, however, that primary proctocolectomy would nullify the option of a future restorative procedure.

The need for loop ileostomy combined with decompression blowhole colostomy has virtually disappeared with improved medical recognition and more sophisticated management of severe colitis. The operation is still useful in extremely ill patients or those in whom colectomy would be especially hazardous such as patients with a contained perforation, high-lying splenic flexure or pregnancy. Contraindications to the procedure include colorectal hemorrhage, intra-abdominal abscess, and free perforation. The operation is considered only a temporizing procedure, and a definitive operation is commonly performed approximately 6 months later.

Extra-intestinal Manifestations

Extra-intestinal manifestations of Crohn's disease occur in nearly 30% of patients with Crohn's disease and the occurrence of one manifestation seems to predispose to others.[41,42] Some extra-intestinal manifestations are temporally related to intestinal Crohn's disease activity, while others follow a course independent of disease activity. Some forms of peripheral arthritis, episcleritis erythema nodosum, and oral aphthous ulcers typically belong in the former group, while primary sclerosing cholangitis, pyoderma gangrenosum, spondylarthropathy, and uveitis are characteristic of the latter. Other disorders such as cholelithiasis, metabolic bone disease,

and nephrolithiasis are disease complications that likely arise from altered intestinal function or medication usage.

Growth Retardation

Abnormal linear growth secondary to delayed skeletal maturation is frequently encountered in children and adolescents with Crohn's disease, especially children with upper gastro-intestinal disease.[43] Specifically, nearly one-half of children may have a subnormal height velocity and approximately one-quarter have short stature.[43,44] Fortunately, surgical resection is often accompanied by growth response and pubertal progression.

Neoplasia

Overall, persons with Crohn's disease are at increased risk for developing cancer compared to the general population. In a recent meta-analysis[45] that identified 34 studies of 60,122 patients with Crohn's disease, the incidence and relative risk of cancer were calculated for patients with Crohn's disease and compared with the baseline population of patients without Crohn's disease. The relative risk of small bowel, colorectal, extra-intestinal cancer, and lymphoma compared with the baseline population was 28.4 (95% CI: 14.46–55.66), 2.4 (95% CI: 1.56–4.36), 1.27 (95% CI: 1.1–1.47), and 1.42 (95% CI: 1.16–1.73), respectively. On subgroup analysis, patients had an increased risk of colon cancer, but not of rectal cancer. Furthermore, a significant association was noted between the anatomic location of the diseased bowel and the risk of cancer in that segment.

The first endoscopic surveillance case series in patients with colonic Crohn's disease included patients with one-third or more of the colon involved by disease.[46] In this study, 259 patients were entered into a surveillance colonoscopy program. Dysplasia or cancer was identified in 16% of patients, including 10 with indefinite dysplasia, 23 with low-grade dysplasia, 4 with high-grade dysplasia, and 5 with cancer. Subsequent follow-up to this study, reported the cumulative risk of detecting any positive dysplasia or cancer after a negative screening colonoscopy to be 25% by the tenth surveillance examination.[47] Accordingly, it is recommended that patients with Crohn's disease with one-third or more of the colon involved and 8 years or more of chronic colitis should be enrolled in an endoscopic surveillance program.[46–49] The finding of multifocal low-grade dysplasia, high-grade dysplasia, or invasive cancer would likely warrant review by a second experienced pathologist and confirmation would prompt a colectomy.

Patients with primary sclerosing cholangitis are a notable exception to the practice of limiting surveillance to patients with 8 or more years of disease because of the heightened risk of colorectal cancer in these patients. Accordingly, yearly surveillance is recommended after a diagnosis of primary sclerosing cholangitis is made in the background of colonic Crohn's disease.

Failed Medical Therapy

Probiotics, antibiotics, 5-aminosalicylate compounds, corticosteroids, immunomodulators, and biologic agents all play a potential role in the management of Crohn's disease depending upon the clinical presentation. Each medication within these therapeutic groups possesses appropriate dosing parameters, associated side effects, and an optimal time interval during which beneficial effects should appear. Prior to initiating treatment with any medication, the patient should be counseled about these features and objective criteria for disease response should be discussed and then sought after an established time interval. If the desired response is not achieved, prohibitive side effects arise, or noncompliance is problematic, the medication has failed and another medication should be trialed. When all appropriate medical therapy has failed, operative intervention is warranted. The continuation of ineffective medical management risks the development of further disease complications that may detrimentally impact surgical outcome. Alternatively, some patients request an operation before exhausting all available medical therapies. A recent survey of outpatients with Crohn's disease, gastroenterologists, and colorectal surgeons underscores this attitude.[50] All participants were interviewed to quantify their preferences for six scenarios by using a prospective preference measure, and significant differences were seen between patients and gastroenterologists for three of six scenarios. Overall, 76% of gastroenterologists were willing to gamble to avoid an ileocolic resection compared with only 37% of colorectal surgeons and 39% of patients.

Operative Considerations

Some fundamental observations that must be considered when operating for Crohn's disease are as follows:

- Crohn's disease is incurable;
- Surgery is most often indicated for intestinal complications;
- Operative options are influenced by myriad factors;
- Asymptomatic disease should be ignored;
- Nondiseased bowel can be affected;
- Resection margins should be conservative (2 cm) as only a grossly normal and not microscopically normal margin is necessary;
- Mesenteric division can be difficult.

Crohn's disease is a chronic inflammatory disorder that cannot be cured by medical therapy or operative intervention. Accordingly, therapy focuses on safely alleviating disease symptoms and restoring life quality while attempting to maintain continuity of the intestinal tract. Of the various operative indications, intestinal complications, including stricturing or penetrating disease that is unresponsive to medical therapy, constitute the bulk of the indications, and the operative options depend upon multiple variables, including patient age, anatomic location, disease behavior, symptoms, prior therapies, nutritional status, comorbid conditions, and associated sepsis. The patient's symptoms are especially important because the disease encountered at the time of surgery is often unanticipated despite preoperative evaluation.[51] In these instances, the findings must be compared to the presenting symptoms and signs, and any extensive disease that does not appear to be contributing to symptoms should be typically ignored. Exceptions to this axiom include the management of out-of-circuit bowel and short, uncomplicated small bowel strictures, which should be addressed in most patients.

Nondiseased bowel can be affected by the disease process through inflammatory adhesions or internal fistulas. Every attempt should be made to conserve the nondiseased bowel, although this goal can be especially difficult when managing enteroparietal or interloop abscesses. Most internal fistulas are best managed by wedge excision and primary closure of the fistula site in the secondarily affected small bowel. However, a short segmental resection with primary anastomosis may be required for fistulas targeting the rectosigmoid region as these often enter the bowel at the mesenteric margin and simple wedge excision may be vulnerable to dehiscence of the suture line.[52,53]

Small bowel disease is best identified by digital palpation because the earliest feature of luminal disease is mesenteric ulceration, which corresponds to areas of paraintestinal neovasculature that obscure the normally distinct mesenteric edge of the bowel wall. In other words, the small bowel lumen will be macroscopically free of disease if the mesenteric margin can be palpated (Figure 30-2). Conversely, the extent of large bowel involvement is best determined by endoscopic inspection of the mucosa. Regardless the site of involvement, the bowel can be divided with a limited (2 cm) margin of grossly normal bowel without significantly jeopardizing risk for recurrent disease.[54] Frozen section analysis has no role and microscopic finding of disease at the margin need not necessitate any additional surgical intervention.

The disease process also typically causes the mesentery to be quite friable and abnormally thickened secondary to tissue
FIGURE 30-2. Mesenteric thickness associated with intestinal disease.

edema, fat deposition, and nodal enlargement. Mesenteric thickening near the vessel origin can make identification, isolation, and division of the ileocolic, middle colic, or inferior mesenteric vessels quite challenging and associated with dire consequences. Furthermore, the vasculature of diseased jejunum or proximal ileum cannot be ligated near its origin because of concerns of devascularizing nondiseased bowel that would mandate a more extensive intestinal resection.

Operative Options

The surgical procedures performed for intestinal Crohn's disease can be divided into groups depending upon whether resection of an intestinal segment is performed. The non-resectional procedures include internal bypass, external bypass, and strictureplasty, whereas the resectional procedures include resection of bowel. Patients often undergo multiple procedures at the time of their single operation and these can be a combination of nonresectional as well as resectional procedures.

Internal Bypass

Internal bypass was the procedure of choice in the early days of surgery for Crohn's disease when mortality rates associated with resection were high because of the lack of transfusion technology, antimicrobial medications, adequate anesthetic agents, and nutritional support services. However, with the advent of these modalities and recognition of complications, such as recrudescent disease, mucoceles, and malignancy arising in diverted segments, this procedure was largely abandoned. However, bypass operations may still be reasonable or even desirable in specific highly unique circumstances. A complicated ileocecal phlegmon with dense attachment to the iliac vessels or retroperitoneum can be aptly managed by an exclusion bypass if the proximal end of the excluded ileal segment is exteriorized as a small mucus fistula and definitive resection is planned to subsequently occur. Continuity bypass is sometimes the preferred method of managing symptomatic gastroduodenal Crohn's disease that is refractory to medical treatment, where resection would entail extensive reconstruction of the upper intestinal tract or pancreaticobiliary system.

External Bypass

External bypass can be permanent or temporary. Many of the stomas created to permanently bypass unresected disease fail to control symptoms secondary to the out-of-circuit bowel, and resection is ultimately warranted. High complex fistulas and deep ulcerations are among the disease characteristics likely to mandate proctectomy with permanent ostomy for persistent disease symptoms despite fecal diversion.[55] Similarly, temporary diversion intended to heal distal disease or its sequelae is usually unsuccessful unless combined with a secondary procedure, such as a rectal mucosal advancement flap that directly addresses the problem.[56] Even for free perforation of the small bowel, exteriorization of the proximal bowel alone is rarely the procedure of choice.

Strictureplasty

The incurable and pan-intestinal nature of Crohn's disease has led to a more conservative operative approach. Intestinal conservation may be maximally achieved for patients with multiple strictures of the small bowel by surgically widening the narrowed segment by performing a strictureplasty. This technique was initially described by Katariya[57] for the successful treatment of tubercular small bowel strictures, and later utilized in strictures secondary to Crohn's disease.[58] The procedure safely relieves obstructive symptoms[59–62] with the operated patients demonstrating weight gain accompanied by improved food tolerance as well as discontinuation or reduction of steroid usage.[63] Although patients undergoing strictureplasty alone experience significantly shorter recurrence-free survival than those undergoing resection and tend to be more likely to develop surgical recurrence, the procedure still plays a prominent role in the management of patients with small bowel Crohn's disease.[61]

The situations for which strictureplasty may be considered are:

- Diffuse involvement of the small bowel with multiple strictures;
- Stricture(s) in a patient who has undergone previous major resection(s) of small bowel (>100 cm);
- Rapid recurrence of Crohn's disease presenting as an obstruction;
- Stricture in a patient with short bowel syndrome;
- Nonphlegmonous fibrotic stricture.

The contraindications to strictureplasty are:

- Free or contained perforation of the small bowel;
- Phlegmonous inflammation, internal fistula, or external fistula involving the affected site;
- Multiple strictures within a short segment;
- Stricture in close proximity to a site chosen for resection;
- Hypoalbuminemia (<2.0 g/dL).

Multiple strictures in a patient with an albumin value <2.5 g/dL, preoperative weight loss, or advanced age may be regarded by some as a situation where strictureplasty should be avoided because of concerns of sepsis, but a proximal diverting stoma with multiple strictureplasties should be considered in this instance.[60] Factors that do not appear to be associated with increased operative risk include perforative or phlegmonous disease remote from the strictureplasty site, steroid dosage, synchronous resection, number of strictureplasties, and length of stricture.

The length of the strictured segment dictates the type of strictureplasty technique utilized (Figure 30-3). Short (<10 cm) strictures are best managed by a Heineke-Mickulicz-type of
Figure 30-3 Strictureplasty techniques.

strictureplasty, while medium length (10–20 cm) strictures can be corrected by a Finney-type strictureplasty.[62] Long (>20 cm) strictures are best managed by a side-to-side iso-peristaltic strictureplasty.[64] Regardless the technique, the bowel is incised along its antimesenteric margin extending 1–2 cm beyond the diseased segment, which is identified by the presence of mesenteric ulceration. Biopsy of any suspicious mucosa is performed to exclude carcinoma[65] and closure is achieved using an absorbable suture in a one- or two-layer fashion. The mesentery at each of the strictureplasty sites is then labeled with metallic clips to allow discrimination among the multiple sites in the unlikely event that postoperative hemorrhage occurs. Selective mesenteric angiography with intra-arterial vasopressin infusion controls most bleeding episodes, but the radio-opaque metal clips help avoid the need to open each of the strictureplasty sites to localize the bleeding site if reoperation is required.[66]

Many centers have safely and successfully employed a Finney-type strictureplasty for the the treatment of recurrent terminal ileal disease with the anastomosis created between the terminal ileum and proximal colon.[67–69]

Resection

The basic principles of resection should be followed whether an open or laparoscopic approach is utilized, and include mobilization of both diseased intestine as well as sufficient nondiseased bowel to facilitate the subsequent creation of a tension-free anastomosis or construction of an ostomy. Extensive mobilization may facilitate operations for terminal ileal disease complicated by fused ileal loops or a phlegmonous mass adherent to matted loops of small bowel, omentum, or retroperitoneal structures. Delivery of the ascending colon and terminal ileum into the wound or to the anterior abdominal wall enables separation of the involved intestinal loops and permits closer inspection to determine which segments require resection. Enteric fistulas commonly originate from diseased bowel that communicates with nondiseased intestine. While the primary site usually requires resection, the secondarily affected bowel segments are typically treated by conservative wedge excision and simple closure of the resultant defect or sometimes closure without wedge resection. The diseased bowel should be resected with conservative margins and the mesentery divided using the methods later described. The specimen should be opened after it has been delivered from the operative field to assure macroscopic disease-free resection margins.

After the diseased bowel has been resected, the surgeon must decide whether to create an end stoma, an anastomosis, or a diverted anastomosis. In general, an end stoma is desirable in patients who are critically ill, have fecal peritonitis, or suffer from coagulopathy. An anastomosis can be safely created in most other instances assuming a few general principles are respected specifically:

- Adequate blood supply must be assured;
- Tension or torsion are unacceptable;
- Luminal size needs to be equivalent;

A temporary diverting stoma should be considered to protect the anastomosis in instances of incompletely drained sepsis, excessive blood loss following a long operation, severe hypoalbuminemia (<2.5 g/dL), or significant immunosuppression.

Disease Locations

The operative approach to Crohn's disease is predicated upon many variables, including disease location and the particular nuances introduced by features unique to that location. The various disease locations include ileal, colonic, ileocolonic, upper gastrointestinal, and perianal disease.

Ileal Disease

Terminal ileal disease is defined as disease limited to the lower third of the small bowel with or without cecal involvement. Approximately one-third of patients with Crohn's disease express this phenotype, and usually present with symptoms suggestive of inflammation or obstruction. In the majority of cases, resection with construction of an ileal-ascending colon anastomosis is feasible and desirable. All nondiseased ascending colon should be preserved to provide the largest possible surface area for water absorption and to avoid a complex fistula involving retroperitoneal structures and a perianastomotic recurrence that overlies the second portion of the duodenum.

With mesenteric division, managing the small bowel vessels with simple ties can be catastrophic because the transected vessels might retract into the thickened mesentery and the resultant hematoma can rapidly dissect to the root of the superior mesenteric vessels; control of this bleeding potentially results in excision of extended lengths of nondiseased small intestine. Instead, clamps and suture ligatures should be applied in an overlapping fashion to best assure adequate hemostasis (Figure 30-4). Enlarged lymph nodes should be included in the excised specimen, unless extirpation of these nodes risks damage to the vessels associated with nondiseased intestine. On occasion and contingent upon the thickness and rigidity of the mesentry and the surgeons expertise, one of the newer energy sources may be an acceptable means of achieving vascular control.

Following operations for terminal ileal disease, the neo-terminal ileum tends to be the usual site of disease recurrence. Accordingly, many surgeons have hypothesized the anastomotic configuration and materials can influence recurrence. A recent meta-analysis reviewed outcomes associated with an end-to-end anastomosis and other anastomotic configurations after intestinal resection for patients with Crohn's disease.[70] The anastomotic leak rate was significantly reduced with a side-to-side anastomosis compared

FIGURE 30-4. Ligation of thickened mesentery.
to an end-to-end anastomosis and persisted when studies included only ileocolostomies. Overall postoperative complications, complications other than anastomotic leak, and postoperative hospital stay were significantly reduced in the side-to-side anastomosis group versus the end-to-end anastomosis cohort. Furthermore, no significant difference was noted between the groups in perianastomotic recurrence and reoperation needed because of perianastomotic recurrence.

A separate review of the literature comparing stapled side-to-side ileocolostomy versus hand-sewn anastomosis concluded the stapled anastomosis is associated with fewer leaks than the hand-sewn anastomosis, but too few patients with Crohn's disease were included to allow subgroup analysis.[71] A more recent randomized trial found no difference in the leak or complication rates associated with a stapled side-to-side versus hand-sewn end-to-end anastomosis in patients with Crohn's disease undergoing ileocolostomy.[72] Regardless, it is important to utilize a hand-sewn technique when the bowel wall is abnormally thickened because the stapling instruments are not designed to safely construct an anastomosis under these conditions.

Some centers have adopted an approach to terminal ileal disease whereby they avoid bowel resection by creating a large Finney-type ileocolostomy encompassing the entirety of the diseased bowel.[68,73] Interestingly, subsequent endoscopic and imaging studies have revealed complete morphologic disease regression.

Terminal ileal disease with sparing of the ileocecal valve and cecum is ideally treated with resection and enteroenterostomy provided there is sufficient length (5–7 cm) of normal-appearing distal ileum after definitive ileal resection. Preservation of the ileocecal valve helps to minimize the risk of postoperative diarrhea. In many instances, a hand-sewn anastomosis is preferred because the distal segment may be too short to accommodate a stapled anastomosis.

Laparoscopic resection can be employed with usually comparable or improved results compared to open surgery. A recent meta-analysis[74] reviewed laparoscopic versus open ileocolic resection for Crohn's disease involving 783 patients, 338 of whom underwent laparoscopic resection. The overall conversion rate was relatively low at 6.8%, but many studies excluded patients with recurrent disease, multiple disease sites, fixed masses, or complex fistulas. Although the operative time was significantly longer in the laparoscopic group, total costs of hospitalization were comparable. Analysis of early postoperative complications found no significant difference between the groups in terms of bowel obstruction, chest infection, intra-abdominal abscess, postoperative anastomotic leak, or wound infection. Times to the first liquid and solid diets, times to the first flatus and bowel movement, and hospital stay were all significantly shorter in the laparoscopic group compared to the open group. Many centers have also described good results with laparoscopic resection of complex disease, including recurrent disease, multifactorial disease, fistulas, and abscesses, showing that such an approach is both feasible and safe.[75–77]

Long-term monitoring suggests that patients undergoing laparoscopic resection are not at any greater risk for disease recurrence than those undergoing an open resection.[78–80] In one series, however, only one-half of the recurrences occurring after laparoscopic ileocolic resection and one-third of recurrences following open ileocolic resection were amenable to successful treatment using laparoscopic techniques.[78]

Colonic Disease

Colonic disease is any colon involvement between the cecum and rectum without terminal ileal disease. Nearly one-third of patients suffer from this disease distribution, and often complains of inflammatory disease symptoms, including abdominal cramping, bloody diarrhea, and urgency.

Persons presenting with segmental disease are best treated with segmental resection to protect against dehydration and electrolyte imbalances associated with loss of the large intestine's physiologic role. A meta-analysis[81] comparing segmental colectomy to subtotal/total colectomy revealed no significant difference between the groups regarding the incidence of postoperative complications, disease recurrence, or need for a permanent stoma. However, the time to recurrence was shorter in the segmental resection group by 4.4 years and patients with two or more affected colonic segments tended to be best treated by subtotal or total colectomy.

In patients with disease limited to the ascending colon, the transverse colon is divided at the level of the middle colic vessels so that the mesenteric root naturally separates the anastomosis from the retroperitoneum, minimizing the risk for recurrent disease complicated by complex fistulas. Alternatively, a more proximal anastomosis may be wrapped with a pedicle of omentum, thereby preventing the anastomosis from lying in direct contact with the retroperitoneum. Disease involving the ascending and transverse colon is treated in a similar manner except an extended right colectomy is recommended as the mesentery of the ileum is more easily approximated to the mesentery of the sigmoid colon than the descending colon. Resection of the additional colonic segment avoids an internal hernia and does not adversely affect the functional outcome. Crohn's disease of the transverse, descending, or sigmoid colon presents a situation where segmental resection and colocolonic or colorectal anastomosis is most commonly employed. Resection with coloproctostomy is used for patients with left-sided disease, and a cecorectal anastomosis is constructed if the transverse colon is also involved. In younger patients and those without prior small bowel resection, the diseased segment and uninvolved proximal colon are resected and an ileosigmoid or ileorectal anastomosis is constructed.

Laparoscopic colectomy can also be safely employed in patients with colonic Crohn's disease. The options for division of the larger vascular pedicles of the large bowel include laparoscopic staplers, laparoscopic clip appliers, suture ligatures, and electrothermal bipolar vessel sealers; ultrasonic shears are not commonly recommended for dividing larger pedicles. The laparoscopic clip appliers and bipolar thermal energy devices can safely manage arteries and veins ≤7 mm in diameter, such as the ileocolic and inferior mesenteric vessels, but the thickness of the surrounding tissue that must be additionally incorporated may limit the utility of these approaches in selected settings. The laparoscopic staplers, on the other hand, can manage arteries <17 mm and veins <22 mm in diameter, which may be more useful because of the surrounding mesenteric tissue.[82] However, great care must be exercised because if the vessels retract unsealed within the thick mesentery, a significant rapidly expanding hematoma may occur. Comparing laparoscopic versus open colectomy, da Luz Moreira and associates[83] reported a conversion rate of 26% in cohorts well matched for age, gender

American Society of Anesthesiologists score, type, and year of surgery. The incidence of postoperative complications was similar between the two groups, but patients treated by laparoscopic colectomy trended toward experiencing shorter time to first bowel movement and lesser lengths of hospital stay.

Colonic strictureplasty has been described for short strictures and appears to be associated with a morbidity rate, risk for surgical recurrence, and postoperative quality of life comparable to that seen with resection.[84] However, given the 7% incidence of malignancy arising in a colonic stricture,[85] some surgeons argue that resection should be exclusively encouraged if all of the outcome measures are comparable.

Patients with extensive colonic involvement, relative rectal sparing, and adequate fecal continence without active perianal sepsis or compromised rectal compliance are candidates for colectomy with ileoproctostomy. Rectal compliance can be subjectively judged by distending the rectum during proctoscopy or objectively quantified with anorectal physiology testing; patients whose maximum tolerated rectal volume measures <150 ml do poorly with an ileoproctostomy.[86] A rare patient presents with pan-colonic disease, significant upper rectal involvement, and sparing of the mid- and distal-rectum. Resection of all disease in this setting leaves an anastomosis only 6–8 cm above the anal verge, and is often associated with impaired function secondary to compromised compliance. Instead, in very carefully selected situations an ileal J-pouch can be configured with 10 cm limbs and joined to the spared mid-rectum after subtotal proctocolectomy.[87] Despite an increased disease recurrence compared to that seen with total proctocolectomy and ileostomy, the patient may enjoy several years without a stoma.

Patients with proctocolitis who warrant operative treatment usually require a total proctocolectomy with the creation of an end ileostomy, especially those persons with colitis whose proctitis, sphincter dysfunction, or perianal sepsis is too severe for rectal preservation and ileoproctostomy. If proctectomy is required, the entirety of the rectum should be excised in a single or staged procedure because of the significant risk of cancer developing in the defunct rectal stump despite surveillance proctoscopy.[88] An unhealed perineal wound that persists 6–12 months following endoanal proctectomy should be evaluated to exclude concomitant pyoderma gangrenosum, perineal sinus, enteroperineal fistula, and malignancy. A simple shallow wound usually responds to repeated wound debridement and diligent wound care with vacuum dressings and split-thickness skin grafts providing additional benefit. Wounds complicated by a perineal sinus or enteroperineal fistula require more extensive procedures that often include omental, muscle, or myocutaneous flaps.[89–91]

At least two centers have chosen to offer selected patients with Crohn's disease isolated to the colon and rectum a total proctocolectomy with ileal pouch–anal anastomosis.[53,92] They have reported that the rate of Crohn's disease-related pouch excision is 10–15% after 10 years of follow-up. Other reports that suggest 45–52% of

patients with Crohn's disease subsequently require pouch excision 10 years following restorative proctocolectomy are looking at a cohort that includes patients who develop post-IPAA symptoms associated with an increased risk for pouch loss.[93–95]

Ileocolonic Disease

Ileocolonic disease affects the terminal ileum with colonic involvement noted distal to the cecum. This disease phenotype occurs as commonly as terminal ileal disease, and the operative approach to these patients is similar to that already outlined for individuals with terminal ileal or colon disease. Specifically, the surgeon must conserve as much of the nondiseased colon as possible and avoid large mesenteric defects. This result might require the construction of two anastomoses, which does not seem to significantly increase operative morbidity.

Upper Gastrointestinal Disease

Upper gastrointestinal disease is defined as any disease location proximal to the terminal ileum occurring in isolation or with concomitant disease located elsewhere. This phenotype is often the most difficult to manage because of its predilection for extensive disease and predominantly stricturing or penetrating behavior.

Small bowel disease proximal to the terminal ileum is often typified by several stenotic segments separated from one another by noninvolved bowel. These diseased segments range in length and can measure >50 cm. The prognosis for Crohn's disease diffusely involving the small bowel is significantly worse than that of localized disease.[96] The operative options in a symptomatic patient with diffuse jejunoileitis include internal intestinal bypass, strictureplasty, and resection. Intestinal bypass is rejected by most clinicians because of concerns about bacterial overgrowth and malignant degeneration. Resection risks immediate or future short bowel syndrome and is not generally recommended. An operation that consists of multiple strictureplasties is the procedure of choice using the previously discussed techniques to safely conserve small bowel and relieve symptoms secondary to luminal stenosis. The involved segments can be ignored only in the rare instance, where the diseased intestine appears to be inflamed without evidence of stricture or penetration.

Gastroduodenal Crohn's disease is relatively rare, and its most common presenting complaints are upper abdominal pain and symptoms of duodenal obstruction. Endoscopy demonstrates macroscopic abnormalities in the majority of patients with the antrum most frequently involved.[97] Isolated gastric disease is exceedingly rare and any reports of successful treatment are purely anecdotal.[98] For duodenal disease, medical therapy is the mainstay of treatment for inflammatory and penetrating disease, while strictures present a different challenge.[99] Ulcer-like lesions are nonspecific, rarely cause stenosis, spontaneously regress, and are usually associated with other diseased sites. Contrarily, stenotic duodenal segments are typically unifocal and often respond poorly to medical management. Endoscopic balloon dilatation has been safely used to treat short duodenal strictures, and the procedure appears to be well tolerated while providing marked symptom relief.[100] In the past, the operative management of duodenal strictures was restricted to gastrojejunostomy, but success with duodenal strictureplasty has been reported by several centers, and the technique appears to be the procedure of choice if the affected bowel is sufficiently supple and devoid of associated sepsis.[101–103] As seen with small bowel strictures, occult malignancies can complicate stricture sites involving the stomach and duodenum.[104]

Perianal Disease

A variety of perianal manifestations can complicate Crohn's disease, including perineal skin lesions such as skin tags and hemorrhoids, anal canal lesions including fissures, ulcers, strictures/stenoses, anoperineal abscesses or fistulas, anovaginal fistulas, and neoplasia. The fissures and ulcers are considered primary disorders, whereas the others are secondary abnormalities.[105]

Perianal disease involvement in patients with known intestinal Crohn's disease is generally obvious, but individuals without a history of Crohn's disease can present a diagnostic challenge as many of the findings are seen in normal individuals or patients with other gastrointestinal maladies. Crohn's disease is the more likely diagnosis if multiple abnormalities, such as laterally located fissures, cavitating anal canal ulcers, and anorectal ring stenosis, are noted. Endoanal ultrasound can be a useful tool for the diagnosis of anorectal sepsis, and may guide combined medical and operative therapy to significantly improve outcome.[106] Pelvic MRI is a similarly valuable means of identifying abscesses and classifying fistulas.[107] Direct comparison of endoanal ultrasound, MRI, and examination under anesthesia has suggested that ultrasound might be most accurate, but ultrasound and MRI used together or separately in combination with examination under anesthesia are 100% accurate.[108]

For many perianal conditions, local measures can provide some symptomatic relief and medical therapy, including antibiotics, immunomodulators, and biologic agents, is often beneficial. Uncontrolled studies have shown a reduction in fistula-associated pain and drainage in adults treated with metronidazole or ciprofloxacin after 6–8 weeks of therapy, but symptoms typically recur immediately after antibiotic discontinuation.[109] Immunomodulation with optimized azathioprine or 6-mercaptopurine is as effective as de novo therapy in nearly one-half of patients, but response is often slow or incomplete. Immunomodulators have also been found to successfully delay fistula recurrence following antibiotic discontinuation in patients initially responding to treatment.[110] Continuous therapy with biologic agents, such as infliximab which is an antitumor necrosis factor antibodies, is associated with complete arrest of fistula drainage in nearly one-half of adults.[111]

The appropriate operative treatment of perianal Crohn's disease must be individualized to the specific patient with adherence to certain management tenets. In general, a conservative surgical approach is adopted because a more aggressive attitude often results in outcomes that are worse than the disease itself. Surgical treatment of skin tags, whether conservative or aggressive, is often associated with morbidity due to chronic, nonhealing anal or perianal ulcers. Fissures should be relatively asymptomatic and nearly one-half heal with medical treatment, especially those that are painless or acute in nature. Refractory symptoms from an uncomplicated fissure may respond to lateral internal sphincterotomy, especially if anal hypertonicity is present and rectal inflammation is absent. Symptoms secondary to large, cavity forming ulcers can often be controlled with debridement of overhanging edges and intra-lesion corticosteroid injection.

An anorectal abscess, regardless of its etiology, is best treated with simple incision and drainage unless perineal sepsis complicates the presentation. The management of anal fistulas is a challenging dilemma, and is based upon the patient's presentation considering the fistula's location and complexity, the presence or absence of concomitant proctitis, and the severity of accompanying anal canal disease. In addition, the surgeon should be cognizant of the known potential for malignant degeneration of the chronic fistula tract and the patient should be counseled regarding this risk.[112] Medical therapy to optimize control of disease-related inflammation is typically recommended to increase the likelihood of healing without adversely impacting surgical outcomes.[113] Most low-lying, simple fistulas without concomitant proctitis can be appropriately managed by fistulotomy. If partial sphincter division would compromise fecal continence, a noncutting seton or rectal mucosal advancement flap is indicated for low-lying, simple fistulas without significant proctitis. Non-

cutting setons establish drainage of the fistula, minimize the risk for future abscesses arising from the fistula tract, rarely cause discomfort, and do not interfere with personal hygiene. Alternatively, the rectal mucosal advancement flap is a versatile procedure that can be used when rectal inflammation is limited and no cavitating ulceration or anal stenosis is present because the flap procedure does not significantly jeopardize continence or risk proctectomy (Figure 30-5). In the event that the above scenario is complicated by anal canal ulceration or stricturing, a rectal sleeve advancement with temporary fecal diversion can be performed in selected patients. If moderate or severe proctitis complicates a low-lying, simple fistula, concomitant sepsis is excluded and medical therapy is then employed with or without a noncutting seton.[114] In a patient with a high, complex fistula and no evidence of Crohn's proctitis, a rectal advancement flap can be performed with the expectation that one-third of complex fistulas treated in this fashion completely heal. If the anal canal is diseased, rectal sleeve advancement may be attempted. The presence of proctitis with a high, complex fistula relegates the patient to medical therapy in combination with seton drainage, temporary fecal diversion, or proctectomy.

More recently described procedures for the management of fistulas in adults with Crohn's disease entail occlusion of the fistula tract with fibrin sealant[115] or collagen plug.[116] Results with fibrin sealant for fistulas related to Crohn's disease have been inconsistent partially because complex fistulas tend to be less responsive to treatment, but the largest series to date revealed more than one-half of treated fistulas remained drainage-free after nearly two years of follow-up.[115] Similar to the fibrin sealant experience, some centers[117] have reported high success rates (>80%) in patients with fistula tracts treated by collagen plug occlusion while others[116] have encountered somewhat discouraging outcomes.

FIGURE 30-5. Rectal mucosal advancement flap.

CCF
©2000
In selected patients with severe perianal disease, fecal diversion is required. While patients undergoing temporary diversion enjoy an improved quality of life,[118] a temporary ileostomy does not generally influence the long-term outcome of perianal Crohn's disease because less than one-quarter of individuals have intestinal continuity restored.[55] The majority of patients who undergo successful closure of their stoma require a secondary procedure (e.g., rectal mucosal advancement flap) to achieve stoma closure. However, the creation of a loop ileostomy as a planned definitive procedure is rarely indicated. Instead, an endoanal proctectomy is necessary in approximately 5% of Crohn's disease patients solely to control perianal disease, especially if high, complex fistulas, deep ulcerations, colonic disease, or anal canal stenosis is present.

Prophylaxis Against Recurrent Disease

Recurrent disease following surgical management of Crohn's disease is commonplace and leads to the need for reinstatement of medical therapy in most instances and eventual surgery in some cases. Accordingly, multiple trials have been conducted using medications intended to decrease the recurrence rate with varying degrees of success. A recent review of the literature[119] revealed 23 studies that appropriately investigated this issue and the pooled results were presented. Probiotics were not superior to placebo for any outcome measured. The use of nitroimidazole antibiotics appeared to reduce the risk of clinical and endoscopic recurrence when compared to placebo; however, these agents were associated with higher risk of serious adverse events. Mesalamine therapy was associated with a significantly reduced risk of clinical and severe endoscopic recurrence relative to placebo. Azathioprine and 6-mercaptopurine were also associated with a significantly reduced risk of clinical and severe endoscopic recurrence when compared to placebo, and neither agent had a higher risk than placebo of serious adverse events. Lastly, mesalamine relative to azathioprine and 6-mercaptopurine was associated with a higher risk of endoscopic recurrence, but a lower risk of serious adverse events. A study not included in this review looked at the impact of postoperative infliximab compared to placebo, and found infliximab therapy after intestinal resection was significantly effective at preventing endoscopic and histologic recurrence without increasing the occurrence of adverse events.[120]

Summary

The operative management of Crohn's disease is predicated upon a thorough understanding of the patient and the nature of their disease. The surgeon must be knowledgeable about the potential disease complications and medical treatment options to appropriately judge which patients are legitimate candidates for surgical intervention. Furthermore, despite recent advances in radiographic and endoscopic diagnostics, the findings at the time of surgery are commonly different than those suggested by the preoperative studies. The surgeon must be accordingly cognizant of the various operative options and confident with their usage when it is necessary to deviate from the planned procedure. Lastly, the surgeon must address not only the immediate issue, but also employ measures that minimize the risk of future complications caused by the recurrent behavior of the disease. The Standards Practice Task Force of the American Society of Colon and Rectal Surgeons has published practice parameters for the surgical treatment of Crohn's disease.[121]

Intestinal Stomas

Laurence R. Sands and Floriano Marchetti

Introduction

Intestinal stomas have long been used by surgeons for fecal diversion and remain an important tool for both the general and colon and rectal surgeon. They are considered a vital element as either a permanent means for stool evacuation or as a temporary bridge in order to treat complicated abdominal problems or to heal more distal anastomoses. The surgeon must always regard fecal diversion as a means to salvage patients from abdominal catastrophy and should never consider stoma creation as a defeat even though many patients may regard it as such.

The History of the Stoma

The colostomy was initially described by Littre in 1710, whereby he fashioned a diverting stoma for a patient with an obstructing colon cancer.[1] The next report of a colostomy actually appeared many years later when it occurred spontaneously due to a strangulated umbilical hernia, whereby the skin sloughed leaving the bowel exposed and draining.[2] Later on, bowel exteriorization became much more popularized with battlefield injuries and was associated with long-term survival.

The ileostomy history is much more short-lived, however. They did not become popular until devices became available that allowed better seals of the devices to the skin because of the more liquid nature of the effluent. Ulcerative colitis made it necessary to use the ileostomy. Initial reports of ablative surgery for fulminating colitis seemed to be unsuccessful and it soon became recognized that patients would either die of their disease or need to function with an ileorectal anastomosis, a rather unsatisfying operation for ulcerative colitis in the face of severe proctitis. As such, Dr. John Young Brown of St. Louis introduced the ileostomy as part of the therapy for ulcerative colitis in 1913.[3] This stoma was used in order to obtain colonic rest in the course of this disease. Once total proctocolectomy was popularized as a cure for ulcerative

colitis by Gavin Miller, surgeons were then forced to deal with the long-lasting effects of the ileostomy.[4] At that time, ileostomies were constructed by creating a flush connection of the bowel to the skin. They were fraught with complications of irritated skin, inflammation, subsequent parastomal scarring, and ultimately stomal narrowing secondary to the severe skin reaction and fibrosis. A chemistry student by the name of Koernig who had an ileostomy for ulcerative colitis developed a bag and seal of rubber with a latex preparation in order to help protect his skin from the caustic effects of the ileostomy effluent. It wasn't until 1952 when Brooke designed the everted stoma, whereby the appliances were now able to easily catch the stoma effluent and stop leakage, thereby preventing surrounding skin irritation and its complications.[5] This rather simple but ingenious design truly revolutionized the ability of surgeons to use an ileostomy as a means of stool diversion on a permanent or temporary basis.

Stoma Incidence

Stomas are used as often as is necessary. The true incidence of stomas is generally unknown. An estimate in the late 1970s within the United Kingdom suggested that there were 10,000 patients with an ileostomy at that time and that 400–500 ileostomies per year were being created.[6] It has also been estimated that about 4,000 ileostomies were created in 1968 alone within the USA.[7] There is no reason to suspect that these numbers have declined over the years since the indications for stoma creation have essentially not changed since then.

What Is an Ostomy?

An ostomy is a surgically created opening between a hollow organ and the body surface or between any two hollow organs. The word, *ostomy*, comes from the Latin word,

ostium, meaning mouth or opening. The suffix *-tomy* implies an intervention, either by surgery or injury. The word, stoma, comes from the Greek word for mouth and is used interchangeably with ostomy. An ostomy is further named by the organ involved. An ileostomy is an opening from the ileum to the skin, a colostomy is from the colon, a gastrostomy is from the stomach, and so forth. When two organs are joined the descriptive term incorporates both. For instance, an anastomosis between the small bowel and colon might be called an ileocolostomy, between colon and the rectum, a colorectostomy or coloproctostomy. A loop ostomy is formed by bringing an intact loop of bowel through the skin and then dividing the antimesenteric side and maturing it so that there are two open lumens, the proximal and the distal.

Indications and Types of Stomas

There are many indications for a stoma (Table 31-1). Permanent stomas are fashioned when there is a need for removal of the anus along with its associated musculature. This procedure may be necessary in patients with distal rectal cancers who require an abdominoperineal resection or those individuals with severe inflammatory bowel disease with involvement of the sphincter mechanisms. In addition, patients of any age with weak sphincter muscles and/or fecal incontinence may be better served with permanent fecal diversion in order to prevent perineal skin breakdown, improve perineal hygiene, and prevent decubitus ulcer formation.

Stomas may also be used on a temporary basis. Temporary stomas are indicated in cases of intra-abdominal catastrophes and may act as a lifesaving bridge in critically ill patients. Patients with diffuse peritonitis from a perforated colon due to an inflammatory condition such as diverticulitis or Crohn's disease are often at risk of anastomotic leak should the surgeon be tempted to perform such an anastomosis.

TABLE 31-1. Indications for a stoma

- Protection of distal anastomosis
- Treatment of anastomotic leak
- Large bowel obstruction
- Bowel perforation
- Abdominal or perineal trauma
- Rectal injury
- Diverticular disease
- Complex anorectal disease
- Complications from radiation
- Fecal incontinence
- Inflammatory bowel disease
- Motility and functional disorders including idiopathic megarectum and megacolon
- Infections – necrotizing fasciitis, Fournier's gangrene
- Congenital disorders – imperforate anus, Hirschsprung's disease, necrotizing enterocolitis, intestinal atresias

These patients are often best served with a temporary stoma in order to allow intra-abdominal healing and resolution of the inflammatory state.

Perhaps one of the most common indications for the creation of a temporizing stoma is for patients undergoing deep pelvic dissections, total mesorectal excisions, a low-lying ileo-anal or colo-anal bowel anastomosis, or in patients who undergo a high-risk distal bowel anastomosis. These stomas serve as a protection for anastomotic dehiscence. Temporary stomas are also often used in patients who undergo a restorative proctectomy after they have completed preoperative chemotherapy and radiation for advanced rectal cancer. The benefits of this type of fecal diversion will be discussed later in the context of this chapter.

Some surgeons may consider performing a diverting stoma at the time of diagnosis of advanced rectal cancer. While preoperative therapy often will shrink a large rectal cancer and improve patient's symptoms, there are many patients who may be so symptomatic that fecal diversion should be considered as the initial management for these patients. A recent British study evaluated whether stoma creation was indicated in patients with rectal cancer prior to undergoing neoadjuvant therapy. In this study, they performed a diverting stoma in nine patients, eight of whom had an inability to have their tumors cannulated at the time of colonoscopy and one who had fecal incontinence. Three of these patients never underwent definitive surgery for their rectal cancer after they completed neoadjuavant therapy because they had progression of their disease or had poor overall fitness to undergo the more definitive surgical procedure. They concluded that the only two indications for initial diversion were the inability to perform a colonoscopy past the lesion and fecal incontinence while worsening diarrhea or bowel function during the neoadjuvant therapy were not good indications for diverting stoma.[8]

Temporary stomas may be created as either an ileostomy or a colostomy, with the type of stoma used, dictated by the circumstances found at the time of the initial surgery as well as the preference of the surgeon. Many surgeons prefer a protective loop ileostomy for low-lying anastomoses because of the relative ease of reversal, easier stoma management by the patient, lower incidence of parastomal hernia formation, and a lower incidence of peristomal sepsis.[9,10]

A study comparing loop transverse colostomy to loop ileostomy for fecal diversion for low colo-rectal or colo-anal anastomoses demonstrated that the patients undergoing loop colostomy had more complications than those patients undergoing loop ileostomy such as parastomal and incisional hernias, stomal prolapse, and fecal fistulas. They suggested that loop ileostomy provided a better means of diversion.[11]

Stomas may be created as either a loop stoma or an end stoma. Loop stomas are often used when they are intended to be temporary since such a creation will often facilitate reversal. They may also be used in cases of distal intestinal obstruction, whereby the primary cause of the obstruction is

left undisturbed. A loop stoma is required in these cases in order to decompress both sides of the bowel and to prevent a closed loop obstruction distally if an end stoma were created instead. Alternatively, an end stoma with a distal mucous fistula may be created in order to provide distal bowel decompression. Loop stomas are often larger than end stomas since both limbs of bowel must be exteriorized through the same fascial defect. This large size may make it more difficult for the patients to care for the stoma with an appropriate appliance. In addition, loop stomas may be more prone to develop parastomal hernias because of the larger abdominal wall defect and may ultimately result in stomal prolapse. These arguments against a loop stoma may make a proximal end stoma and a distal mucous fistula a more desirable option.

End stomas are often smaller and easier to manage. They are rarely associated with stomal prolapse and may have a lower incidence of parastomal hernia formation. However, if the end stoma is done on a temporary basis, they often require more extensive surgery for reversal since the other end of the bowel is often buried within the abdominal cavity. Many surgeons opt to tack the distal limb of bowel near the site of the end stoma if possible in order to facilitate reversal.

Another alternative in stoma creation is the loop end stoma. This may be performed in the obese patient where it is difficult to bring up an end stoma because of the large thick abdominal wall and the greater stretch applied to the bowel mesentery in these patients. The stretched mesentery may result in ischemia of the end of the bowel if it is brought up as a simple end stoma. In such cases, many surgeons prefer to bring the bowel up to the skin as a loop with the distal end being closed off in order to improve vascularity of the stoma itself since this will no longer be the end of the bowel.

Stoma Physiology

The physiological changes that occur in patients with ostomies are primarily related to the loss of continence and reduced colonic absorptive surface area. These affect fluid and electrolyte balance and lifestyle but generally have little effect on nutrition. However, once more than 50 cm of terminal ileum has been removed or taken out of continuity, nutritional consequences are likely.

Output

Ostomy output is directly related to the location of the opening in the bowel. Distal left or sigmoid colostomies normally produce formed stools that are of similar consistent to that of the anorectum. The more proximal the colostomy, the less surface area is available for water and electrolyte absorption and so the more liquid the stools. Right sided colostomies not only produce a high volume but also have the additional disadvantage of a malodorous output because of the effects of colonic bacteria.

Initially after creation the output from an ileostomy tends to be fairly watery and green or bilious in color. Within a few days to a week of resumption of a regular diet, the material becomes thicker and more yellow-brown, although a greenish tinge often remains. The typical consistency is of watery porridge or applesauce. It is affected by diet, fluid intake, medications, and on-going problems such as Crohn's disease or adhesions. If a substantial amount of small bowel has been removed the output is looser and the patient is more prone to dehydration. It is not uncommon for some food to pass out in a recognizable state. Notable foods for this occurrence include corn, other vegetables, and nuts. Some pills may also not be broken down in the small bowel, decreasing the bioavailability of these medications. Most patients with an ileostomy notice little odor from the output; however, certain foods, such as eggs and fish, may produce an offensive smell.[12]

Volume

In the healthy control subject, about 1,000–2,000 ml of fluid passes through the ileocecal valve daily. This quantity is reduced by 80–90% to 100–200 ml of fluid volume in normal stool as it passes through the colon. Unless the patient has diarrhea, left-sided colostomy output is similar to the feces that would be passed trans-anally, and there is little loss of total body fluid or sodium.[13]

Although postoperative ileostomy output may be high, it quite rapidly settles down to a more acceptable volume. "Ileostomy dysfunction," although a general sounding term, refers to increased ileostomy output due to partial obstruction caused by inflammation and stenosis. This term was coined in the era of secondary maturation. Historically, high outputs were anticipated for weeks after creation of an ileostomy, but this was found to be due to inflammation of the exposed small bowel serosa (serositis). Once primary maturation was adopted, this problem essentially disappeared.[5,14]

Postoperative colostomy output is also often liquid, but it rapidly becomes formed with the resumption of a normal diet and the return of ordered motility. The average colostomy produces about 200–700 ml with a median of about 500 ml per day. Total bowel rest results in a decrease in output by at least one-half and may be as low as 50–100 ml per day.[13]

The volume of ileostomy output fairly widely varies among patients but only mildly varies from day to day in an individual patient. Although the average output is about 500 ml per day, a healthy, functioning ileostomy may produce up to 1,000–1,500 ml in a day. Output above this level are usually associated with dehydration.[15–19] Large amounts of fluid intake usually do not alter the output volume very much as most of it is absorbed and excreted through the kidneys.[17]

Ileostomates may generally eat a regular diet without restrictions. Decreased fluid intake slows the output and thickens it, while fatty food and large amounts of liquid increase transit and the fluidity of the effluent.[12] Prunes and

cabbage may also increase the output.[17] Ileostomy effluent is generally weakly acidic at a pH of about 6.3.[13] When the terminal ileum has been resected but colon remains in situ, more of the bile salts will enter the colon, which may result in a secretory diarrhea. This problem may be ameliorated by the use of oral bile binding agents such as cholestyramine (Questran).

Transit

An ileostomy continuously functions and its output is not eliminated by the timing of meals or rest. Yet, in most patients the output increases with meals and certain foods. Surgical resection of the anorectum and/or colon has effects on the function of the proximal gastrointestinal tract and the integration of hormonal and neuroenteric activity. These interactions are complex and not well understood in health, much less in postoperative patients. Although the data are limited, it appears that small bowel transit times decrease after ileostomy, possibly related to mucosal hypertrophy and adaptation. The specific mechanisms are not known. Gastric emptying has been a subject of several studies but the results are conflicting. Soper and his colleagues[20] found that gastric emptying is not altered in ileostomy patients. Yet, small bowel transit is longer than in control subjects (348 vs. 243 min). In a more recent study, Robertson and his colleagues[21] found that gastric emptying of liquids is not altered but emptying of solids is slowed.

Ileostomy output and dehydration may be decreased by prolonging the transit time to allow for more absorption. Codeine, loperamide, and Lomotil® have all been shown to have this effect.[22,23]

Fluid and Electrolyte Balance

The average ileostomy puts out about 500 ml of water and 60 mmol of sodium per day, amounts approximately two to three times higher volumes than found in normal fecal output.[13] Consequently, the ileostomate must compensate by increasing intake or conserving other losses. Urinary volume is relatively decreased in patients with ileostomies by as much as 40%, while renal sodium losses may be decreased by 55%.[24,25] Yet, in spite of the efforts of the kidneys to maintain balance, total body water and sodium reductions may be a chronic condition in ileostomy patients.[26–28]

The chronic dehydration and loss of fluid and electrolytes make ileostomy patients prone to dehydration. Rehydration is best accomplished with fairly large amounts of normal saline.[13] There is a direct relationship between absorption of nutrients and electrolytes and transit time.[29]

Flora

The normal terminal ileum harbors few organisms in the healthy individual. After creation of an ileostomy, the distal ileum is rapidly colonized with a variety of bacteria. The microflora of an individual is fairly stable over time, whereas there is great variability between individuals.[30] Staphylococci, streptococci, and fungi are increased while Bacteriodes fragilis is rarely found in ileostomy effluent. The major variations in the flora of effluent from ileostomies, transverse colostomies, and feces per anum are in the relative numbers of anaerobes with log differences increasing from proximal to distal.[31,32]

Nutrition

The colon plays little role in the maintenance of normal nutrition, working primarily to absorb fluid and to store feces so that the frequency of bowel evacuation may be limited. Thus, removal of the colon alone has little effect on nutrition. Patients who require a total proctocolectomy for diseases such as ulcerative colitis or Crohn's disease are often malnourished due to their underlying problem. Postoperatively, they are able to gain weight and return to a much better level of nitrogen balance and general nutrition.

Loss of more than a few feet of the terminal ileum, may result in loss of bile acids and poor absorption of fat and fat-soluble vitamins[17,33] Specifically, Vitamin B12, necessary for normal hemoglobin synthesis, may not be adequately absorbed in patients with terminal ileal loss or significant Crohn's disease. This loss results in pernicious or macrocytic anemia, and these patients may require monthly administration of Vitamin B12 (intramuscular or nasal). Absorption may also be impeded by distal ileal bacterial overgrowth.[34–36] Kidney stones may be a consequence of chronic dehydration and acidic urine. Adding sodium bicarbonate to the diet as well as increasing fluid intake may help to prevent uric acidic stone formation.[37–39]

Preoperative Considerations

Stomas need to be constructed in both the elective and emergency situations. If stomas are to be electively created during scheduled surgical cases then proper preoperative planning needs to be initiated. This planning includes both preoperative counseling and stoma marking. The counseling must encompass several critical aspects for the patient. First, the patient must understand the need for the stoma and whether the surgeon plans for the stoma to be placed on a permanent or temporary basis. Second, the patient should be provided with ample opportunity to ask questions related to the stoma and the overall surgery. Most patients will experience a great deal of anxiety related to the creation of a stoma. Third, the patients should be offered reading material, videos, and online Web sites that may help relieve this anxiety and answer their many questions. The patients should be shown the appliances and stoma-related products in advance of the surgery as well. Often times it is beneficial for the

patient to speak to other willing patients in a similar situation who have a stoma so that many of their questions may be appropriately addressed by those dealing with a stoma. Support group participation may be very valuable. Lastly, the patients should be properly marked by the enterostomal therapist for the ideal site(s) of the stoma on the abdominal wall since stoma sites may greatly vary in individuals based upon body habitus. Stoma sites should be modified to avoid scars, skin creases, and other skin disorders. Stoma markings should be done with the patient in both the sitting and standing positions and attention must be given to the beltline and pant height. The site must be checked to ensure skin folds or crevices do not interfere with appliance fitting. In obese individuals, the stoma must not be hidden below a large abdominal pannus or stoma care will be very difficult (Figure 31-1). In this circumstance a supraumbilical stoma is often more functional. Stomas should be placed through the rectus sheath and not lateral to it in order to have the rectus muscle provide support and reduce the incidence of parastomal hernias.

Once proper placement is ascertained, the spot is marked with indelible ink. This may be done with a water-resistant marker if the marking is done close to the surgery date, or it may be done by using ink and then puncturing the skin under the ink thereby forming a permanent tattoo. In complex cases, a stoma appliance can be fixed to the proposed site and worn for 24 h to test placement. Hernias can also be used for temporary marking.

Siting a stoma through the umbilicus is a reasonable alternative when there is no other good location. Raza and colleagues[40] felt that this was a good option based on their series of 101 patients; only four needed revision and there were no parastomal hernias or prolapse. Fitzgerald et al.[41] noted that after closure in infants and children, the scar resembles a normal umbilicus and is cosmetically superior to that of an ostomy placed elsewhere.

FIGURE 31-1. Example of poorly placed stoma.

Stoma counseling is an important part of stoma acceptance. This finding has been confirmed in a study that used multiple regression analysis to show that stoma adjustment was related to learning how to care for the stoma by the patient, interpersonal relationships that the patient has developed, and better stoma placement. The authors concluded that addressing the psychosocial concerns of the patient should become a part of the care routinely given to stoma patients and preoperative counseling plays a major role in this care.[42] Another randomized controlled trial comparing preoperative stoma teaching with postoperative stoma teaching after elective colorectal surgery showed far greater proficiency with the stoma, shorter hospital stays, and lower overall hospital costs if patients were educated about the stoma in advance of the surgery.[43]

Quality of Life with a Stoma

While many surgeons may feel that patients were "let down" after stoma creation a recent study evaluating the quality of life of patients who underwent surgery for rectal cancer showed that those patients undergoing stoma creation reported a higher global health status and fewer GI problems after surgery.[44] This result may be due to the fact that the patients were so debilitated with their initial disease that having a stoma significantly improved their overall status.

However, a Danish study evaluated the quality of life of colorectal cancer patients with and without a stoma. As one might expect, they found that those patients with a stoma experienced far great signs of depression, worse social functioning, greater issues with body image, greater problems voiding, and more sexual problems particularly in male patients. They also found that if the stoma was created at a later time rather than at the initial surgery, the patients also experienced a poorer quality of life.[45]

A study comparing the quality of life of patients with temporary ileostomy vs. temporary colostomy revealed that both groups of patients had a significant impairment in quality of life assessments. These authors found that the ileostomy effluent was more tolerable and that these patients had fewer issues with personal hygiene and better appetites than those with a colostomy. There were no differences in the two groups in terms of travel, daily activities, or sexual activity.[46]

While we may believe that patients are pleased to have their stomas reversed a study from Germany may suggest otherwise. They evaluated the quality of life of patients who underwent temporary stoma reversal. While they found that the patient's body image and leisure activities improved, there was no change in overall quality of life since many of the patients experienced an increase in gastrointestinal problems after stoma reversal. Many patients actually felt overall worse than before the stoma was reversed. The authors concluded that the surgeon should engage in preoperative counseling of patients prior to stoma reversal.[47]

In summary, there is no doubt that patients would prefer to live their lives without a stoma. However, with proper education and counseling by the surgeon, enterostomal therapists, and support groups both before and after the surgery, patients can learn to adapt and maintain a healthy and happy existence with a stoma.

Techniques of Stoma Creation

The basic surgical principles that apply to stoma creation include the following:

1. The bowel to be exteriorized must be well vascularized and the mesentery must not be stretched to the point of inducing stomal ischemia or necrosis.
2. The bowel must reach the skin without tension in order to prevent stomal retraction.
3. The intestine must be brought through the rectus sheath and the facial opening should be just two fingers breadth in width in order to reduce the incidence of parastomal hernia and prevent obstruction of the bowel as it exits through the opening.
4. A disc of skin should be excised where the stoma is to be placed rather than simply creating a slit in the skin. This will prevent stomal stenosis and obstruction.

A disc of skin is removed in the site where the stoma will be placed. The anterior and posterior fascia is then opened in an up and down manner in order to accommodate the portion of bowel. Some surgeons prefer a cruciate fascial incision instead. Care should be taken to avoid the inferior epigastric vessels as one approaches the posterior rectus sheath. The bowel is then grasped with a babcock clamp and then exteriorized. In loop stomas some surgeons prefer making a mesenteric window just underneath the bowel edge and placing an umbilical tape around the bowel and then pulling this through the abdominal wall with the bowel (Figures 31-2–31-4).

After exteriorization of the bowel the abdomen is closed and then the stoma is matured. A stoma rod is typically
FIGURE 31-2. Stomal placement. The site is selected to bring the stoma through the rectus abdominus muscle (with permission from Beck DE. Intestinal stomas. In: Beck DE, editor. Handbook of colorectal surgery. 2nd ed. Taylor and Francis; 2003).

placed under a loop stoma while end stomas are matured with a simple eversion technique using an absorbable suture material such as 3-0 chromic suture. While eversion is essential in ileostomies because of the greater liquid and voluminous effluent, not all colostomies need to be everted.

Some surgeons may choose to tack the mesentery to the lateral sidewall to prevent internal hernia formation around the stoma site while others may suture the stoma to the undersurface of the fascia in an attempt to prevent parastomal hernia formation or prolapse. While there is no data to suggest that these techniques may in fact be effective, Goligher in the 1950s advocated delivering the bowel via an extraperitoneal approach in order to reduce the incidence of these complications.[48] More recent innovations have included a variety of biologic and synthetic meshes employed in a prophylactic setting at the time of stoma construction. A range of sublayer underlay and overlay techniques have been described.

Laparoscopic Stoma Creation

Today many stomas are created laparoscopically. Laparoscopy has emerged as a frontrunner in terms of stoma creation because of the minimally invasive technique and the rather quick recovery. The advantages of laparoscopy include smaller incisions, less postoperative pain, reduced use of pain medication thereby reducing postoperative ileus and the time to first stool. The laparoscopic technique is ideally suited to stoma creation since it often does not require much dissection or specimen extraction, thereby making this one of the easiest laparoscopic procedures to perform. In addition, there are no incisions except for the port sites thereby facilitating the placement of the appliance over the stoma site.

If the patient is undergoing a colonic resection with a planned stoma, then the surgeon will often place a port at the site of the stoma marking and exteriorize the bowel through this area at the completion of the surgery. However, some care must be taken upon using this laparoscopic technique with regard to bowel orientation. Since many surgeons prefer placing the proximal portion of a loop stoma at the upper aspect of the skin and abdominal wall defect, one must ensure that the bowel is properly oriented upon delivery through the abdominal wall and that the bowel is not twisted or kinked. Twisting of the bowel at this level may result in a mechanical obstruction at the level of the stoma site.

More importantly one must assure that the proximal portion of the bowel is exteriorized in those patients undergoing an end stoma. Division of the bowel and maturation of the incorrect limb will result in a complete bowel obstruction and will ultimately require a return to the operating room to correct this problem. While this problem would rarely occur in open stoma creation, it is a possibility in the laparoscopic technique if one fails to identify the proper orientation of the bowel especially in cases of colonic redundancy. This problem may be avoided by ensuring complete visualization of the bowel and, in the case of an end colostomy, by identifying the upper aspect of the rectum noted by the convergence of the teniae coli and following the bowel proximally from that point. Another technique that may be used is to insufflate the rectum with air at the time of stoma creation in order to identify which end is most distal. If one is still having trouble identifying the proximal and distal portions of the bowel, then a loop stoma should be performed in order to prevent maturation of the incorrect side. Alternatively, one can always convert to an open procedure if there is still uncertainty about the correct anatomy. Conversion to an open procedure often shows good judgment rather than defeat.

There have been a variety of techniques described for laparoscopic stoma creation using zero, one, or more ports. Hellinger and his colleagues at the University of Miami have described a laparoscopic technique through a trephine incision and without a port and without gas insufflation for stoma creation in those patients who may not be able to tolerate a pneumoperitoneum. This technique simply uses abdominal wall retraction and placement of the laparoscope within the trephine opening in order to identify and orient the bowel. In addition, this technique allows for visualization and possible mobilization of the colon along the white line of Toldt should that be necessary.[49]

Most laparoscopic stomas are created using two or more ports. One port is typically placed at the site of the stoma
FIGURE 31-5. Port placement for stoma creation.

while the other ports are placed either peri-umbilical or on the opposite side of the abdomen in a triangular manner (Figure 31-5). This port configuration facilitates working within the abdominal cavity and allows the surgeon to identify and raise the limb of bowel for the stoma. The white line of Toldt is identified and dissected if bowel redundancy does not exist in order to allow the bowel greater mobility to be brought up for a stoma. As in any laparoscopic case, care must be taken to avoid inadvertent injury to other loops of bowel as well as the ureters in the retroperitoneum. Another laparoscopic technique for colostomy creation has been described by placing the camera in the right side of the abdomen, thereby facilitating dissection of the colon on the left side and detaching it from the white line of Toldt and thereby allowing it to easily reach a preselected stoma site in the left side of the abdomen.[50]

Laparoscopic stoma creation has been compared to open stoma creation in several studies. A study from Germany showed fewer operative complications from open stoma creation compared to laparoscopic stoma creation. However, the mortality associated with the laparoscopic group was considerably lower. They concluded that for palliative stoma creation there were significant advantages using the laparoscopic technique for stoma creation.[51]

The Cleveland Clinic Florida colorectal surgery team reported their experience with laparoscopic stoma creation in 1997. In their early study of 32 patients who mostly underwent loop ileostomy, they converted to open surgery in five patients. Two of these conversions were related to a noted enterotomy at the time of surgery that was repaired. In addition, two other patients required reoperation for stoma outlet obstruction, one of which was twisted at the level of the fascia. The mean operative time was 76 min and the mean length of stay was 6.2 days.[52]

Many surgeons now believe that laparoscopy should be the primary means of stoma creation and a recent study of a 10-year period confirmed this conclusion. In this review of 80 patients who mostly suffered from advanced unresectable colorectal cancer, all but one patient underwent successful laparoscopic stoma creation. While the majority of patients underwent loop stoma formation of either the ileum or colon, only five patients suffered complications requiring re-operation including parastomal abscess, stomal retraction, small bowel obstruction, postoperative bleeding, and port site hernia. The average length of stay was 10.3 days. While this length of stay may seem long it is most often related to proper patient teaching in stoma use and care.[53]

Morbidly obese patients present a significant challenge in stoma creation. Some have advocated a loop end stoma in this patient group.[54] Another technique has been described to assist in the stoma creation in the morbidly obese patient. This method involves the use of an Alexis wound protector placed in the abdominal wall, facilitating the bowel to pass through the abdominal wall with less friction and resistance because of the extensive subcutaneous tissues in these patients.[55]

Controversies of Intestinal Stomas

When Should Stomas Be Used to Provide Distal Anastomotic Protection

One of the most controversial topics regarding stomas relates to their use in protecting distal bowel anastomoses. While there are many advocates of diverting proximal stomas, there are also many others who believe that the complications of the stoma itself as well as the potential difficulties encountered in stoma reversal make the stoma extremely undesirable. This topic of fecal diversion to prevent distal leak is so controversial in that some surgeons believe that all distal anastomoses should be diverted while others feel that it should almost never be done. Still, there are others that believe there may be subsets of patients who should be diverted while others may avoid diversion altogether.

A recent meta-analysis of both retrospective and prospective series reviewed the results of a defunctioning stoma in patients undergoing surgery for distal rectal cancer. While the retrospective studies did not show any difference in the anastomotic failure rate with a defunctioning stoma in place, they did prove that there were far fewer major problems once these leaks occurred. The prospective series revealed a lower leak rate with a diverting stoma in place. The study concluded that there were true benefits from proximal anastomotic diversion in patients undergoing surgery for low rectal cancer.[56]

A surgical group from Italy tried to determine whether patients should receive a protective stoma after undergoing neoadjuvant therapy for rectal cancer and then definitive surgery. They studied 55 patients who underwent surgery without diversion; they experienced 15 anastomotic leaks, five of which were considered requiring major immediate surgery for diversion. One of these patients ultimately died of sepsis. They concluded that a diverting stoma was only necessary in 10% of their patients and therefore most patients may avoid the additional surgery, morbidity, or high complication rate of a temporizing stoma.[57]

Another study assessing diverting stoma compared two groups of patients who either underwent or did not undergo fecal diversion. Two patients in the undiverted group died of complications from anastomotic leakage. In addition, four patients in whom initial fecal diversion was not undertaken ultimately required permanent stomas. Conversely, no patients in whom initial diversion was undertaken required a permanent stoma. The authors concluded that there were clear and significant advantages to a proximal stoma in patients undergoing low resection for distal rectal cancer.[58]

The group from UC Irvine compared their patients who underwent surgery for rectal cancer, most of whom underwent neoadjuvant chemotherapy and radiation therapy for their disease. Most of their patients underwent a single-stage procedure with a lower overall and a lower anastomotic-associated complication rate than those who underwent fecal diversion at the initial procedure both of which reached statistical significance. However, most of their single-stage procedures involved a higher level anastomosis (3.8 cm above the anal verge vs. 2.6 cm) compared to the anastomoses constructed in patients who underwent fecal diversion. They felt that many patients may be safely operated on with a single-stage procedure and that fecal diversion may be reserved in selected patients.[59]

A publication from Germany evaluating 881 patients undergoing a low anterior resection with a protective stoma revealed virtually identical leak rates compared to the 1,848 patients who did not have fecal diversion. While both groups of patients had a leak rate of roughly 14%, the number of patients requiring operative intervention for a leak were significantly lower in the diverted group. In addition, the mortality was lower in the diverted patients. They also found that the morbidity associated with colostomy reversal was lower than it was for ileostomy reversal suggesting that patients may be better served with a colostomy rather than an ileostomy.[60]

Some surgeons have advocated anterior resection of rectal cancer without bowel preparation and without fecal diversion. In a study from the Netherlands of 144 patients who underwent anterior resection of the rectum without mechanical bowel preparation or fecal diversion, the authors reported a leak rate of only 4.9%. They found a trend toward higher leak rates amongst men with lower anastomoses and more advanced cancers. They concluded that performing anterior resection without bowel preparation or diversion is safe.[61]

One must clearly take into account the morbidity of a stoma as well. In a recent study from Norway where a protective stoma was used in 72 patients who underwent surgery for rectal cancer over a 12-year period, the authors found that five patients developed stomal complications immediately after the primary surgery, and another 20% developed problems after hospital discharge. Only 62 patients underwent stoma reversal, five of whom had problems with the reversal while in the hospital. In addition, two patients died of complications from the reversal surgery. In total 19 patients (26%) suffered complications of the stoma in general and eight of these patients required re-operation. They concluded that there was considerable morbidity to the stoma creation, many patients may never undergo reversal of the stoma, and the stoma does not prevent anastomotic leak.[62]

The need for a defunctioning stoma after low anterior resection was recently evaluated in a large meta-analysis of over 11,000 patients. Four randomized control trials and 21 nonrandomized studies were reviewed in this analysis. Both sets of studies showed a lower clinical anastomotic leak rate and a lower re-operation rate while the nonrandomized trials also showed a lower mortality rate in the stoma group. They concluded that stomas should routinely be used in patients undergoing low anterior resection.[63]

This study was reinforced by yet another randomized controlled trial that intraoperatively assigned to either receive a diverting stoma or be left in continuity while undergoing a low anterior resection; 34 patients were enrolled in the study and the symptomatic anastomotic leak rate was significantly higher in the undiverted group (37.5%) compared to the diverted group (5.5%). Six patients in the undiverted group required reoperation. The authors concluded that protective stomas are a necessary part of the healing process after proctectomy with total mesorectal excision.[64]

Stomal Complications

The difficulties of a stoma should not be underestimated. The true incidence of stoma-related complications is unknown since there is great debate as to what actually defines a stoma-related problem. As most patients will experience some sort of skin irritation from the stoma or the stoma appliance, this represents the largest subset of stoma-related issues.

The prevalence of intestinal stoma complications was assessed from a colorectal group in Chicago. They reported the incidence of stoma complications in 1,616 patients. A total of 34.2% of these individuals suffered a complication related to their stoma, 27.7% of those individuals having an early complication, and only 6.5% suffering a late complication. The authors noted that the highest complication rate was in patients with a loop ileostomy.[65]

In a study from the United Kingdom, patients who underwent laparoscopic colectomy had a significantly prolonged hospital stay (6 days vs. 10 days) from the mere presence of a stoma due to the teaching and comfort level that patients needed to attain with the stoma. Interestingly, conversion to open surgery did not pose a significant increase in length of stay compared to the presence of a stoma.[66]

A surgical group from Italy compared the complications of loop ileostomy, loop colostomy, and end colostomy. In this retrospective review, there was no correlation in complication rates associated with stomas created either on an elective or emergent basis, the indications for surgery, the patient's gender, or the stoma site. There was an overall stoma complication rate of 60% mostly related to dermatitis, parastomal hernia, leakage from the appliance, and stomal stenosis. The fewest complications were noted in end colostomies and in patients less than 68 years of age.[67]

Skin Irritation and Leakage

While many surgeons would consider skin irritation and leakage commonplace issues relating to stomas, most surgeons consider this a complication only if the problem is so severe that it warrants surgical correction. Most of the skin issues related to the stoma do not require surgery. Many surgeons will refer their patients to an enterostomal therapist in order to help with this problem. However, many institutions may not employ an enterostomal therapist. Therefore, many colorectal training programs today provide their trainees an opportunity to work one on one with an enterostomal therapist in order to learn how to care for stomal-related problems. Often times the surgeon may be required to mark the patients in advance of surgery for proper stomal placement. It is imperative that surgeons have a good understanding of stomal care. Many of the skin problems from a stoma may be traced back to poor site selection in the first place whereby the stoma was placed under a skin crease. In these cases, it is important to try various other appliances of a convex nature in order to raise the lip of the stoma to get a better fit. In addition, a good seal may be achieved by using a variety of adhesives, powders, or sealants. Eakin cohesive seal rings form a waterproof barrier around the skin and the applied pouch and are designed to prevent pouch leakage in addition to extending the wear time of the pouch. They may also be useful to fill in uneven skin surfaces around the stoma site.

One study showed that 51% of patients questioned, reported problems with a rash and 36% had experienced leakage. Both problems were seen more often in patients with ileostomies rather than colostomies. In addition, nearly one-third to one-half of the patients also experienced a reaction to the stoma adhesive. However, only 8% of ostomates reported significant difficulty associated with skin irritation.[68]

Surgical correction for severe skin problems from the stoma may need to be done if enterostomal care has failed. If the stoma was used on a temporary basis then the stoma

FIGURE 31-6. Stoma with severe skin problems.

FIGURE 31-7. Stoma revision.

should be reversed as soon as it is feasible to do so. If, however, the stoma was created on a permanent basis, then stoma revision may need to be performed. Oftentimes the stoma will need to be resited to a more desirable area on the abdominal wall (Figures 31-6 and 31-7).

Parastomal Hernia

Parastomal hernia remains a major problem following stoma creation. While the true incidence of parastomal hernia is unknown, this complication is so frequent that most surgeons do not classify this as a complication until it becomes necessary to surgically repair the hernia. In fact, the creation of a defect in the abdominal wall for a stoma by definition places a weakness in the abdominal wall where there once was complete continuity. The truth is that many patients with parastomal hernia often have some disability related to this problem. The problems may be as minor as skin breakdown

near the stoma site or an inability to fit an appliance around the stoma, or it can be as devastating as incarcerating a loop of bowel within the hernia and requiring emergency surgery for resection and repair.

A recent prospective audit of parastomal hernias found that the overall rate of parastomal hernia was 33% and that aperture size and patient age were independent predictors of this problem. They found that for every additional millimeter increase in aperture size there was a 10% increase in risk of developing a hernia and for every additional year of patient age the risk increased by 4%. In addition, colostomies were at higher risk for hernia formation than ileostomies.[69]

As a result, many surgeons have advocated prophylactic mesh placement at the time of the stoma creation in order to prevent parastomal hernias. These meshes have been placed at varying levels in the abdominal wall and the use of the newer biologic and synthetic meshes may be more promising. A recent prospective study using polypropylene mesh simply placed in the pre-peritoneal space without sutures was performed in a total of 42 patients. While the majority of the created stomas were end colostomies, five patients in this study underwent surgery for stoma resiting. In the postoperative follow-up there were four parastomal hernias noted (9.52%), three of which were asymptomatic while the fourth required re-repair due to a poorly fitting appliance. There were no complications related to the mesh itself. The authors concluded that these results justify the placement of a parastomal mesh on a prophylactic basis.[70]

One randomized trial of 54 patients undergoing permanent intestinal stoma revealed that none of the patients who underwent prophylactic mesh placement developed a parastomal hernia while 8 of 27 without mesh did develop a hernia.[71]

Guzman-Valdivia retrospectively reviewed incisional hernias occurring at the previous stoma site in 70 patients after stoma reversal. While all of these patients underwent identical, relatively simple procedures for stoma reversal, the authors found an incisional hernia rate of 31% at the previous stoma site leading the author to conclude that the mere presence of a stoma had some degree of morbidity in its own right. The rate of incisional hernia formation was higher in the first year of follow-up and in patients with comorbidities particularly diabetes.[72]

Another study evaluating risk factors for parastomal hernia after APR evaluated 41 patients who underwent either laparoscopic (22) or open (19) procedures. Parastomal hernias developed in nearly half the patients and in nearly equal numbers in both groups of patients. The authors concluded that the only risk factor for parastomal hernia formation after controlling for surgical approach, age, sex, or adjuvant therapy was obesity and waist circumference. They found that waist circumference over 100 cm was associated with a 75% probability of developing a parastomal hernia.[73]

Parastomal hernia prevention is perhaps the best method of treatment. As a general rule, stomas should be placed through the rectus sheath for additional muscular support, fascial openings should be of the appropriate size for the portion of exteriorized bowel, prophylactic use of mesh may be considered for those patients requiring a permanent stoma, and extraperitoneal tunneling of the bowel may also be considered.

Once parastomal hernias are present and repair is necessary, there are several surgical options available. The stoma may be resited to an area on the opposite side of the abdomen that has never been used. This operation may be performed by mobilizing the stoma via a parastomal incision and simply pushing the bowel over to the opposite side of the abdomen. This may be easily done if there are no adhesions to the anterior abdominal wall and if the bowel has sufficient length.

Other options for parastomal hernia repair include a laparoscopic approach with mesh implantation around the stoma and covering the fascial defect or an open technique around the stoma itself with either suture closure of the fascial defect or with the placement of mesh. Biologic meshes may be more suitable for this approach since the operation is considered a clean contaminated field.

A recent review from Hershey Medical Center regarding parastomal hernia repair evaluated their results in 25 patients over a 7-year period. Twelve patients underwent laparoscopic repair successfully completed in 11 patients while the remaining patients underwent open repairs. While the operative times were longer for the laparoscopic repairs (172 min vs. 137 min), the length of stay was shorter (3.1 days vs. 5.1 days). However, the recurrence rates were high in both groups occurring in four laparoscopic cases (33.3%) and seven open cases (53.8%).[74]

High Output Stomas

The long debate as to which stoma is best for the patient, colostomy or ileostomy will likely continue for years to come. The advantages of the colostomy include more formed stool with the ultimate possibility of stomal irrigation and not using an appliance. Many claim that the more solid effluent is easier to manage and there are far fewer cases of dehydration associated with the colostomy. However, others feel that the ileostomy with its smaller size and ease of reversal may be better. But the more voluminous and more liquid effluent typical of the ileostomy may make these patients more prone to electrolyte disturbances and dehydration with marked diarrhea and dehydration occurring in 5–20% of ileostomy patients particularly in the early postoperative period. An ileostomy typically begins to function by the third or fourth postoperative day with peaks of over 3 l of output by the fourth postoperative day.[75] Hyponatremia may ensue since the ostomy effluent is rich in sodium. In fact, even healthy patients with an ileostomy have been shown to in a chronic state of sodium and water depletion.[15] The normal ileostomy may lose in the range of 600 ml per day and 75 mmol

of sodium per day. Therefore, serum electrolytes must be checked postoperatively and replenished with appropriate intravenous fluid selection. The small bowel often adapts quickly and the stoma output will thicken up especially when a diet is resumed. Patients should be told to drink plenty of fluids should they have a stoma with many of the popular sport drinks being suitable for fluid and electrolyte replenishment.

Once patients become dehydrated they also become uremic, often resulting in nausea secondary to the uremia. As such they have less desire to drink more fluids causing them to become more uremic and then more nauseated. This vicious cycle will continue until the patient is hospitalized and the intravascular volume is replenished with intravenous fluids. The stoma output will need to be controlled with anti-diarrheal agents or bile salt binders. Opiates may also be used to slow down small bowel transit. In extreme cases, injections of somatostatin may be used to reduce salt and water excretion and slow gastrointestinal tract motility.[76] Elements of the diet that increase stoma output such as foods high in sugar, salt, or fat should also be avoided.

Stone Formation

Another problem in patients with an ileostomy is the development of urinary stones. It has been estimated that up to 12% of patients with an ileostomy may develop urinary stones and the numbers seem to be higher in those patients who have had small bowel resected in addition to having an ileostomy.[77] While serum calcium, Vitamin D, and urinary calcium are often normal in these patients, it appears that a high level of uric acid is the main cause of the stone formation. As such, serum uric acid levels should be monitored in these patients and they should be started on allopurinol prophylactically if the levels remain high.[78,79]

The mechanism of urinary stone formation seems to be multifactorial. However, it is likely related to the fact that the uric acid crystals act as a nucleus for the precipitation of calcium salts. In addition, the hyperuricemia may allow the calcium oxalate crystals to form more readily by lowering the saturation index.[80] This may also be facilitated by the excess loss of fecal water, sodium, and bicarbonate, all of which reduces urinary pH and volume.[81] The acidic urine also favors the precipitation of uric acid. Patients should be advised to increase their fluid intake and possibly eliminate foods rich in oxalate such as spinach and some leafy vegetables.[82]

Whether there is a higher incidence of gallstone formation in patients with an ileostomy remains controversial. There does seem to be, however, a higher incidence of gallstones if there has been a resection of more than 10 cm of terminal ileum because of the increased loss of bile salts. This loss leads to a reduction in the bile salt pool causing instability in the solubility of cholesterol, thereby causing gallstone formation.[83]

Intestinal Obstruction

Intestinal obstruction may occur after any abdominal surgical procedure. Therefore, the true incidence of intestinal obstruction after stoma formation is not really known. In addition, how many obstructions are directly related to the stoma itself is not clear. However, there have been papers reporting bowel obstruction occurring in up to 20% of patients with an ileostomy. As in most cases, adhesions are probably the most common cause, but small bowel volvulus, internal hernia, or even incarcerated parastomal hernias may also be contributing factors. Some surgeons have suggested closing off the lateral peritoneal reflection around the stoma site or even bringing the bowel up to the skin in an extraperitoneal fashion in order to prevent internal hernia formation and torsion. However, there has never been proven true benefit to any of these methods.

Intestinal obstruction in patients with a stoma is handled as in any other case of bowel obstruction. The patients should be supported with intravenous fluids and nasogastric tube decompression of the bowel with serial abdominal exams and X-rays. Unresolving obstructions will need operative exploration and lysis of adhesions. If patients present with peritonitis with a bowel obstruction or signs of bowel ischemia then patients should be quickly resuscitated and taken to the operating room emergently for exploration. In this setting, many surgeons prefer a laparotomy to a laparoscopic approach since bowel distension may make laparoscopy difficult. If one suspects torsion of the bowel around the stoma site then it is unlikely that this will resolve without operative intervention.

Mention must be made of food bolus obstruction. Many patients with an ileostomy will develop signs and symptoms of bowel obstruction owing to the accumulation of poorly masticated or digested food (e.g., popcorn, peanuts, fresh fruits, meat, and vegetables). A careful history may reveal dietary indiscretions. Further, the possibility of a food bolus obstruction should be considered in any patient with an ileostomy who has radiologic evidence of a distal obstruction. A well-lubricated finger can be gently inserted into the stoma to feel for impacted material. A red rubber catheter is inserted gently into the ostomy and saline irrigation initiated. If suspicious concretions begin to pass into the stoma, the irrigations may be carefully repeated until the obstruction is relieved. A water soluble contrast enema through the obstructed stoma may also be both diagnostic and therapeutic by dislodging the bolus. Most of these food bolus obstructions resolve on their own and do not require surgery.

Ischemic Stomas

Many stomas may initially appear edematous and congested after stomal creation due to mechanical trauma and the compression of the small mesenteric vessels as they traverse the abdominal wall. This often resolves within a few days to weeks after surgery. However, true stomal ischemia is a

much more serious problem and often occurs due to tension of the mesentery as the bowel exits the abdominal wall. It may also be related to the exteriorized portion of bowel being excessively stripped of its mesentery. Stoma creation becomes challenging in the morbidly obese patient and these patients in particular will require extensive mobilization of the bowel prior to exteriorization in order to avoid tension. In addition, the fascial opening will need to be of sufficient size in order not to compromise the mesenteric blood supply. If there is concern about bowel viability after surgery, one can simply insert a glass test tube or sigmoidoscope into the stoma in order to determine if the bowel is viable beneath the tip of the stoma. If the stoma is viable at the fascial level, then the patient may be carefully observed. However, if there is question about the viability of the stoma at the fascial level, the patient should be returned to the operating room in order to undergo stoma revision.

Proper stoma creation remains one of the most vital parts of the surgical procedure even though it is often the last part of a possibly long operation. Patient lifestyle and comfort depends on a well formed and viable stoma. The few extra efforts made during the stoma construction is often worth the days, weeks, or months of misery for the patient from a poorly done and ischemic stoma. While early stomal ischemia has been reported in 1–10% of colostomies and 1–5% of ileostomies,[84] stoma viability does not often get better once the patient is awake.

Stoma Prolapse

Stomal prolapse is a more common complication of loop than end stomas. This problem often occurs in patients with redundant segments of bowel and in those with a large enough fascial opening to permit such prolapse and intussusception. These patients commonly have parastomal hernias associated with the prolapse. Once again, the most conservative manner in which to manage this problem may be found with good enterostomal care. Often the appliances are cut to fit appropriately around the enlarged stoma with particular attention to providing good skin care around the stoma. A study investigating the cause of loop transverse colostomy prolapse revealed that the prolapse is the result of a redundant colon that invades the stoma with increased abdominal pressure. A suggestion of fixating the colon to the fascia may prevent this complication.[85]

The best way to treat a stomal prolapse is to reverse the stoma. If the stoma was initially planned as a temporizing stoma then the enterostomal therapist should assist the patient with managing the prolapse until the patient is ready to have the stoma reversed. Stoma reversal in these patients is usually straightforward and is often easily accomplished through a parastomal incision. Since these stomas are often loop stomas, both sides of the bowel are easily accessible and the bowel may be reanastomosed with sutures or stapling devices. However, if the stoma is a permanent one, then a technique to correct this problem under local anesthesia by amputating the excess bowel and reconstructing the stoma at the desired level with a linear stapler has been described.[86]

Stomal Irrigation and Continence

For those patients not desiring to wear an appliance, colostomy irrigation may provide an alternative. Colostomy irrigation may be learned by patients and may improve their quality of life and reduce overall costs. A study from Singapore in 26 patients who underwent abdominoperineal resection and ultimately learned stomal irrigation reported an improvement in stomal continence, sleep, sex, and skin complications compared to patients who did not learn or practice this technique and were clearly more satisfied. In addition, this study showed a cost reduction with this technique since the patients no longer needed appliances.[87]

However, colostomy irrigation requires a level of motivation, intelligence, and dexterity on the part of the patient. The device to irrigate consists of a reservoir with tubing that is placed via a stoma cone into the colostomy. About 500 ml to 1 l of room temperature water is infused into the bowel depending on patient tolerance. Then a drainage sleeve is placed over the stoma to allow for stool drainage. An earlier study reported that 71% of patients were continent with stomal irrigation while only 20% complained of leakage of gas.[88]

Many patients with a permanent stoma would prefer continence rather than wearing an appliance. Continent colostomy reservoirs have been tried but have largely been abandoned due to high rates of failure, sepsis, and generalized poor results. Attempts at using the cecum for such a reservoir with its less solid stool have also proven to be relatively unsuccessful as well.

The Kock pouch, or continent ileostomy, today remains the best option for patients seeking to maintain some degree of continence of liquid stool and gas. Dr. Nils Kock designed this pouch in 1969. He then described a continent internal reservoir from the patient's small intestine by involuting a segment of small bowel to make a "nipple valve." Patients are required to empty these pouches with a catheter several times a day via a flat slit created in the abdominal wall.[89] While there have been reports of improved lifestyle particularly in younger patients, problems remain with nipple valve slippage and nearly 50% of these patients will require another operation rate as a result of this. A relatively recent study evaluating the benefits of continent stomas constructed with various segments of bowel showed that while there are good outcomes there is an overall complication rate of 23.5%.[90]

Stoma Reversal

Stoma reversal may be either one of the easiest or most challenging procedures to perform depending on the type of stoma and the length of time the stoma has been in place. The procedure may be associated with significant

morbidity as well. While most patients recover well from such surgery, severe complications can result in death. A recent systematic review of 48 studies of ileostomy reversal included over 600 patients from 18 countries. The overall morbidity after loop ileostomy reversal was 17.3% with a mortality rate of 0.4%. Less than 4% of patients required a laparotomy in order to facilitate the reversal. The most common postoperative complications were small bowel obstruction (7.2%) and wound infection (5.0%). The authors of this review concluded that while stoma creation may be considered necessary for anastomotic protection, the reversal is certainly far from a risk-free procedure.[91] Another study confirmed these same results reporting complications in as many as one-third of the patients who underwent ileostomy reversal with 3% of the patients dying after the surgery.[92]

Prior to stoma reversal the patients must be appropriately studied to ensure that it is safe to reverse the stoma. If the stoma was an end stoma, the surgeon must ensure that there is adequate length of bowel distally in which to perform the anastomosis. The patient may require a sigmoidoscopic evaluation of this portion of the bowel or a contrast enema. In addition, the proximal colon should always be evaluated prior to end colostomy reversal to ensure that there are no lesions present. This assessment may be done endoscopically or radiographically.

If the patient has a loop stoma that was performed to protect a distal anastomosis, one must ensure that this anastomosis is healed prior to the stoma reversal. If the anastomosis is low enough, it may be examined by digital rectal examination. Nevertheless, many surgeons prefer to visualize it with a sigmoidoscopic examination as well as a contrast enema to ensure anastomotic integrity. However, a prospective study reviewing contrast radiology of colonic j-pouches in 48 patients revealed that 46 of these patients had no clinical or radiographic evidence of leak. The authors concluded that the radiologic tests did not add much to the clinical assessment of these patients and was not necessary.[93]

The easiest stomas to reverse are traditionally the loop stomas. As discussed previously, both limbs of bowel are present and as such they simply need to be reanastomosed and returned to the abdominal cavity. This is often accomplished through a parastomal incision. However, if the bowel is stuck to the underlying tissues, the fascia or other loops of bowel within the abdominal cavity, then a formal laparotomy may need to be performed. Since the visibility around the stoma site is often limited, it is important to ensure that there are no inadvertent injuries made to any other loops of bowel. Once fully mobilized, loop stomas may be closed with the use of linear staplers by converting the bowel into a side to side or functional end to end bowel anastomosis. Alternatively, they may be closed by leaving the back wall intact and sewing the anterior wall of the bowel together. Many surgeons prefer using the side to side technique since this often leaves a wider anastomosis. After returning the bowel

to the abdominal cavity the fascia is simply closed leaving the skin open for drainage and packing.

Hartman's stoma reversal is often more challenging. The abdominal cavity must be explored in order to locate the distal portion of the bowel. The distal bowel is often atrophied and may be friable from long standing diversion. This may make it difficult to use staplers especially circular stapling devices. Care must be taken in order not to tear or injure the serosa of the distal limb of bowel. In some select difficult cases, the surgeon may opt to redivert the patient with a proximal loop stoma after performing end stoma reversal if there is concern about the anastomosis. Salem and his colleagues found that the length of time from stoma creation to reversal made a difference in terms of whether or not another stoma was used in the reversal procedure suggesting that increased time made the reversal a more difficult operation.[94] Other surgeons have shared this feeling anecdotally as well.

Laparoscopic end stoma reversal may be a very difficult procedure to perform particularly if the initial stoma was created for a severe inflammatory process. The abdomen may be filled with adhesions making it harder to identify the distal segment of bowel and requiring an extensive laparoscopic adhesiolysis. A recent study from Israel comparing their results of laparoscopic to open Hartman's reversal revealed a conversion rate of 19.5% mainly due to dense adhesions and difficulty in identifying the rectal remnant. There were no mortalities, no anastomotic leaks, slightly shorter operative times (193 min vs. 209 min), less blood loss, shorter time to return of bowel function (4.1 days vs. 5.2 days), and shorter hospital stay (6.4 days vs. 8.0 days) in the laparoscopic group. They concluded that there were significant advantages in the laparoscopic approach for Hartman's reversal.[95] Another study comparing laparoscopic to open Hartman's reversal reported a high morbidity for both procedures while it was significantly lower for the laparoscopic group. While the operative times were longer in the laparoscopic group, the hospital length of stay was shorter in the laparoscopic group (4.8 days vs. 6.8 days). They too concluded that laparoscopic Hartman's reversal was a reasonable procedure with some obvious advantages over the open reversal.[96]

Not all patients are candidates for Hartman's reversal. In fact, many studies have suggested that many patients may never undergo stoma reversal because of their comorbidities. A recent review from the Cleveland Clinic showed that 30% of their patients studied did not undergo Hartman's reversal. They reviewed several variables including American Association of Anesthesiologist's score, patient age, pulmonary comorbidities, patient's use of anticoagulants, preoperative blood transfusion, and initial surgery due to bowel perforation in order to derive at a predictive score to determine if patient's should be considered for stoma reversal. This may help surgeons use objective criteria to select the best patient's for stoma reversal in order to improve surgical outcomes.[97]

Summary

Intestinal stomas remain a surgical option used for many different reasons but most importantly as a measure to treat or attempt to prevent complications. However, ironically, intestinal stomas are also associated with significant complications and as with any procedure the surgeon must weigh the risks and benefits of stoma creation in order to decide if it is truly necessary for the disease process being treated.

Constipation and Functional Bowel Disorders

Madhulika G. Varma and Brooke H. Gurland

Definition and Prevalence

Constipation is one of the most common complaints voiced to primary care physicians, internists, gastroenterologists, and colorectal surgeons alike, with prevalence in North America estimated between 2 and 27%.[1,2] This broad range reflects a lack of agreement between how patients and physicians perceive constipation because definitions are variable and may refer to infrequent or hard bowel movements, or to difficulty with evacuation. In addition, complaints of constipation are two to three times more common in women than men. Knowles et al. reported that of 2,004 patients evaluated by transit study at three European tertiary referral centers for intractable constipation, 92% were women.[3] In a cohort of 2,000 women aged 40–69 years, 60% self-reported symptoms of difficult rectal evacuation over the last 12 months while 12% reported these symptoms weekly.[4] This difference can be explained by the vast diversity of how women define normal female bowel habits. Zutshi et al.[5] identified that women were more inclined to view their own habits as normal and perceive other habits unlike theirs as abnormal through self-reported questionnaires.

The incidence of constipation increases with age, and it is higher in nonwhites than whites, in people from a lower socioeconomic and educational status, and in the southern USA. A study done by Talley et al.[6] looking at elderly residents of Olmstead County in Minnesota further underscored the enormity of the problem by finding that nearly one in two women and one in three men over the age of 65 either had complaints of constipation or took laxatives.

The ROME Criteria were established to develop definitions, to augment research, and to evaluate treatment outcomes for functional gastrointestinal disorders.[7] Criteria for constipation are as follows:

- Less than three bowel movements per week.
- Straining more than 25% of the time.
- Hard stools more than 25% of the time.
- Incomplete evacuation more than 25% of the time.

When utilizing the standardized definitions of the Rome Criteria,[7] the prevalence of constipation in North America is estimated at 15%.

Validated symptom severity scores for constipation have also been developed, which are useful to assess the response to treatment, but their role in routine clinical practice has not been defined yet.[8–11] The Bristol stool scale is a visual representation of stool form and helps to subtype functional bowel disorders (Figure 32-1).[8]

Etiologies of Constipation

Constipation can be secondary to a myriad of conditions and medications. Physiologically, a number of complex interactions are necessary for the development of formed stool, the passage of stool through the colon, and the elimination of the stool bolus. The normal process of defecation requires the coordinated effort of colonic motility, rectal sensation, and pelvic floor relaxation.

Diet affects the size, consistency, and frequency of bowel movements; dietary fiber intake is highly correlated with stool bulk. For instance, inhabitants of countries with higher fiber intake pass more voluminous stool than those in countries with a lower intake of dietary fiber. Inhabitants of Western countries typically ingest inadequate amounts of fiber, secondary to reliance on processed grains. Since colonic distension triggers peristalsis, bulkier stools are a stronger and more efficient stimulus for colonic propulsion than smaller stools.

Many medical conditions are also recognized to affect bowel function. Metabolic and endocrine disorders such as hypothyroidism and diabetes, connective tissue disorders such as lupus and scleroderma, neurologic illness, immobilization, and psychiatric disease are a few of a long list of medical maladies associated with elevated rates of constipation. More colorectal-specific conditions, such as intrinsic colonic disease, can lead to decreased motility. Hirschsprung's disease and Chagas' disease alter the function of the colon through damage to the enteric nervous system. Colonic stricture,
FIGURE 32-1. Bristol Stool Scale. (Adapted with permission from Lewis and Heaton, © 1997 Informa Healthcare. Reproduced with permission).

secondary to carcinoma, inflammatory bowel disease, radiation, or endometriosis, can cause colonic obstruction and altered function. Additionally, there is an ever-increasing list of medications for certain medical disorders like hypertension that can actually promote the development of constipation. Opiate and anticholinergic use, as well as laxative abuse, may also be associated with constipation. Factors associated with constipation are summarized in Table 32-1.

Subtypes of Constipation

Patients can be further classified by associated findings such as slow transit (motility disorders), irritable bowel syndrome (IBS), and pelvic floor dysfunction, also described as obstructed defecation syndrome (ODS) or mixed disorders. Motility disorders can be isolated to the colon (colonic inertia aka slow-transit constipation) or can affect the stomach and small bowel. Colonic inertia (CI) is frequently associated with constipation since childhood, fewer than 3 BMs per week, and laxative dependence. IBS-C (constipation subtype) is associated with abdominal pain, irregular bowel habits, and pain relieved by defecation. ODS refers to a constellation of symptoms such as prolonged repeated straining at bowel movements, sensation of incomplete evacuation, and the need for digital manipulation. Overlap between the various subtypes of constipation can coexist. Although clinical history can be suggestive as to which type of constipation motility disorders and ODS can coexist in the same patient, diagnostic testing is confirmatory.

History and Physical Examination

The evaluation of constipation begins with a thorough history. Specific details of the patients' complaints, stool size, frequency, consistency, and ease and efficacy of evacuation should be noted. The age at onset of symptoms, diet and exercise details, medical history, surgical history, and medications should be recorded. A patient diary of dietary intake, evacuation frequency, stool consistency, and any associated symptoms can be very helpful to both the patient and the medical provider. Query into psychiatric illness and sexual and physical abuse must be performed as they are often associated with defecation difficulties.[9] Multicompartment pelvic floor symptoms such as urinary dysfunction, pelvic organ and prolapse, and sexual dysfunction needs to be elicited, and appropriate referrals to other pelvic floor specialists in urology and urogynecology should be made for combined treatment.

Physical examination in patients with motility disorders and IBS-C will be frequently unremarkable, but abdominal distension may be noted. Evaluation for pelvic floor dysfunction includes vaginal, perineal, and rectal examination. Bulging of the posterior vaginal wall beyond the hiatus is consistent with advanced prolapse and may represent a rectocele, enterocele, or sigmoidocele. Examination in the standing position with a finger in the rectum and vagina may be performed to elicit the maximal prolapse of the pelvic organs as they descend through the pouch of Douglas and genital hiatus. A gaping patulous anus may indicate neurological injury, intraanal intussusception, or full-thickness

TABLE 32-1. Factors associated with constipation

Lifestyle
    Inadequate fluid intake
    Inadequate fiber intake
    Inactivity
    Laxative abuse
Medications
    Opiates
    Anticholinergics
    Iron
Medical illness
    Neurologic
        Spinal cord dysfunction/damage
        Parkinson's disease
        Multiple sclerosis
    Endocrine/metabolic dysfunction
        Diabetes mellitus
        Hypothyroidism
        Electrolyte abnormalities
        Uremia
        Hypercalcemia
        Porphyria
Psychological
    Depression
    Anorexia
    Psychiatric illness
    Sexual abuse

Pelvic floor abnormality
    Nonrelaxing puborectalis
    Anal stenosis
    Rectocoele/enterocoele

rectal prolapse. Flattening of the perineum during Valsalva beyond the ischial tuberosities is suggestive of excessive perineal descent. Sphincter coordination is noted on anorectal examination when patients are asked to squeeze, relax, and push. Digital examination evaluates resting anal tone and squeeze strength, and can identify a large rectocele, sphincter defect, or no movement of the pelvic floor muscles. Valsalva maneuver or simulated defecation on a commode is useful to elicit full-thickness rectal prolapse. Anoscopy is performed to evaluate patients for mucosal abnormalities and rectoanal intussusception.

Diagnostic Testing

The subtypes of constipation are not mutually exclusive, and careful evaluation is important to guide treatment. Laboratory testing with thyroid studies and calcium levels are useful to exclude metabolic etiologies of constipation. Obstructing colon lesions and inflammatory conditions such as IBD or diverticulitis must be excluded by colonoscopy or GI contrast studies before considering functional etiologies.

Additional testing is reserved for patients who fail medical therapy. Radiological and anorectal studies are very useful to determine different pathologic mechanisms and to distinguish between normal versus slow transit and outlet dysfunction constipation.

Diagnostic Studies to Evaluate Intestinal Transit

Intestinal transit time can be estimated through various modalities. The most widely available technique for determining colonic transit uses radiopaque markers and radiographs of the abdomen. The concept of assessing transit using markers was first developed by Hinton et al.[10] modified by Martelli et al.,[11] and further changed by Metcalf et al.[12]

The patient should refrain from all enemas, laxatives, and most medications for 2 days prior to the ingestion of 24 radiopaque markers. The patient is required to ingest 30 g of fiber daily during the test and must continue to refrain from taking medication and laxatives. An abdominal radiograph is obtained on the fifth day, and the distribution and number of markers present in the colon is noted. Eighty percent of normal patients will have passed all the markers by 5 days. If the markers remain scattered throughout the colon and more than 20% of the markers remain in the colon, colonic inertia can be diagnosed. If the markers are found to have accumulated in the rectum, traditional teaching suggests that this is a diagnostic of outlet obstruction constipation (Figure 32-2). However, Cowlam et al.[13] refuted this hypothesis after evaluating the distribution of markers in 108 patients with functional constipation. They found no correlation between the pattern of marker distribution and any of the parameters denoting outlet obstruction.

There are many variations described for marker distribution. A more precise assessment of transit delay can be obtained by having the patient ingest radiopaque markers for three sequential days while following the same instructions and obtaining a radiograph on the fourth and seventh day. The number and distribution of the markers are tabulated and totaled. The resultant numeric values can then be compared to the established value for normal controls. The mean colon transit time through the entire colon in humans has been shown to be 31 h in males and 39 h in women. In the general population, 95% of patients will have a transit time of less than 65 h in men and 75 h in women. Patients with normal transit constipation will have a colon transit time that is in the normal range.

Another variation is to have the patient ingest a marker capsule (with 24 markers) on Sunday night and obtain abdominal films on Monday, Wednesday, and Friday morning. All markers in the colon on the Monday morning film provides a gross assurance that gastric and small intestinal transit are normal. The other two films provide additional documentation of colonic transit. The transit study can also be performed

FIGURE 32-2. Marker study revealing colonic inertia.

with ingestion of one capsule and a single X-ray image on either day 5, 6, or 7. More than 20% of the markers remaining in the colon may suggest colonic dysmotility.

Scintigraphic evaluation of intestinal transit, though not as widely available as other evaluative tools, is useful in the assessment of transit in the colon and proximal gut.[14] Transit times obtained through scintigraphy are generated by following the passage of a radiolabeled meal. Small-bowel and gastric emptying rates can also be estimated with this examination.

Small-bowel transit time may also be measured with a lactulose hydrogen breath test. The principle of this examination is that hydrogen produced through lactulose fermentation only occurs in the colon. If one records the time from ingestion of lactulose to hydrogen production, small-bowel transit time can be inferred.

A wireless capsule, Smartpill® (Smartpill Corp., Buffalo, NY), is now available in the USA to measure intestinal motility. The SmartPill® Capsule collects pH, pressure, and temperature data throughout the entire gastrointestinal tract estimating total gut transit.[15] However, the availability, reimbursement, and expertise in interpretation of the Smart-Pill® Capsule make it difficult to determine its ultimate use in clinical practice.

Diagnostic Studies to Evaluate Pelvic Floor Dysfunction

Anal manometry evaluates resting and squeeze pressure of the sphincter over the length of the anal canal and any rectal sensory deficits. Often with constipation, patients exhibit internal sphincter hypertonia with poor incremental squeeze pressures. The volume noted at first sensation can be blunted, i.e., requiring larger volumes to obtain a sensory response, and the maximum tolerated volume can also be blunted. The presence of the rectal anal inhibitory reflex (RAIR) is useful to exclude Hirschsprung's disease. Electromyography aids in the diagnosis of puborectalis syndrome by indicating a paradoxical or nonrelaxing muscle. Balloon expulsion is an inexpensive method to assess ability to evacuate. Normal studies indicate the ability to evacuate a 50–100 cc balloon in less than 1 min.[16]

Defecography is the gold standard to confirm evacuatory dysfunction due to intussusception, rectal prolapse, enterocele, sigmoidocele, rectocele, and perineal descent. Defecography is done with contrast in the small bowel to demonstrate an enterocele, or in the vagina, rectum, and sigmoid to demonstrate a sigmoidocele and to evaluate the anorectal angle, rectocele, and the residual content after evacuation.[17] Some centers use a dynamic MRI, but the technique varies. For the best images, complete evacuation of the contrast during the MRI after valsalva will most likely simulate defecation. Defecating MRI has advantages over traditional defecography because it involves less radiation and provides multicompartment images. However, defecating in the supine position is not physiologic, and the sitting MRI is not universally available. [18]

Pelvic floor findings may be asymptomatic or may be secondary to chronic straining as a result of underlying motility disorders, and clinical correlation is highly recommended prior to considering surgery based on radiologic diagnoses. For patients with pelvic floor dysfunction who demonstrate dysnergic defecation, randomized controlled trials show that biofeedback is superior to laxatives, sham treatments, and alternative therapies.[19] In the setting of rectal intussusception, rectocele and mucosal prolapse, stapled transanal rectal resection (STARR) can be offered. STARR employs a double stapled circumferential full-thickness resection of the lower rectum using specialized stapling guns (Ethicon Endosurgery, Cincinnati, OH, USA). Modifications to the design of the staples and the device since its initial reports involve a reloadable curved cutter stapler, the Countour® Transtar™ (Ethicon Endosurgery, Cincinnati, OH, USA), for perineal proctectomy.[20] The first staple line placed anteriorly reduces the intussusception and the bulging rectocele, correcting the anterior wall defect, and the second staple line placed posteriorly is aimed at correcting the intussusception. Prospective multicenter trials reveal initial and long-term symptom improvement of obstructed defecation after STARR.[21–24] A randomized controlled trial of STARR versus biofeedback revealed that STARR is more effective for treatment of evacuatory dysfunction.[25] For patients with a clinical or radiologic rectocele and retained rectal contrast, rectocele repair can be suggested. A rectocele occurs

due to a defect in the rectal vaginal septum and protrusion of the anterior rectum into the posterior vagina wall. Rectocele repair can be performed via transvaginal, transperineal, or transperineal approach with 75–80% reported bowel symptoms improvements.[26] Enterocele involves descent of small bowel into the lower pelvic cavity, leading to mechanical obstruction of the rectum. An enterocele results from a defect in the integrity of the endopelvic fascia at the vaginal apex, and repair can be performed via a transabdominal, laparoscopic, or vaginal route and is usually performed in conjunction with other pelvic floor procedures. A sigmoidocele refers to descent of the sigmoid colon into the lower pelvic cavity leading to compression and mechanical obstruction of the rectum. Sigmoid resection or sigmoidopexy in conjunction with posterior compartment repair has been shown to be effective in relieving symptoms of obstructed defecation in a limited number of patients.[27,28]

Medical Treatment of Constipation

Treatment of constipation is initiated with careful listening and validation of the patient's disability. Unfortunately, the community and health-care providers often fail to recognize or acknowledge the severe debilitation associated with this condition, and thus many patients do not get the attention or credibility associated with other diseases. Medical providers should strive to decrease patient anxiety over the act of defecation, to dispel the fear of malignancy, and to reassure the patient that a daily bowel movement is not requisite to good health.

Initial treatment of constipation focuses on review and modification of medications, lifestyle changes, and the intake of agents that affect the formation and composition of stool. Simple measures that can influence the passage of colonic content are increasing physical activity and fluid intake. Exercise, as limited as even gentle walking, can facilitate the elimination of stool. Fluid intake can cause the stool to be softer and easier to pass, along with other agents that can act to stimulate the colon to propel stool. Osmotic laxatives, stimulants, and enemas should be reserved for treatment of acute bouts of discomfort.

Lack of dietary fiber intake is a major factor in the development of constipation symptoms. Bulk forming agents are a first line therapy in the prevention and treatment of constipation. These agents facilitate an increase in the size of the stool bolus as well as make the stool softer. Bulking agents promote these changes by delivering a mass of nondigestible substrate to the colon and due to their hydrophilic nature, facilitate the absorption and retention of fluid in the stool. These substrates are derived from the nondigestible components of plants or are synthetic methylcellulose derivatives. Common bulk agents are psyllium (Metamucil®, Konsyl®), methylcellulose (Citrucel®), and calcium polycarbophil (Fibercon®). Side effects of fiber therapy include bloating and flatulence.

Osmotic laxatives are a class of medications that promote the accumulation of large volumes of fluid in the colon lumen through the delivery of osmotically active molecules into the small and large bowel. The osmotically active particles can be derived from sugars or salts such as sucrose-based sorbitol and lactulose. Lactulose is degraded in the colon yielding the production of fatty acids, hydrogen, and carbon dioxide. MiraLAX® (polyethylene glycol 3350) is an over-the-counter osmotic laxative that increases the frequency of bowel moments and softens the stool, so it is easy to pass. It is one of the most commonly recommended laxatives found to be safe and effective for everyday use.

Osmotic laxatives can also be based on nonabsorbable ions, commonly derived from magnesium or phosphate. Examples are magnesium hydroxide (Milk of Magnesia®) or sodium phosphate (Fleets® Phosphosoda). Caution must be exercised in patients with renal insufficiency as hypermagnesemia and renal failure can result. Other polyethylene glycol-based products such as NuLYTELY® or GoLYTELY® are used in many bowel cleansing regimes. Chronic use can lead to electrolyte disturbances and dehydration.

Colonic irritants are a class of agents that diminish constipation through stimulation of colonic motility. Examples are anthracene derivatives, which include senna and cascara and are found in Senekot® and Pericolace®. Long-term anthracene intake can generate a characteristic brown discoloration of the mucosa called pseudomelanosis coli. Bisacodyl is another irritant and can be found in the agent Dulcolax®. Long-term utilization of anthracene irritants may lead to poor colon function; therefore, such use is discouraged.

Mineral oil and docusate sodium (Colace®) are laxatives that act through the manipulation of stool composition. Mineral oil coats the stool bolus, preventing fluid loss. Docusate sodium lowers the surface tension at the stool–water interface, allowing greater penetration of the stool with fluid.

Enemas and suppositories are used to stimulate bowel movements. Strategies include promotion of defecation through distension (saline enema), rectal irritation (soapsuds, bisacodyl), or physical softening of the stool (glycerine). Enema therapy can be habituating and therefore should be used with caution to avoid dependency.

There have been a number of promotility agents that were initially available but were later recalled based on their toxicity profile. Lubiprostone (Amitizia®) is still commercially available for use in patients with functional constipation and IBS-C.[29,30] Lubiprostone (a bicyclic fatty acid) is a chloride channel activator that induces intestinal secretion without elevating serum electrolyte levels. It activates C1C-2 chloride channels in the apical membrane of the intestinal epithelium. It is Food and Drug Administration (FDA) approved for the treatment of chronic idiopathic constipation in the adult population (including patients > 65 years old) at the dose of 25 μg bid and for IBS constipation subtype patients at 8 μg bid. The most commonly reported adverse reactions include nausea, diarrhea, and headaches, causing patients to discontinue treatment. The cost of the medications can also be prohibitive for some patients.

Colonic Inertia

Colonic inertia (CI) represents a severe functional disturbance of colonic motility, which results in significant disability to the patient. In CI, there is ineffective colonic propulsion and a failure of a meal or stimulant to enhance colonic phasic contractile activity.[31] Patients with CI have heterogeneous clinical presentations and, like patients with normal transit and obstructed defecation syndrome, exhibit infrequent defecation and may suffer from abdominal pain, bloating, nausea, difficulty with and incomplete evacuation of stool. In the majority of patients, symptoms have been present since childhood, while others present with symptoms later in life without a sentinel event. However, some women report a change in bowel habits following hysterectomy or childbirth.[32]

Surgical management of constipation has changed little since its initial reports in 1908 when Lane described improvement in two thirds of patients after the removal of the abdominal colon.[33] Surgical intervention can be a good tool, but precise evaluation of colonic motility and pelvic floor function using the testing paradigm (described earlier in this chapter) is critical to identify which patients are most likely to benefit from surgical intervention. Issues like slow-transit constipation may be part of a more widespread disease affecting the whole gut, and patients with gastric and small-bowel dysmotility have less favorable results after surgical intervention than patients with colonic inertia alone.[34] Glia et al.[35] demonstrated a trend toward worse outcomes in patients with abnormal antroduodenal manometry.

Patients with slow-transit constipation and concomitant pelvic floor dysfunction represent a challenging subgroup to treat. Bernini et al.[36] evaluated 16 patients who had a combination of colonic inertia and nonrelaxing pelvic floor. All patients completed preoperative biofeedback training and could demonstrate relaxation of the pelvic floor musculature. Postoperative symptoms of difficult evacuation persisted, and nearly one-half were dissatisfied with their surgery. Hassan et al.[37] reports contradictory results. Patients with CI and pelvic floor dysfunction treated with preoperative biofeedback had equivalent long-term functional results and quality of life compared to patient with isolated CI. Psychological evaluation and management is important, especially in patients in whom surgery is being contemplated. Significant abnormalities have been documented with simple psychologic testing with instruments such as the Minnesota multiphasic personality inventory.[38]

Colectomy

The following surgical options for CI have been reported in the literature: total abdominal colectomy with ileorectal anastomosis, subtotal colectomy with ileosigmoid anastomosis, and subtotal colectomy with cecorectal anastomosis.

All three of these procedures are effective at increasing the number of bowel movements, but may vary with regard to functional results such as diarrhea and fecal incontinence. All three of them are also generally amenable to being laparoscopically performed. It is thought that sparing of the cecum, the ileocecal valve, and the distal ileal loop will leave a physiologic reservoir with colonic flora that promotes normal stool consistency and normal absorption of fluid and electrolytes.[39] However, the possibility of recurrent constipation still exists. Feng et al.[40] compared ileosigmoid anastomosis to cecal rectal anastomosis in 79 patients with a 2-year follow-up and found that ileosigmoid anastomosis resulted in higher defecation frequency, less use of laxatives and enemas, and higher patient satisfaction.

Knowles et al.[41] reviewed 32 series published in the English language whose publications included ten or more patients treated with colectomy for colonic inertia through the year 1999. None of the studies were controlled with respect to the outcome from other surgical or medical interventions. Inconsistent functional results were reported, and it was difficult to compare outcomes because patient selection was not well defined. A median success rate was reported at 86% (range 39–100%), and results of subtotal colectomy proved to be inferior to those with total abdominal colectomy with ileorectal anastomosis. Postoperative fecal incontinence was reported in 16 series with a median incidence of 14% (range 0–52%). Persistent abdominal pain was reported in 14 series. Recurrent constipation following surgery was still present in 15 series with a median incidence of 9% (range 0–33%). The median incidence for small-bowel obstruction was 18% (2–71%) with a median reoperation rate of 14% (0–50%) (Table 32-2). In addition, permanent ileostomies were created in 5% of patients due to poor functional outcome (0–28%).

Preoperative functional evaluation is very important but does not guarantee successful outcome following colectomy for constipation.[45] Routine evaluation of the entire GI tract is recommended by some authors due to data that suggests that gastric and small-bowel dysmotility have less favorable results after surgical intervention than patients with colonic inertia alone.[34,35,46] However, Zmora et al.[49] identified good results after colectomy in patients with delayed small-bowel transit compared to those patients with normal small-bowel transit. Thus, the presence of delayed gastric or small-bowel motility on preoperative testing is not an absolute contraindication but may be a poor prognostic indicator resulting in persistent symptoms and continuous use of promotility and antinausea medications.

Furthermore, patients with prior sexual trauma have been shown to have more functional diagnosis, more precolectomy operations, and require more postcolectomy medical care for abdominal complaints.[50] Patients should be extensively counseled prior to surgery about the postoperative persistence of preoperative symptoms and the occurrence of new symptoms.

Segmental Colon Resection

Segmental colon resection has also been suggested to avoid the diarrhea associated with abdominal colectomy. In a consecutive series of 28 patients with slow-transit constipation, as determined by scintigraphic transit study, who were subsequently treated with segmental colectomy, 23 patients were pleased with the outcome.[51] The median stool frequency increased from 1 to 7 per week with a median follow-up of 50 months. Since the ability to define segmental colonic transit is inexact and not universally available, total abdominal colectomy remains the most widely accepted surgical treatment option in the treatment of CI.

Proctocolectomy and Ileal Pouch Anal Anastomosis

Proctocolectomy with ileoanal pouch reconstruction has been described as a salvage operation for patients with recurrent constipation after abdominal colectomy with ileorectal anastomosis for slow-transit constipation. Keighly et al.[52] reported the results of eight patients, 50% required pouch excision for recurrent constipation. Furthermore, two of fifteen patients required pouch excision within eighteen months because of intractable pelvic pain.[53] Proctocolectomy has also been used as initial treatment for slow-transit constipation and rectal inertia. Overall, significant improvements in lifestyle scores were recorded in the categories of physical function, social function, pain, and general health for the group during the follow-up period following proctocolectomy.

Stoma

Fecal diversion with a permanent stoma is a last resort for the patients who fail other modalities. There is little data published to guide choice of ileostomy or colostomy, and symptoms such as distention and abdominal pain may persist.[54] Although very drastic, this is sometimes the only option for patients who fail all other management.

Sacral Nerve Stimulation

Sacral nerve stimulation (SNS) involves low-level chronic electrical stimulation to the sacral plexus, producing a physiologic effect on the end organs. As a coincidental finding in patients undergoing SNS for lower urinary tract dysfunction, many patients experienced improved fecal continence, an increase in bowel frequency, and improved defecation. Small series have investigated its efficacy in patients with slow-transit constipation and evacuation dysfunction refractory to medical therapy.[55–58] In general, the number of weekly BMs increased, and difficulty with evacuation (here defined as unsuccessful visits to the toilet) and time necessary to evacuate decreased. The exact mode of action is not known; however, it is postulated that sacral neuromodulation may involve afferent cortical stimulation, leading to increased motility and rectal sensitivity. The mechanism of SNS is poorly understood, making it difficult to give precise indications for eligible patients. However, there is a potential to alter colonic motility, pelvic floor and anal sphincter function, and afferent sensation. SNS is presently not approved for use in the USA for patients with bowel dysfunction as their primary indication.

Antegrade Colonic Enema

Patients with severe bowel dysfunction who are contemplating a permanent colostomy may find the antegrade colonic enema (ACE) procedure as an affirmative viable option. This procedure allows easy access to the colon through the abdominal wall with intermittent catheterization, irrigation of the colon, and rapid, controlled bowel purging (Figure 32-3).
FIGURE 32-3. Antegrade colonic enema (ACE) procedure for colonic inertia. This procedure allows easy access to the colon through the abdominal wall with intermittent catheterization, irrigation of the colon, and rapid, controlled bowel purging (Reprinted with permission, Cleveland Clinic Center for Medical Art and Photography © 2009. All Rights Reserved).

The patient can avoid a stoma bag while independently managing their own bowel activities. The ACE technique was first described by Malone in 1990, using the appendix as the conduit, but since then the cecum, ileum, and left colon have been utilized as the continence mechanism.[59–61] These procedures have become an increasingly popular treatment option for children with spinal dysraphism and anorectal malformations and are well reported in pediatric literature.[62] The ACE procedure is also gaining recognition in the adult population for patients who would like to avoid a colostomy bag. Success has been reported in adults with neurologic dysfunction, obstructed defecation, and fecal incontinence.[63–68] Complications are related to the cutaneous stoma, which may sometimes need multiple revisions.

Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is a functional bowel disorder in which abdominal pain or discomfort is associated with defecation or a change in bowel habits with features of disordered defecation. Organic pathology is absent, and diagnosis is made on clinical symptoms and exclusion of other disease states. Although there is overlap between patients in this category and those individuals described in the previous section, the key features include chronic symptoms such as abdominal pain relieved by defecation and/or associated with a change in the consistency or frequency of stools. These symptoms are variably associated with mucorrhea and/or abdominal bloating. IBS can be categorized into the following: constipation predominant (IBS-C), diarrhea (IBS-D), or mixed (IBS_M). The Rome criteria for a clinical diagnosis of IBS are listed in Table 32-3.

Epidemiology

Population-based studies in Western countries report an overall prevalence of IBS of 10–20%.[69] The prevalence is similar in Western minority populations, with the exception of Hispanics in Texas and Asians in California, who may have a lower rate.[70,71] Overall, the incidence in Western countries is 1–2% per year. In non-Western countries in Asia and Africa, some studies suggest that IBS incidence may be lower. In Western

TABLE 32-3. Rome criteria for irritable bowel syndrome[7]

Abdominal pain or discomfort characterized by the following
  Relieved by defecation
  Associated with a change in stool frequency
  Associated with a change in stool consistency
Two or more of the following characteristics at least 25% of the time
  Altered stool frequency
  Altered stool form
  Altered stool passage
  Mucorrhea
  Abdominal bloating or subjective distension

countries, women are two to three times more likely to develop IBS than men; in India, this phenomenon is reversed.[72] Retrospectively, many patients report childhood symptoms, and 50% of patients have symptoms before age 35.[73]

It has been recognized for many years that there are a variety of disorders associated with a clinical diagnosis of IBS. These include nonulcer dyspepsia, fibromyalgia, chronic fatigue syndrome, dysmenorrhea, urinary tract symptoms, and psychiatric disorders. Patients with IBS who present for evaluation are also at least twice as likely to meet criteria for psychiatric disorders as patients with organic disease with elevated scores of depression, anxiety, somatization, and neuroticism on standardized tests. However, no specific pattern of personality traits in patients has been identified. The most frequent of these disorders are depression and generalized anxiety. Interestingly, individuals with clinical symptoms of IBS who do not seek medical care have a similar prevalence of psychiatric disorders as the general population.[74] This suggests that the psychiatric disorder may be more important in health-care-seeking behavior than as an etiologic agent of the syndrome.

It has been estimated that only 10% of patients with IBS symptoms consult a physician for evaluation or treatment of their symptoms. With the exception of countries like India, women are more likely than men to present for physician evaluation. The socioeconomic impact of this disorder is also significant. There are 3.5 million physician visits estimated in the USA, and IBS is the most common diagnosis in gastroenterologist practice. Patients with IBS have more work absenteeism, more physician visits, and report a lower quality of life.[75]

Pathophysiology

The pathophysiology of IBS remains uncertain and several theories are listed below. Despite extensive investigations, no specific physiologic abnormality has been identified, and IBS remains a diagnosis of exclusion.

Gastrointestinal Motility

The current theories regarding the pathophysiology of IBS are of a complex interaction between altered gut motility and or visceral hyperalgesia and neuropsychopathology. Many studies measuring myoelectric activity in the colon have demonstrated abnormalities in patients with IBS. Normal colonic myoelectric activity consists of background slow waves with superimposed spike potentials. Bueno et al. demonstrated increased long spike bursts in patients with constipation and irregular short spike burst in patients with diarrhea.[76] Myoelectric studies in the small bowel have demonstrated shorter intervals between the migrating motor complex, which is of course, the predominant interdigestive small-bowel motor pattern.[77] Patients with IBS have variations in the colonic slow wave frequency and a blunted late peaking postprandial response

of spike potentials in the colon. Transit studies in the small bowel have demonstrated delayed meal transit in patients with constipation-predominant IBS and accelerated meal transit in patients with diarrhea predominant IBS.[78,79] Overall, these studies and others suggest an underlying generalized hyper-responsiveness of smooth muscle in patients with IBS.

Visceral Hypersensitivity

Visceral hyperalgesia appears to be another component of this disorder. Studies measuring the perception of gut distension using various techniques have demonstrated abnormally high sensitivity in both the small and large bowel.[80,81] It appears that patients with a diagnosis of IBS have both an increased awareness of gut distension and experience such distension as painful at lower volumes and pressures as normal subjects – this is especially in response to rapid distension.[82] While there has been some argument regarding a reporting bias in patients with IBS (i.e., routinely reporting pain at lower subjective intensities than normal controls), such differences do not account for all of the sensory abnormalities seen.[83] Furthermore, patients with IBS have widened dermatomal referral pain patterns than normal controls from gut distension,[84] though this visceral hypersensitivity is not associated with a somatic hypersensitivity.[85] It is thought that patients with IBS may have sensitization of the intestinal afferent nocioreceptive pathways in the spinal cord.

The central nervous system modulates gut function for optimal digestive function. The limbic system, medial prefrontal cortex, amygdala, and hypothalamus communicate emotional changes to the gut via the autonomic nervous system. In turn, signals from the gut to the brain can affect reflex regulation and mood states.[86] Recent studies have suggested that patients with IBS may process visceral afferent input in the central nervous system in an abnormal way, and this response may be modified by attentional factors acknowledging that stress, anxiety, and prior unpleasant life events increase the perception of painful events.[80,87] On a biochemical level, patients with IBS have been demonstrated to have increased hypothalamic corticotropin-releasing factor in response to stress, as well as an exaggerated colonic motility response.[88]

Small Intestinal Overgrowth Syndrome

Small intestinal bacterial overgrowth syndrome (SIBO) ($>10^5$ bacteria/ml) has been implicated as possible etiology for IBS. There is a striking similarity between the symptoms of bloating and abdominal pain associated with IBS and SIBO. Pimental et al.[89,90] showed that 78% of patients with IBS had abnormal hydrogen breath test, and a 7-day course of neomycin was associated with improvement of their symptoms. Using jejunal aspirates to detect SIBO, Posserud et al.[91] found higher bacterial counts in IBS patients compared to placebo (43% vs. 12%). Treatment with oral antibotics has become an accepted course of therapy for some patients with suspected SIBO and IBS.

Mucosal Inflammation

The presence of low-grade inflammation and immune activation suggests that alterations in the indigenous intestinal flora may play a role.[92] A correlation between abdominal pain in IBS and the presence of activated mast cells in proximity to colonic nerves has been reported.[93] Probiotics may be helpful to restore the depleted bifidobacteria species found in the human intestine.

Psychological Abnormalities

The relationship between psychopathology and IBS is unclear. As previously noted, patients with IBS have a higher incidence of panic disorder, major depression, anxiety disorder, and hypocondriasis than do normal populations.[94] In addition, they report a higher prevalence of physical or sexual abuse.[95] Two thirds of patients with IBS report the onset of GI complaints with an Axis 1 disorder.[96]

Genetics

The relationship between learned behavior and genetics in IBS is under investigation. Twin studies found that concordance rates for IBS were as high in monozygotic twins compared to dizygotic twins.[97] It has also been hypothesized that genetic differences in serotonic reuptake may play a role in the pathophysiology of IBS.

Symptoms

The altered stool habits reported by patients with IBS can be constipation, diarrhea, or alternating constipation and diarrhea. Constipation can be described as hard and/or infrequent stools, or painful defecation requiring laxative use. Diarrhea is usually described as small-volume, frequent, urgent, and watery stool and when present is often postprandial in nature. Usually patients have either constipation or diarrhea alone; however, alternation between each can be present. What differentiates these patients from those with functional constipation is the presence of significant abdominal pain and bloating. Abdominal pain is usually perceived as diffuse and is most common in the lower abdomen, especially on the left. Sharp pain may be superimposed on a more chronic duller component. Pain may be precipitated by meals and is often relieved by defecation. Patients often report increasing bloating and gas through the daytime hours, which may or may not be associated with objective evidence such as mucorrhea, either white or clear. Patients with IBS are more likely to report upper gastrointestinal symptoms of nausea, vomiting, and heartburn. Overall symptoms may be worse in times of stress. Symptoms not typical of IBS that should alert the clinician to organic disease include the following: onset in middle age or older, progressive or nocturnal symptoms, anorexia, weight loss, fever, hematochezia, and painless diarrhea or steatorrhea.

Treatment of IBS-C

Although there are emerging novel medications for IBS that may prove useful, much of the current medical therapy depends on diet modification and reassurance. Explanation and patient education play an important role in the management of this chronic disorder. Treatment strategies depend not only on the type of symptoms present but also on their severity and chronicity.

Medical Therapy

Fiber supplementation may improve symptoms of either constipation or diarrhea, although studies are inconclusive due to a strong placebo effect. Many physicians feel that polycarbophil based bulking agents may be tolerated better than psyllium-based compounds due to an exacerbation of bloating symptoms in some patients with the latter. Similarly, ingesting more water, avoiding caffeine and legumes are all reasonable patient advice. For patients with constipation-predominant IBS who do not respond to fiber supplementation (20 g/day) or do not tolerate it, osmotic laxatives such as MiraLAX®, Milk of Magnesia®, or sorbitol may be tried.

Tegaserod (Zelnorm®), a partial 5HT-4 agonist, accelerates transit in the small bowel and colon. It was shown to improve constipation and global IBS symptoms in women with constipation-predominant IBS.[98] However, Tegaserod is no longer available because its use can induce cardiac conduction abnormalities.[98]

Lubiprostone (Amitizia®) chloride channel activator has been approved for patients with IBS-C at a lower dose 8 mcg bid to decrease constipation, abdominal discomfort, and bloating.[30]

Antibiotics have been recommended to treat patients with SIBO and IBS. The following oral antibiotics have been suggested: neomycin orally for 10 days; levofloxacin or ciprofloxacin for 7 days; metronidazole for 7 days; rifaximin (Xifaxan®) for 10 days at higher than normal doses of (1,200 mg/day) compared to standard lower doses (800 or 400 mg/day).[99] Retrospective studies suggest that rifaximin is superior to other oral antibiotics, but the cost and the unwillingness of insurance companies to cover the higher dose make it a challenge for the patients and prescribing physician.[100]

Probiotics

Probiotic bacteria may inhibit other symptom-causing bacteria in the intestine, or the probiotic bacteria may act on the host's intestinal immune system to suppress inflammation. The most common probiotic bacteria are lactobacilli (also used in the production of yogurt) and bifidobacteria. Both of these bacteria are found in the intestine of normal individuals. Probiotics are thought to have both qualitative and quantitative effects restoring the type of bacteria and the amount of normal bacteria (i.e., small intestinal bacterial overgrowth). Commercially available probiotics are available and have been shown to be effective; there is no evidence on the superiority of any particular strain.[101]

Other agents undergoing evaluation primarily focusing on symptoms of pain include clonidine (an alpha adrenergic agonist), fedotozine (a kappa opioid agonist) and ammonium derivatives (an antimuscarinic and neurokinin-receptor antagonist). Of these, fedotozine is clinically available for this indication and has shown to be helpful in reducing symptoms of pain in patients with IBS.[102]

An adjunctive therapy to medication is psychological treatment. Psychologic treatment is appropriate when there is evidence that stress or psychological factors are contributing to an exacerbation of symptoms, or patients have failed to respond to medical treatment. A clear explanation of the rationale for such treatment is important in patient acceptance of such therapy.

Conclusion

Constipation is an extremely prevalent problem that can often be treated with minimal changes to diet and lifestyle, but there is a subset of patients who will have severe symptoms that are difficult to treat or are associated with irritable bowel syndrome. The magnitude of the problem requires the colon and rectal surgeon to understand the etiology of constipation, be facile with the tests utilized in the evaluation of the constipated patient, and be able to recommend both medical and surgical therapies when appropriate. The Standards Practice Task Force of the American Society of Colon and Rectal Surgeons has published practice parameters for the evaluation and management of constipation.[103]

Rectal Prolapse

Steven Mills

Rectal prolapse is a telescoping of the rectum out of the anus; an intussusception is when the telescoping does not protrude through the anal canal. Either condition can be uncomfortable or less commonly painful, and are often associated with varying degrees of embarrassment for the patient. They rarely present with ischemia or necrosis of the rectum; these advanced states represent an emergent situation.

Many patients have other associated pathologies of the pelvic floor and often there is a long history of straining and constipation. Fecal incontinence is also a common associated symptom. Further, there is a frequent association with anterior compartment pathologies such as urinary incontinence, voiding disorders, cystocele, or rectocele. Careful history and physical examination can lead to their diagnosis, which is essential as repair of the rectal prolapse without concurrent treatment of the associated anterior pathology can worsen symptoms.

Many theories have been proposed in an effort to explain the etiology of rectal prolapse. Nearly 100 years ago, Moschcowitz[1] suggested that rectal prolapse occurs as a sliding hernia through a defect within the pelvic fascia. Later, Broden and Snellman[2] demonstrated, with the aid of cinedefecography, that rectal prolapse is an intussusception of the rectum.

Rectal prolapse is more common in women than in men, likely due to childbirth, prolonged straining at stool, and/or anatomical considerations such as a wider pelvis. In women, the disorder increase in frequency with age whereas men with prolapse tend to be younger, around 20–40 years old, and often have a predisposing condition (such as anal atresia or prior surgery). In women, the pudendal nerves can be damaged during childbirth and/or chronic straining at stool, resulting in pelvic floor disturbances such as incontinence or prolapse. Whereas rectal prolapse is almost always treated surgically, every effort should be made to avoid surgery for rectoanal intussusception.

A wide variety of different procedures have been described to treat rectal prolapse (Table 33-1). The surgeon must determine which procedure is the best for an individual patient. Multiple patient and procedural factors need to be considered in determining which of the over 100 operations to perform. Important patient factors include gender and age of the patient, the patient's overall medical condition, bowel function, and whether or not fecal incontinence is also present. Procedural factors to consider include extent of prolapse, impact of procedure on bowel function and incontinence, morbidity of procedure, recurrence rates, and the individual surgeon's experience.

Unfortunately, a dearth of high quality data exists regarding the optimum method by which to treat rectal prolapse. An attempt in 2008 to perform a comprehensive review of randomized trials found that there were insufficient data to analyze, though a few patterns did emerge.[3] The method of fixation during rectopexy did not change outcome. Division of the lateral stalks was associated with a higher incidence of constipation whereas resection and rectopexy was associated with less constipation. Finally, laparoscopy was associated with a shorter hospitalization and less morbidity.

Patient Evaluation

Most patients with rectal prolapse present to the surgeon with complaints associated with the prolapse itself. They often describe a sensation of "something falling out," especially at the time of bowel movements. Many will complain of the feeling that they are "sitting on a ball" until spontaneous or manual reduction occurs. There is a common association with soiling of their undergarments or a feeling of mucous discharge. As constipation and straining, fecal incontinence, and erratic bowel habits are commonly associated with prolapse as well as other functional bowel diseases and mucosal abnormalities, evaluation prior to surgical management is necessary.

Physical examination can be variable for patients with rectal prolapse. While a spontaneous prolapse is obvious (Figure 33-1),[4] other patients may require straining to demonstrate the prolapse. In these cases, the prolapse usually is best examined in the squatting or sitting position. The patient

can be examined while he or she is on the toilet by having the patient lean forward. Alternatively, one can place a long rod to which a mirror is attached between the patient's legs to view the prolapse. A third option is to place a flexible endoscope into the toilet with the viewing end pointed toward the perineum. A more modern alternative might be a digital video or a digital photograph demonstrating the prolapse.

Interestingly numerous patients present to the office with this rather unusual imagery already captured and eager to share with the surgeon.

Prior to choosing the appropriate procedure for prolapse, differentiation between full-thickness and mucosal prolapse is necessary. Full-thickness prolapse is identified by its concentric rings and grooves as opposed to the radially oriented grooves associated with mucosal prolapse (Figure 33-2). During the examination, one should also evaluate for any maceration or excoriation of the perianal skin. A thorough digital rectal examination is important to detect concomitant anal pathology and to evaluate adequacy of resting tone and squeeze pressure of the anal sphincters and function of the puborectalis muscle.

Further evaluation is indicated for patients with rectal prolapse. Either colonoscopy or flexible sigmoidoscopy with air contrast barium enema should be performed to exclude or otherwise address any associated mucosal abnormalities. Defecography is often unnecessary in the evaluation of full-thickness prolapse because it is diagnostically obvious; however, it can be an essential part of the evaluation of internal or occult procidentia (rectorectal intussusception) or as part of pelvic floor musculature evaluation. Anal manometry can help assess sphincter function, as chronic prolapse typically damages the internal anal sphincter, resulting in poor resting pressures.[5] In such patients, synchronous levatorplasty

should be considered at the time of prolapse repair and may further improve continence.[6] In a manometric study evaluating patients with rectal prolapse, Spencer[5] reported that the anorectal inhibitory reflex was frequently absent or abnormal, that resting anal pressures were abnormally low, and that squeeze pressures were normal. Anal electromyography and pudendal nerve terminal motor latency are generally not clinically useful for this disorder unless there is a history of severe straining. In such a case, anal electromyography can be used to evaluate for the presence of inappropriate or paradoxical puborectalis contraction (anismus, nonrelaxing puborectalis or spastic pelvic floor). When discovered, biofeedback or botulinum toxin can be employed for therapy. Colonic transit times should be performed in patients with a history of severe constipation so that an appropriate operation can be chosen. Individuals with slow transit constipation typically benefit from a synchronous sigmoid colectomy with rectopexy versus rectopexy alone or even perineal rectosigmoidectomy. However, certain well-selected patients with concomitant slow transit constipation may be better served by a subtotal colectomy and ileorectal anastomosis at the time of rectopexy.

Surgical Procedures

There are two general approaches for surgery for rectal prolapse – abdominal operations and perineal operations. Men are at risk for neurologic injury resulting in sexual dysfunction from an abdominal operation; therefore, this option should be cautiously chosen. The risk of impotence for abdominal rectopexy should approach 1–2% in skilled hands and thus young males should be counseled to consider banking sperm prior to surgery.

The most common abdominal operations for prolapse are rectopexy with or without concomitant sigmoid resection. The typical perineal procedures are perineal rectosigmoidectomy (Altemeier) or a mucosal sleeve resection (Delorme). The specific operation must be tailored to the condition and pathology of each patient but some generalizations can be made. Elderly, high-risk patients are best treated with perineal procedures which can be performed under a regional anesthetic or even under a local anesthetic with IV sedation. Healthy adults with normal bowel habits can undergo either rectopexy with or without sigmoid resection or perineal rectosigmoidectomy with or without levatorplasty. Bowel function plays a role in determining the surgical plan. Constipated patients should usually undergo sigmoid resection and rectopexy, whereas incontinent patients should undergo either abdominal rectopexy or perineal rectosigmoidectomy with levatorplasty. Recurrent prolapse mandates knowledge of the prior repair as that information will dictate future options; the prior dissection may limit the available alternatives because of the remaining blood supply.

Perineal Procedures

Perineal Rectosigmoidectomy (Altemeier Procedure)

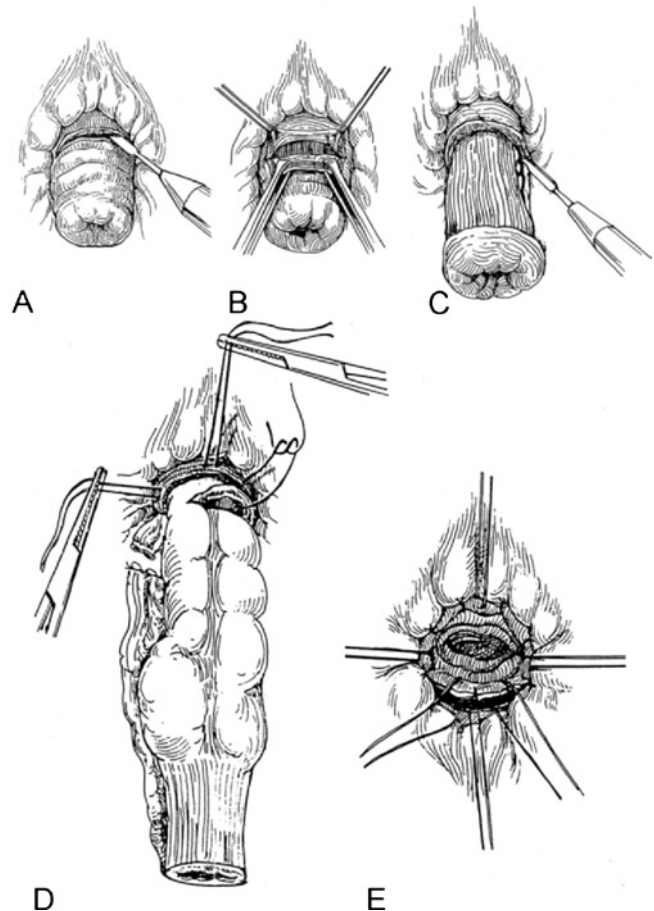
Perineal rectosigmoidectomy was popularized by Altemeier and his name is the eponym attached to the procedure.[7] The operation can be performed under a general or spinal anesthetic. Generally, the patient receives a full bowel preparation. The prone position is preferred; however, the left lateral (Simm's) or lithotomy position can also be effectively used. After prolapsing the rectum, the rectal wall is injected with an epinephrine-containing compound for hemostasis. A circumferential incision is made in the rectal wall approximately 1–2 cm above the dentate line (Figure 33-3). The incision is deepened until the full-thickness of the rectal wall


FIGURE 33-3. Perineal rectosigmoidectomy. **A**, **B** Incision of rectal wall. **C** Division of vessel adjacent to bowel wall. **D** The prolapsed segment is amputated. has been divided. Once a full-thickness incision has been made, the rectum is withdrawn out of the body while progressively dividing and ligating the mesorectum, advancing more cephalad. An energy source device can expedite this phase of the operation. Anteriorly, the peritoneal reflection (hernia sac) is opened. The dissection continues until there is no further redundancy remaining in the rectum/sigmoid colon, a judgment requiring some experience. After the redundant rectum has been adequately mobilized, it is divided and a hand-sutured coloanal anastomosis is performed. A colonic J pouch has also been described which may potentially improve function during the immediate postoperative period.[8] Alternatively, a circular stapler can be used to perform the anastomosis. In cases of severe fecal incontinence, a levator plication can be performed prior to the coloanal anastomosis which has been reported to improve continence in two-thirds of patients.[6,9] Following the procedure, patients are allowed to ambulate and eat regularly on postoperative day 1.

Several studies have been reported on perineal rectosigmoidectomy as summarized in Table 33-2. Mortality has been low with morbidity ranging from 5 to 24%.[7,10–19] Most of the reported morbidity stems from preexisting medical problems; however, a small number of patients do suffer anastomotic complications. Recurrence rates ranging from 0 to 10% are reported with a follow-up ranging from 6 months to 5 years; recurrence rates are higher for series with longer follow-up. An improvement in incontinence is reported in the majority of patients in whom levatorplasty was performed.[20] Indeed, levatorplasty may even be more beneficial as Chun et al.[21] reported a lower recurrence rate when perineal rectosigmoidectomy was combined with levatorplasty compared to perineal rectosigmoidectomy alone.

Mucosal Sleeve Resection (Delorme Procedure)

Another perineal option is the mucosal proctectomy first described by Delorme in 1900.[22] It is ideally suited to those patients with a less extensive prolapse (e.g., about 5 cm in length) or with full-thickness prolapse limited to partial circumference (e.g., anterior wall).

The Delorme procedure differs from the perineal rectosigmoidectomy (Altemeier) in that only the mucosa and submucosa are excised from the prolapsed segment (Figure 33-4). Delorme's procedure can be performed under general, spinal, or local anesthesia. Prone position is preferred; however, lithotomy position can also be successfully utilized. The bowel is prolapsed and the submucosa infiltrated with epinephrine solution; 1 cm cranial (proximal) to the dentate line the outer cylinder is incised through the mucosa only. The mucosa and submucosa are dissected off the underlying muscle (muscularis propria of the rectal wall). The mucosectomy may be more difficult in patients with prior anal surgery or a history of diverticulitis. The plane of dissection may be facilitated by continued submucosal injection of epinephrine solution as the dissection continues toward the apex of the prolapse. Four absorbable sutures (2-0) are placed sequentially in the rectal muscle at the anterior, posterior, and lateral positions as the dissection continues. These sutures plicate the muscle and provide traction. The dissection is carried inside the apex and the mucosa, which has been dissected free, is transected. After the mucosa is transected, the previously placed absorbable sutures (2-0) are used to reconnect the edges of the bowel. Four additional sutures are used to approximate the bowel between the placating sutures. Additional 3-0 sutures are placed in an interrupted fashion to complete the circumferential approximation of the mucosal edges.

Results of Delorme's procedure are summarized in Table 33-3. Reported operative mortality rates from a series of patients treated by Delorme's procedure range from 0 to 2.5%.[23–30] Morbidity rates were wide ranging (0–76%), with most morbidity associated with preexisting medical conditions. Surgery-specific morbidity includes hemorrhage, anastomotic dehiscence, and stricture. Recurrence rates (6–26% at 1–13 years postoperatively) are generally higher than with a perineal rectosigmoidectomy. Incontinence is improved in 40–50% of patients.[20] Constipation was not a problem in most series.

An alternative to the mucosal resection with muscular plication is the mucosal plication procedure (Gant–Miwa Procedure). Though not frequently performed in the USA, it has been associated with good results in Japan.[31] The best results seem to be when the mucosal plication is combined with an anal encircling procedure (see section "Thiersch Procedure" below).

Thiersch Procedure

Anal encirclement was first described by Thiersch in 1891.[32] He placed a silver wire subcutaneously around the anus under local anesthesia. The goal of this procedure was to mechanically supplement or replace the anal sphincter and stimulate a foreign body reaction in the perianal area, thereby increasing resistance at the anus. There were several reports of the use of this procedure in the early part of this century, especially in Europe.[33]

William Gabriel is credited with reviving interest in Thiersch's operation in the 1950s.[33] He reported on 25 cases of incontinence or minor rectal prolapse. He did not recommend this operation for major degrees of prolapse.

Anal encirclement is performed with the patient placed in the prone jackknife, lithotomy, or left lateral position (Figure 33-5). A local anesthetic is administered and a radial incision made on both sides of the anus about 2 cm from the anal verge. A curved hemostat is used to tunnel from one incision to the other, keeping "outside" of the external anal sphincter. The encircling material is brought through the tunnel so that the two ends meets. It is then secured by tying snuggly over an index finger in the anus. A variety of materials used for encirclement include nylon, silk, Silastic rods, silicone, Marlex mesh, Mersilene mesh, fascia, tendon, and Dacron.[34]

Complications of this procedure include breakage of the suture or wire, fecal impaction, sepsis, and erosion of the encircling material into the skin or anal canal. The Thiersch operation is not intended to correct the prolapse,

but rather to narrow the anus enough to confine the prolapsing rectum above the anus. This goal is accomplished in 54–100% of cases.[35] Because of its failure to correct prolapse and the potential morbidity of this procedure, it is reserved for the most seriously ill patients who are unable to undergo one of the previously described perineal procedures. Results of the Thiersch procedure are summarized in Table 33-4.[36–42]

Abdominal Procedures

Abdominal Rectopexy and Sigmoid Colectomy

Abdominal rectopexy and sigmoidectomy was initially described in 1955 by Frykman[43] for management of full-thickness rectal prolapse, and it remains one of the main treatment options. The operation consists of four essential components (1) Complete mobilization of the rectum down to the levator musculature, leaving the lateral stalks intact, (2) elevation of the rectum cephalad with suture fixation to the presacral fascia just below the sacral promontory, (3) obliteration of the cul-de-sac, and (4) sigmoid colectomy with anastomosis. The current operation is essentially the same with the exception that some surgeons no longer obliterate the cul-de-sac (Figure 33-6). This procedure has become one of the most commonly performed operations for rectal prolapse. Results of sigmoid resection and rectopexy are summarized in Table 33-5. Morbidity is low (0–23%) with recurrence ranging from 0 to 3% (one study had recurrence as high as 9%).[44–51]

Abdominal Rectopexy

Simple suture rectopexy without sigmoid colectomy has been reported as an effective surgical treatment for rectal prolapse.[52,53] As rectopexy without resection can lead to worsening of constipation, this operation is typically utilized in patients who do not have associated constipation. The rectal mobilization and fixation is similar to that described above (complete to the pelvic floor musculature, preserving the lateral stalks) and is illustrated in Figure 33-7. Results are summarized in Table 33-6. Recurrence rates are under 5%.[52–54]

Ripstein Procedure

Described in 1963 by Ripstein and Lanter,[55] the Ripstein operation had been one of the most popular procedures for management of rectal prolapse. It is less frequently used today, likely due to the success of alternate therapies, the incidence of postoperative constipation, and because this particular operation requires the use of prosthetic material.

The rectum is mobilized posteriorly down to the coccyx, again preserving the lateral stalks. A 5-cm piece of prosthetic mesh (Marlex or Prolene) is sutured to the presacral fascia within the sacral hollow, about 5 cm below the sacral promontory in the midline. The rectum is retracted cephalad and the sling is wrapped around the rectum and sutured to it. Finally, the sling is sutured posteriorly from the opposite side (Figure 33-8). Care must be taken to avoid making the wrap too tight thus causing an obstruction. The results are summarized in Table 33-7. Recurrence rates are low, but morbidity is 13–33%.[55–60]

[a]Laparoscopic approach.

Ivalon Sponge/Posterior Mesh Rectopexy

The Ivalon sponge wrap operation was first described in 1959 by Wells.[61] Traditionally, Ivalon (polyvinyl alcohol) sponge was used for the wrap, but other prosthetic meshes such as Prolene and Marlex (polypropylene) have also been successfully used. The operation begins with mobilization of the rectum posteriorly down to the levator ani. The rectum is also mobilized anteriorly, but the lateral stalks are again preserved. A piece of Ivalon sponge or mesh is then placed in the sacral hollow and sutured to the presacral fascia with nonabsorbable sutures. The lateral edges of the Ivalon or mesh are then wrapped around the rectum which has been retracted cephalad. The sponge/mesh is then sutured to the rectum such that only three-fourth of the rectum is wrapped (the anterior rectum is left free of the wrap material). The peritoneum is then closed over the sponge excluding it from the peritoneal cavity. Results of posterior wraps are summarized in Table 33-8. Recurrence rates are less than 3% with morbidity under 20%.[46,48,54,62]

Anterior Mesh Procedures

Multiple other mesh procedures have been described, some of which employ an anterior suspension technique. Among the most popular of these has been the Orr–Loygue procedure.[63] In this procedure, two ribbons of synthetic mesh is sutured to the anterior-lateral rectum (one on each side) after mobilization of the rectum as described earlier. The opposite ends of these mesh ribbons are then sutured to the sacral promontory under enough tension to hold the rectum from prolapsing. Loygue[63] reported on more than 250 patients treated for rectal prolapse using this procedure. Their recurrence rate was 5.6% (follow-up period up to 23 years) and 84% of patients with preoperative anal incontinence had continence restored.

Laparoscopic Approaches

Laparoscopic approaches to colorectal surgery have gained in popularity in recent years and have been shown to be appropriate for many indications. A laparoscopic approach to treat full-thickness rectal prolapse has been employed for multiple abdominal prolapse repairs, namely rectopexy, resection with rectopexy, and mesh repairs.[51,62,64–68] In general, success and morbidity are comparable to traditional approaches, with the benefit of shorter hospitalizations and a rapid recovery.

Ashari et al.[51] reported a 10-year, single-institution experience with laparoscopically assisted resection rectopexy in 117 patients with rectal prolapse. Mortality occurred in 1 (0.8%) patient and morbidity in 10 (9%) patients; 77 of the 117 patients (66%) were followed a median period of 62 months. Recurrent full-thickness rectal prolapse occurred in 2.5% while mucosal prolapse occurred in 18%.

Dulucq et al.[62] evaluated 77 patients who underwent laparoscopic posterior mesh rectopexy (modified Wells procedure). They only encountered one conversion to open for severe adhesions and two minor intraoperative complications which were managed laparoscopically with success. Only one patient had recurrence and 90% of patients were satisfied at long-term follow-up (34 months).

Solomon et al.[67] reported a trial involving 40 patients with full-thickness rectal prolapse. They were randomized to laparoscopic versus open posterior mesh rectopexy. They demonstrated a decrease in morbidity and shorter hospitalization in the laparoscopic group, though operative times were longer in that group. At 24 months follow-up, they reported one recurrence in the open group and none in the laparoscopic group.

A meta-analysis of six studies and 195 patients (98 open and 97 laparoscopic) comparing laparoscopic versus open suture rectopexy was reported by Purkayastha et al.[68] in 2005. They found no significant difference in terms of morbidity or recurrence of prolapse between the two approaches. Though operative time was longer in the laparoscopic group, there was a decrease in the length of hospitalization by 3.5 days as compared to the open group.

The use of robotics has recently increased in colon and rectal surgery. Although robotics have been considered by many surgeons to be an extension of laparoscopic surgery, some technical aspects of the robot (e.g., the need for "re-docking" when changing fields of operation and a steep learning curve), have lead to slow widespread acceptance of the robot. However, surgery for rectal prolapse has been considered by some surgeons to be ideal for utilizing the robot as the operation is only performed in the pelvis (obviating the need to move the robot). Multiple small series have been reported.[69–73] To this point, there is not adequate length of follow-up to show long-term success, but results seem to be as good as those with laparoscopy. de Hoog et al.[73] reported on 82 patients treated with open, laparoscopic, or robotic repair and found higher recurrence with both laparoscopic and robotic approaches compared to the open procedure. They suggested that randomized trials were needed.

All in all, laparoscopic approaches to performing abdominal surgeries for rectal prolapse are acceptable for surgeons

with skill and experience performing complex laparoscopic surgery. In the near future, robotics will likely play a more significant role in prolapse surgery as adoption of robotic techniques increases. Further down the line, natural orifice transluminal endoscopic surgery (NOTES) procedures may become feasible for treating prolapse.

Recurrent Prolapse

Though rectal prolapse has historically had a high recurrence rate (up to 50% or more), recent reports note recurrent prolapse following resection with rectopexy to be less than 10%. In general, perineal operations for prolapse have a higher risk of recurrence compared to abdominal approaches. Over a 30-year period, Hool et al.[74] reported recurrent rectal prolapse in 24/234 (10%) patients. In their retrospective report, the recurrent prolapse was repaired more often with an abdominal operation (86% of cases).

When full-thickness rectal prolapse recurs it is important to re-evaluate the patient for both constipation and other pelvic floor abnormalities in order to tailor the management best to address those issues. Therefore, patients with recurrent prolapse may require evaluation with manometry and/or defecography. It is important to inform the patient that although the recurrent rectal prolapse is repaired, the associated bowel dysfunction, including constipation and diarrhea, is largely unimproved following correction of the recurrence.[74–76]

One of the most important considerations in determining the best surgical option to treat recurrent prolapse is the residual blood supply of the remaining large bowel. The initial operative procedure performed for prolapse plays a dominant role in determining the selection of the next operation, as a prior resection will leave an interrupted colonic blood supply. Any patient who has undergone a prior rectal or sigmoid resection with anastomosis requires very careful evaluation prior to undergoing a secondary procedure, including a thorough review of the first operative report. The obvious risk to a secondary resection is ischemia to the segment of large intestine between two anastomoses. For example, if the patient has undergone an initial perineal rectosigmoidectomy, then a repeat perineal rectosigmoidectomy or abdominal rectopexy (without resection) can be safely performed. However, in such cases, abdominal rectopexy with sigmoid colectomy should be avoided because of the risk of ischemia to the retained rectal segment. For those patients who have undergone prior abdominal rectopexy but who now have recurrent prolapse, a redo abdominal rectopexy is an acceptable approach.

Recurrent full-thickness rectal prolapse can be successfully managed using the same operative options applied to initial disease. Reports in the literature place successful treatment of recurrence at between 85 and 100%.[75,76] Unfortunately, while most authors indicate the initial operative technique, the recurrence, and the secondary operative technique, they fail to describe adequately their rationale for selection of the secondary procedure. For that reason, there are a paucity of data upon which to base an intelligent treatment decision for management of recurrent rectal prolapse. There is no specific algorithm available which can be applied to select the best operation for treating recurrence, except that many reports suggest treating young patients using an abdominal approach and elderly patients employing a perineal approach. With that (lack of) information in mind and with consideration of remaining blood flow, a treating surgeon can make an individualized recommendation based upon the options summarized in Table 33-9.

Fengler et al.[75] reported the results of management of recurrent full-thickness rectal prolapse in 14 patients (13 repaired with perineal approach). The average length of time to recurrence was 14 months. Salvage operations performed to manage the recurrence included nine perineal operations and five abdominal operations. Patients were followed for 50 months after treatment for their recurrence. One patient died from an unrelated problem. None of the 13 remaining patients suffered a re-recurrence of the prolapse. Pikarsky et al.[76] reported on 27 patients with recurrent full-thickness rectal prolapse in a case-match study. Re-recurrence of prolapse occurred in 4/27 (15%) after a median follow-up period of 24 months, with similar results for abdominal and perineal approaches.

Steele et al.[77] performed a large retrospective study of 78 patients with recurrent rectal prolapse selected from a cohort of 685 patients who had undergone primary repairs. By evaluating re-recurrence after second and even third repairs, they demonstrated that approach (abdominal versus perineal) was associated with recurrence rate. Abdominal operations

TABLE 33-9. Management options for recurrent rectal prolapse

Initial operation	Options for management of recurrence
Perineal rectosigmoidectomy	Redo perineal rectosigmoidectomy
	Abdominal rectopexy (avoid resection)
Abdominal rectopexy	Redo abdominal rectopexy (+/− sigmoidectomy)
	Perineal rectosigmoidectomy
Abdominal rectopexy + resection	Redo abdominal rectopexy (+/− re-resection)
	Avoid perineal rectosigmoidectomy

to treat a recurrent rectal prolapse were associated with a lower re-recurrence rate. They concluded that when possible, abdominal approaches should be used for recurrent rectal prolapse repairs.

Solitary Rectal Ulcer Syndrome and Colitis Cystica Profunda

Solitary rectal ulcer syndrome (SRUS) and colitis cystica profunda (CCP) are uncommon and controversial conditions associated with rectal prolapse.[78] SRUS is a clinical condition characterized by rectal bleeding, copious mucous discharge, anorectal pain, and difficult evacuation. Despite its name, patients with this condition can have single, multiple, or no rectal ulcers. When present, the ulcers usually occur on the anterior rectal wall just above the anorectal ring. They generally are shallow with a "punched out" gray-white base surrounded by hyperemia.

CCP is a benign condition characterized by mucin-filled cysts located within the submucosa.[79] These lesions generally appear as nodules or masses, most commonly on the anterior rectal wall. Patients can be asymptomatic (with the lesions identified on screening endoscopy) or complain of rectal bleeding, mucous discharge or anorectal discomfort. Most patients complain of some difficulty with bowel movements. CCP is a pathologic diagnosis whose most important aspect is to differentiate it from adenocarcinoma, especially a well-differentiated mucinous adenocarcinoma. Obtaining the correct diagnosis can prevent unnecessary radical operations to treat a benign process.

CCP and SRUS are closely related diagnoses and some authors consider them interchangeable. The etiology of these conditions remains unclear, but a common feature is chronic inflammation and/or trauma. The inflammation may result from inflammatory bowel disease, resolving ischemia, trauma associated with internal intussusception or prolapse of the rectum, direct digital trauma, or the forces associated with evacuating a hard stool. Some suggest that CCP is the result of trapping of mucosal cells at the time of healing of an ulceration.

An endoscopic evaluation of the distal colon and rectum in symptomatic patients will reveal the above-described lesions. Defecography is generally abnormal in most patients.[80,81] The differential diagnosis of both CCP and SRUS includes polyps, endometriosis, inflammatory granulomas, infectious disorders, drug-induced colitides, and mucus-producing adenocarcinoma. Differentiation based upon histopathologic evaluation is possible, though snare excision or large biopsies via rigid scopes may be needed to obtain adequate tissue. SRUS is associated with characteristic obliteration of the lamina propria by fibrosis and a thickened muscularis mucosa with muscle fibers extending to the lumen.[80] Mucous cysts lined by normal columnar epithelium located deep to

the muscularis mucosa characterize CCP pathologically.[79] The overlying mucosa may be normal or ulcerated and the submucosa surrounding the cysts is fibrotic and contains a mixed inflammatory infiltrate. By comparison, the epithelium in adenocarcinoma, is dysplastic and the surrounding stroma is reactive.

Treatment is directed at reducing symptoms or preventing some of the proposed etiologic mechanisms. Conservative therapy (high fiber diet and modifying bowel movements to avoid straining) will reduce symptoms in most patients and should be tried first. Patients without rectal intussusception should be offered biofeedback to retrain their bowel function.[82] If symptoms persist, a localized resection may be considered in selected patients.[83] Those few patients potentially suitable for localized resection should be highly symptomatic, be good surgical risks, have failed all conservative nonoperative management and have localized, accessible areas of disease. Patients with prolapse are considered for surgical treatment via an appropriate procedure as outlined previously. Those without prolapse may be offered excision which varies from a transanal excision to a major resection with coloanal pull through.

Conclusion

Optimal management of patients with rectal prolapse requires careful patient evaluation for synchronous functional bowel disorders. Although, the precise etiology of rectal prolapse remains unclear, the condition is frequently associated with constipation and straining; intuitively, these coexisting symptoms seem to play a role in the development of prolapse in many patients. Management of any associated constipation seems important to the ultimate outcome of treatment, although it remains unclear as to whether successful management of constipation results in a lower risk of recurrent prolapse. The preoperative evaluation of any associated anterior compartment problems such as urinary incontinence, voiding disorders, cystocele, and rectocele is essential. If those preexisting conditions are unrecognized and remain untreated correction of the rectal prolapse may exacerbate them. Fecal incontinence is a frequent complication of full-thickness rectal prolapse; unfortunately successful treatment of the prolapse results in only a 50% chance of improvement in preexisting fecal incontinence.

Operative management can be divided into abdominal approaches and perineal approaches. Generally, abdominal procedures have a higher morbidity but a lower rate of recurrence compared to the perineal approaches. Selection of the best specific procedure for a given patient is at the surgeon's discretion and remains highly dependant upon such variables as the patient's general medical condition, comorbid disorders, the presence of incontinence or constipation, and any prior history of colon resection. Typically, the surgeon balances the risk of recurrent prolapse against the operative morbidity

in deciding between abdominal and perineal approaches. The use of mesh is acceptable, whereas anal encirclement is rarely used. Laparoscopic approaches to treat rectal prolapse have been shown to be safe and effective. The use of robotic-assisted surgery for rectal prolapse will likely increase.

SRUS and CCP are uncommon colorectal conditions often associated with prolapse. As they are benign conditions, efforts are directed to establishing the diagnosis, excluding malignancy, and treating symptoms. Initial conservative therapy is to modify bowel movements and habits and is associated the most success. If these measures fail, surgical therapy to correct any coexisting rectal prolapse or to excise locally the lesions may be considered.

Other Benign Colorectal Disorders

Justin A. Maykel and Scott R. Steele

Introduction

Multiple different disease processes may affect the colon and rectum, each challenging in varying aspects for both patient and physician alike. Though considered benign, they encompass a wide spectrum of pathology ranging from infectious, radiation-induced, and vascular etiologies to more obscure and difficult to diagnose conditions such as collagen vascular and microscopic colitides. Confounding the situation, patients may present with a variety of clinical symptoms spanning from chronic, nonspecific diarrhea, vague abdominal pain, and low-grade fevers, to florid sepsis. As such, clinicians caring for these patients must be aware of not only the many subtleties associated with each condition, but also possess a sound, and often stepwise, approach for evaluation and treatment. In this chapter, we review the extensive gamut encompassing these less common conditions, highlighting the critical diagnostic and therapeutic strategies to maximize patient outcomes.

Bacterial Enteritis/Colitis

Escherichia coli

Escherichia coli normally resides in the human gastrointestinal (GI) tract. Five pathologic variants exist including enterotoxigenic *E. coli* (ETEC), enteropathogenic *E. coli* (EPEC), enterohemorrhagic *E. coli* (EHEC, also called Shiga toxin-producing *E. coli* or STEC), enteroinvasive *E. coli* (EIEC), and enteroaggregative *E. coli* (EAEC or EAggEc). These strains are not commonly distinguishable with standard laboratory testing, although EHEC H7-O157 is the only strain readily identified in the clinical laboratory. Typically, infection from all strains leads to variable degrees of diarrhea, from mild to severe, resulting in large volume GI tract losses and electrolyte abnormalities. Subtle differences can help distinguish between the strains clinically. Enteropathic *E. coli* (EPEC) primarily causes outbreaks of severe diarrhea

in nurseries. The bacteria adhere to the mucosa of the small bowel and secrete a toxin that results in watery diarrhea, vomiting, and fever. ETEC is a major cause of traveler's diarrhea, with 30–50% of travelers from industrialized nations spending 3 weeks or more in developing nations experiencing this infection.[1] EHEC has occurred in the United States (US) during outbreaks associated with undercooked hamburger meat. Cases caused by EHEC can result in severe dysentery more commonly with bloody diarrhea than the other strains. Treatment in all cases is typically supportive, although antibiotics (fluoroquinolone or trimethoprim-sulfamethoxazole) are added for complicated and persisting cases, and in those with underlying immunosuppression. Additionally, there is some evidence that the duration of diarrhea from EAEC is decreased with antibiotics (i.e., ciprofloxacin) administration.[2]

Shigella

Named after the Japanese scientist Shiga who discovered them over 100 years ago, *Shigella* is the classic cause of dysentery in developing and industrialized countries. From the several variety of species of *Shigella* bacteria, *Shigella flexneri* (~1/3) and *Shigella sonnei* (~2/3) are far and away the most common causes of Shigellosis around the world that may be transmitted via person-to-person or through contaminated food, milk, or water. These bacteria are resistant to the low gastric pH, multiply in the small bowel, and eventually infiltrate colonocytes, resulting in clinical infection. *Shigella* is capable of colonizing the intestinal epithelium by exploiting epithelial-cell functions and circumventing the host innate immune response.[3] Patients commonly present with high fevers, abdominal cramps, tenesmus, and initially watery (though later bloody/mucoid) diarrhea. Malnourished and immunocompromised patients are most at risk for developing the debilitating and septic complications of infection.[4,5] In addition to the clinical presentation, diagnosis is confirmed by elevated fecal leukocytes and stool cultures. Endoscopic exam reveals a nonspecific friable, edematous, erythematous mucosa with focal ulcerations and bleeding. The most

often affected area is the rectum and sigmoid, although more severe infections often result in more proximal progression. Symptoms typically last 4–7 days, but vary depending on the infecting bacterial subtype and underlying immune status of the patient. Intestinal complications including rectal prolapse (particularly in infants and young children), toxic megacolon (3%),[6] intestinal obstruction (2.5%),[7] and perforation may also develop. Systemic complications may include bacteremia (in children and immunosuppressed), metabolic disturbances (i.e., SIADH hyponatremia, protein-losing enteropathy), leukemoid reaction, seizures (fever-related), reactive arthritis, and hemolytic uremic syndrome. Treatment is generally supportive, while in the immunocompromised host or when dysentery develops, trimethoprim-sulfamethoxazole, ciprofloxacin, and ampicillin have demonstrated effectiveness at shortening the duration and severity of illness.[8] Paradoxically, antidiarrheal agents such as loperamide (Imodium™) or diphenoxylate with atropine (Lomotil™) can make the illness worse, and should be avoided.

Salmonella

Salmonella, named for the pathologist Salmon who first isolated *Salmonella choleraesuis* from porcine intestine,[9] are gram-negative bacilli that grow under both aerobic and anaerobic conditions. They are the most commonly isolated pathogens from the stool of patients with gastroenteritis.[10] *Salmonella enteritidis* (which most frequently causes gastroenteritis) and *Salmonella typhi* (which more often causes enteric fever in underdeveloped countries) are also quite different in their epidemiology. In the US, the incidence rate of nontyphoidal *Salmonella* infection has doubled in the last two decades, with an estimated 1.4 million cases occurring annually.[11] *Salmonella* live in the intestinal tracts of humans and animals, and are usually transmitted to humans by eating foods contaminated with animal feces, including beef, poultry, milk, or eggs. Unlike *Shigella*, the organism is ingested and is susceptible to destruction by normal gastric acidity, pancreatic enzymes, and enteric secretions.[1] Gastroenteritis due to *Salmonella* is clinically indistinguishable from gastroenteritis caused by many other pathogens, commonly presenting with nausea, vomiting, fever, diarrhea, and cramping. *Salmonella* gastroenteritis is usually self-limited. Fever generally resolves within 48–72 h, though diarrhea takes longer at 4–10 days. Hemorrhage, obstruction, and perforation may occur, albeit infrequently, requiring emergent surgical intervention with resection and proximal diversion.[12] Up to 8% of patients with nontyphoidal *Salmonella* gastroenteritis develop bacteremia.[13] Of these, 5–10% also develop severe localized infections, including endocarditis, mycotic aneurysm, and osteomyelitis.[14] Similar to other bacterial infections, the clinical diagnosis is confirmed via stool culture. Treatment remains controversial and depends in part on the host immune status. In general, fluid and electrolyte replacement are administered. Based on available data, antibiotic therapy is not recommended in healthy immunocompetent individuals.[15] However, for those with severe disease (typically requiring hospitalization) or for those who are immunocompromised, antibiotics are recommended. Fluoroquinolones are the most frequent first line therapy, followed by trimethoprim-sulfamethoxazole, and are given for a 3- to 7-day course, with a longer minimum 14-day period in the immunosuppressed. Unfortunately, some *Salmonella* spp. bacteria have become resistant to antibiotics, largely as a result of the use of commercially used antibiotics to promote the growth of food-source animals. This should be kept in mind for patients not responding in the expected fashion.

Campylobacter

This spiral or "twisted" gram-negative rod is the most frequently identified cause of acute diarrheal illness in the US and industrialized nations. Of the various species, *Campylobacter jejuni* is the most common. Outbreaks generally occur during warm weather and are most frequently traced back to poor handling or preparation of beef or chicken products at barbecues. The organism can produce a spectrum of disease from watery diarrhea to dysentery, depending upon the strains' ability to produce enterotoxin, cytotoxin, or directly invade the mucosa.[5] Most cases present with fever, abdominal pain, diarrhea, nausea, and malaise within 2–5 days after exposure. Symptoms are generally self-limited, resolving within 1 week, though may linger up to 3 weeks or longer. The terminal ileum and cecum are most commonly involved sites. Rarely, when the organism elaborates mucosal invasive properties, mesenteric lymphadenopathy may simulate appendicitis or produce an enteric fever-like syndrome. Immunocompromised patients are at even greater risk for severe complications including perforation, obstruction, and sepsis. Long-term consequences of infection include arthritis, Reiter's syndrome, and Guillain–Barre syndrome.[16,17] Endoscopic findings range from segmental colonic ulcerations to a diffuse colitis. Further complicating this diagnosis, disease limited to the ileocecal region may also mimic Crohn's disease. Stool studies may reveal leukocytes or the characteristic organisms that are identifiable only by dark-field or phase-contrast microscopy.[18] Definitive diagnosis requires stool cultures as the disease clinically resembles both *Salmonella* and *Shigella*. As in other bacterial colitis, treatment with ciprofloxacin or erythromycin should be reserved for severely ill or immunocompromised patients. Otherwise, treatment is simply supportive with bowel rest, intravenous fluid, and correction of metabolic abnormalities. Surgical intervention may rarely necessary to treat complications such as megacolon, hemorrhage, or perforation; though more commonly occurs as a result of suspected appendicitis.

Yersinia

Three species of *Yersinia* produce human illness: *Yersinia pestis* (the causative agent of human plague), *Yersinia pseudotuberculosis* (rare in the US), and *Yersinia enterocolitica*

(i.e., yersiniosis). Contaminated food (typically pork) and water serve as the major routes of transmission of infection, and typically affect children and young adults. After invading the intestinal epithelium, these gram-negative coccobacilli localize to lymphoid tissues of the intestinal mucosa (i.e., Peyer's patches) and regional mesenteric lymph nodes. Symptoms associated with yersiniosis include diarrhea, abdominal pain (especially right lower quadrant), fever, and less frequently nausea and vomiting. Symptoms typically develop 4–7 days after exposure and may last 1–3 weeks or longer. Similar to *Campylobacter* infection, this clinical presentation may be confused with other conditions such as appendicitis and Crohn's disease, often called pseudoappendicitis or mesenteric adenitis. As the bacteria tend to infect lymphoid tissue throughout the body, concomitant tonsillar symptoms of pharyngitis symptoms can help distinguish *Yersinia* from other causes of colitis. Gastrointestinal complications of acute yersiniosis include suppurative appendicitis, diffuse ulcerative ileitis and colitis, intestinal perforation, peritonitis, intussusception, toxic megacolon, small bowel necrosis, cholangitis, and mesenteric vein thrombosis.[19] Stool cultures remain the gold standard for diagnosis, although specific culture for *Campylobacter* is normally not standard, and typically requires a special request. Serologic tests are commercially available to help in diagnosis as well. While antimicrobial treatment has been shown to decrease fecal shedding,[20] there are no studies that have demonstrated a benefit in uncomplicated enterocolitis, and are generally not given. If clinically indicated for the treatment of complicated illness (i.e., septicemia),[19] therapy with a fluoroquinolone (adult) or trimethoprim-sulfamethoxazole (children) are first line choices, with a third-generation cephalosporin combined with gentamicin intravenously used in more severe disease. Following treatment, chronic sequelae are frequent, including erythema nodosum and reactive arthritis.[19] These usually develop approximately 1 month following the initial episode of diarrhea, and generally resolve spontaneously after 1–6 months.

Tuberculosis

Tuberculosis affecting the gastrointestinal tract in the US is almost always due to either *Mycobacterium tuberculosis* or *Mycobacterium bovis*. In general, infection is unusual in Western countries, outside of immigrants and people infected with HIV.[21] Tuberculous enterocolitis is generally contracted via consumption of unpasteurized milk or from swallowing sputum infected from pulmonary tuberculosis. From the time of exposure to the organism, clinical manifestations can be delayed for up to a year, further confounding the diagnosis. Gastrointestinal tuberculosis manifestations can be divided into three categories: the ulcerative form (60%), hypertrophic form (10%), and mass-like lesions (30%) that mimic malignancies. Which type the patient exhibits depends in part on the host's immune system.[22] Distal small bowel and cecal infections are most common and present with abdominal pain, weight loss, and fever, often mimicking Crohn's disease or malignancy.[23] Ulcers of varying depth, fistulas, and stenosis may also result from the infectious process, thus causing further difficulty in distinguishing this entity from inflammatory bowel disease. Clinically, tuberculosis can present in a wide variety of ways. Physical findings include generalized wasting, with up to 50% of patients having a palpable mass in the right lower quadrant. Barium enema, ultrasound, and CT may suggest the diagnosis, but findings are too often nonspecific.[24] Significant lymph node reaction may be seen, so-called tuberculous peri-colonic adenitis, producing extrinsic compression leading to symptoms of partial or complete intestinal obstruction. Tuberculous peritonitis can present as a surgical emergency mimicking acute appendicitis or a perforated hollow viscous. Colonoscopic biopsy or fine needle aspiration have permitted detection of acid-fast bacilli or caseating granulomas while awaiting culture reports. Diagnostic laparoscopy demonstrated tuberculous peritonitis with 95% accuracy in one series in select patients.[25] Anorectal involvement results in ulceration and stricture formation, often mimicking malignancy. Stool cultures for viable *Mycobacterium* organisms rarely demonstrate growth, but may be more likely positive in active cases of pulmonary tuberculosis. Serology tests have been developed and demonstrate sensitivity for intestinal tubercular disease of over 80%, though still are difficult in differentiating from Crohn's disease.[26] A positive tuberculin skin test may be useful, but not necessarily diagnostic, as this may result from remote disease or a prior exposure without any current clinical activity.

Treatment is usually medical with multidrug regimens. Isoniazid and rifampin are first line treatment, with pyrazinamide and streptomycin or ethambutol often required until sensitivity analysis can be determined in the immunocompromised host.[27] In more established cases, obstruction of the bowel secondary to sclerosing lesions or fistulous disease may require surgical intervention. It is still recommended that a medical trial be attempted as many patients will improve and resolve without surgery.[28] Rectal tuberculosis, while rare, can result in stricturing. Most cases will improve with antituberculous drugs, though dilation may be required, and operative treatment only for severe or recalcitrant symptoms.

Neisseria gonorrhea

First identified in 1879 by the German physician Albert Neisser, *Neisseria gonorrhea*, a gram-negative diplococcus, remains the second most common sexually transmitted infection in the United States and Europe.[28] Gonococcus can lead to genital or extragenital infections, particularly the pharynx and the rectum, occurring more commonly in men having sex with men (MSM). Gonococcal urethritis presents with purulent penile discharge and dysuria. Cervical gonococcus also results in pruritis and/or discharge, but may be asymptomatic in 50% of cases. Anorectal gonorrheal infections typically occur among men who engage in anoreceptive
FIGURE 34-1. Endoscopic appearance of Gonoccocal proctitis. Notice the mucopurulent discharge.

intercourse. Symptoms of proctitis start 5–7 days after exposure and include a mucopurulent rectal discharge, tenesmus, constipation, and classically co-existent moderate to severe pain; although infection may infrequently be asymptomatic.[29] Physical examination may reveal edema, erythema, or fissuring of the anorectal mucosa (Figure 34-1). A mucopurulent discharge is the most common finding.[30] Culture for *N. gonorrhoeae* requires a Thayer–Martin chocolate agar and remains the "gold standard" for diagnosis. Cultures are taken with a cotton swab from the urethra, anal canal/rectum, or pharynx. Other options include gram stain (urethra), DNA probe, DNA amplification, and real-time PCR. Antimicrobial treatment must consider not only drug resistance, but co-pathogens such as *Chlamydia trachomatis* as well. Third generation cephalosporins (single dose 125 mg ceftriaxone, intramuscularly) are considered first-line therapy. Based on susceptibility, sulfonamides, penicillin, tetracycline, and fluoroquinolones are no longer recommended for the treatment of gonorrhoeae in the United States due to resistance patterns. Co-infection with *C. trachomatis* should be treated empirically with either doxycycline (100 mg BID for 7 days) or azithromycin (1 g in a single dose).[31] Patients should also alert their sexual partners for evaluation and treatment, to prevent disease spread or continued reinfection.

Lymphogranuloma Venereum

Although endemic to Africa, Southeast Asia, the Caribbean, and Central and South America, lymphogranuloma venereum (LGV) has become an increasingly common cause of proctitis in Western Europe and the United States, particularly among MSM (mainly in HIV-infected patients undertaking high-risk sexual activities).[32,33] LGV is caused by *C. trachomatis* serovars L1, L2, and L3. As LGV is primarily a disease of the lymphatics, infection extends from the primary inoculation site to the draining lymph nodes, producing a lymphangitis, with subsequent nodal necrosis and abscess formation.[33] The primary lesion of LGV occurs at the site of inoculation 3–30 days after sexual contact in the form of a painless pustule, shallow ulcer, or erosion. A secondary stage can occur 3–6 months after exposure and manifests as acute proctitis and inguinal lymphadenopathy that can suppurate and ulcerate. Excruciating pain helps to distinguish it from many other forms of proctitis. Left untreated, a chronic inflammatory response along with tissue destruction occurs, resulting in late sequelae including pelvic abscess, fibrosis, rectal stricture, fistula, and ulceration. Lymphedema and genital elephantiasis, with persistent suppuration and pyoderma, can also be seen.[33] The anal findings include ulcers, fistulas, and strictures, which, along with endoscopic findings, closely resemble Crohn's disease. Accordingly, treating physicians should consider this diagnosis in the proper clinical scenario. Specific LGV-associated serovars of *chlamydia* can be detected in those with positive PCR by genotyping. However, the diagnosis is usually initially based on clinical findings in association with a positive rectal *chlamydia* culture as genotyping results are not readily or immediately available.[34] The preferred treatment is doxycycline 100 mg twice daily for 3 weeks, with erythromycin used as an alternative. Administration of antibiotics both cures the infection and helps prevent further damage to tissues, although long-term scarring can ensue in areas of tissue reaction, particularly if diagnosis and treatment are delayed.

Syphilis

Treponema pallidum is a spirochete that invades subcutaneous tissues through abrasions caused during sexual intercourse. The spirochete establishes a painless ulcer (chancre), replicates, and infects draining lymph nodes (Figures 34-2 and 34-3). The painless nature of the chancre distinguishes it from the other major causes of a genital ulceration, herpes simplex virus (genital herpes), *C. trachomatis* (lymphogranuloma venereum), and *Hemophilus ducreyi* (chancroid). While the host immune system targets and heals the initial chancre within weeks, widespread dissemination of spirochetes occurs at the same time, leading to subsequent clinical manifestations of secondary or tertiary syphilis in untreated patients. Weeks to a few months later, approximately 25% of individuals with untreated infection develop a systemic illness that represents secondary syphilis, with symptoms including a rash on the palms, soles, and mucosal surfaces, fever, headache, malaise, anorexia, and diffuse lymphadenopathy. Similar to primary disease, these manifestations of secondary syphilis typically resolve spontaneously, even

FIGURE 34-2. Painless posterior-lateral ulceration (chancre) of anal syphilis.

FIGURE 34-3. Suppurative inguinal lymphadenopathy of syphilis.

without therapy. When patients are untreated during the earlier stages of syphilis, they are at risk for the manifestations of late or tertiary syphilis, including central nervous system, cardiovascular, and gummatous syphilis. Condylomata lata occurring in the perianal region appear as moist wart-like lesions that may be confused for human papilloma virus infection. While the chancre of primary syphilis is best diagnosed by darkfield microscopy, serologic testing is the mainstay of diagnosis, traditionally involving a nonspecific nontreponemal antibody test followed by a more specific treponemal test for diagnostic confirmation.[35] Since *T. pallidum* divides slowly, long-acting penicillin preparations are the preferred drugs for the treatment of all stages of syphilis. A single dose of benzathine penicillin G (2.4 million units intramuscularly) remains the standard therapy for primary, secondary, or early latent syphilis. Late latent syphilis or

latent syphilis of unknown duration requires three doses of 2.4 million units intramuscularly each at 1-week intervals.[36] Fortunately, there have been no cases of penicillin resistance reported. Options for the treatment of syphilis in penicillin allergic patients include tetracyclines, macrolides, or ceftriaxone.

Brucellosis

Brucellosis is a bacterium that is transmitted through unpasteurized goats' milk or cheese, contact with infected animals, or inhalation of aerosols. The constellation of symptoms is similar to the flu and may include fever, sweats, headaches, back pains, and weakness. It is encountered predominantly in underdeveloped nations, and is rarely seen in the US, with only 100–200 cases reported each year. Symptoms are that of a nonspecific colitis. Cultures of the exudate will reveal the organism and are required for confirmation. Endoscopic examination reveals inflammatory changes that are incapable of discriminating from other causes. Serologic tests are available to aid in early diagnosis and installation of treatment. Single agent therapy has an unacceptably high relapse rate so that currently, doxycycline 100 mg orally twice daily for 3–6 weeks and streptomycin 1 g IM q 12–24 h for 14 days are preferred. A more recent metaanalysis suggests that triple therapy by adding an aminoglycoside may result in lower failure rates.[37] Overall mortality is low (<2%), and is usually associated with the development of endocarditis.[38]

Actinomycosis

Actinomycosis is an uncommon, chronic granulomatous disease caused by *Actinomyces israelii*, an anaerobic gram-positive bacteria. The bacteria exists in the gastrointestinal tract, but can invade necrotic tissue and cause infections leading to granulomatous tissue, extensive reactive fibrosis and necrosis, abscesses, draining sinuses, and fistulas.[39] While infection in the cervicofacial area is most common (~50%), abdominal actinomycosis typically involves the appendix and ileocecal region. Similar to many of these infections, actinomycosis is a difficult disease to diagnose as its presentation mimics more common conditions such as malignancy, Crohn's disease, and tuberculosis. Therefore, the diagnosis is often made postoperatively. Colonoscopic findings can include thickened appearing mucosa, colitis, ulceration, nodularity, and a button-like elevation of an inverted appendiceal orifice.[40] Diagnosis is confirmed upon histological identification of characteristic yellow sulfur granules and/or culture of *A. israelii*. Medical treatment consists of a prolonged course of penicillin, intravenously for 4–6 weeks, followed by oral therapy for 6–12 months to prevent relapse. Surgical options are most often for disease complications such as resection of an obstructive segment or abscess drainage, which occur most often prior to a confirmative diagnosis. When necessary, surgery is coupled with systemic antibiotic therapy.[41]

Viral Enteritis/Colitis

Cytomegalovirus

Cytomegalovirus (CMV) is a member of the *herpes* virus family, and is considered an opportunistic infection in immunocompromised hosts. Yet it can also manifest as a spectrum of diseases in the immunocompetent host. In both of these patient populations, infections are not rare, as sero-prevalence for CMV worldwide ranges from approximately 60 to 100%,[42] thus making the differentiation between endogenous reactivation and exogenous reinfection difficult. Infection typically occurs late in the course of HIV infection when CD4 cell counts plummet or in immunosup-pressed transplant patients.[43] Involvement is most common in the colon, although concomitant disease may occur in the proximal gastrointestinal tract. The clinical manifesta-tions of CMV colitis vary greatly, from asymptomatic car-riers to fulminate life-threatening infections. Symptoms include fever, weight loss, abdominal pain, and diarrhea, which may be bloody. As the disease progresses, frank ulceration, toxic megacolon, and perforation may occur. The diagnosis of CMV colitis may be challenging, although fairly reliable findings on endoscopic examination include patchy erythema with or without ulcerations of variable size and depth. Biopsies should be obtained for histopathologic examination to evaluate for the characteristic inclusion bodies (Figure 34-4). Currently, there are several agents avail-able for the systemic therapy of CMV infection, including ganciclovir, val-ganciclovir, foscarnet, and cidofovir. Surgi-cal therapy is generally relegated to complications such as bleeding and perforation, where a subtotal colectomy with ileostomy is often required.

Herpes Simplex Virus Proctitis

Most colorectal infections are as a result of *herpes simplex virus* (HSV) type 2. HSV 1 is not common, accounting for 13% of rectal HSV infections, though most likely represents oro-anal transmission.[44] Gastrointestinal tract involvement usually manifests as proctitis following anal intercourse in MSM who are more commonly HIV positive. Presenting symptoms include anorectal pain, discharge, tenesmus, and rectal bleeding as well as difficulty in urinating, temporary impotence, fecal incontinence, and sacral parasthesias. The diagnosis is established by a suggestive history in combina-tion with physical examination findings including herpetic vesicles, pustules, and ulcerations that affect the perianal skin and anal canal, though rarely extend into the rectum. Sigmoidoscopic exam demonstrates an acute proctitis. Labo-ratory evaluation of rectal samples allows the virus to be iso-lated by culture. A variety of immunoassays currently exist to aid in diagnosis. Oral acyclovir has been demonstrated to be effective in alleviating symptoms although other formu-lations may allow for twice or once daily dosing regimens. Immunocompromised patients should be treated with intra-venous acyclovir followed by chronic suppressive therapy.[45]

Parasitic Enteritis/Colitis

Amebiasis

Entamoeba histolytica, while uncommon in the United States, is highly prevalent worldwide with approximately 40–50 million cases annually, accounting for 40,000 deaths.[46] This protozoan exists in either the cyst or trophozoite stages. Cysts are ingested in contaminated food or water, or via fecal–oral sexual transmission, and become trophozoites in the small intestine. Upon reaching the colon, they adhere to a specific lectin on the epithelial cell and penetrate the mucosa caus-ing colitis and bloody diarrhea. The rates are much higher in developing countries and in homosexual males. Approxi-mately 90% of *E. histolytica* infections are asymptomatic, with invasive disease depending on host genetic susceptibil-ity, age, and immunocompetence.[47] In most patients, symp-toms range from mild diarrhea to severe dysentery. Cases of fulminant colitis with bowel necrosis, perforation, and peri-tonitis occur in ~0.5%, but are associated with a mortality rate of more than 40%.[48] Localized colonic infection may also occur that results in a mass of granulation tissue, or an ameboma, which can mimic colon cancer. Perianal cutaneous amebiasis and rectovaginal fistulae are other reported rare complications. The diagnosis can be aided via antigen test-ing or serology tests. Colonoscopy classically demonstrates characteristic flask-shaped amebic ulcers where scrapings or biopsy specimens, best taken from the edge of ulcers, may be positive for cysts or trophozoites on microscopy. Treatment consists of oral metronidazole administered to eliminate the

invading trophozoites and to eradicate intestinal carriage of the organism, with success reported in approximately 90% of cases.[46] Surgical intervention is reserved for complications including toxic megacolon, uncontrolled abscesses, and intestinal perforation.[49]

Balantidiasis

Balantidium coli is the largest and least common protozoal pathogen affecting humans and is the only ciliate that produces important human disease.[50] While rare in the US, it is most commonly found in tropical and subtropical regions, thus travel history is an important aspect in diagnosis. Communities that live in close association with pigs have an increased prevalence of disease due to the high rate of carriage of this organism by these animals. *B. coli* infection is spread to humans by ingestion of cysts spread by contaminated water and food. Similar to other protozoa, the trophozoite invades the distal ileal and colonic mucosa to produce intense mucosal inflammation and ulceration. In the symptomatic patient, diarrhea with blood and mucus is accompanied by nausea, abdominal discomfort, and weight loss. If allowed to progress, it can develop into fatal fulminant colitis with peritonitis and colonic perforation. The diagnosis is made by the identification of trophozoites excreted in the stool or from the margin of rectal ulcers associated with infection. The most commonly used treatment is tetracycline 500 mg four times daily for 10 days.[51,52]

Cryptosporidiosis

Cryptosporidium is an intracellular protozoan parasite that infects and the epithelial cells of the digestive or respiratory tracts, causing a secretory diarrhea that can be associated with malabsorption, and biliary tract disease (i.e., stricturing and cholangitis).[53] Cryptosporidiosis presents in one of three main settings: (1) sporadic: often water-related outbreaks of self-limited diarrhea in immunocompetent hosts; (2) chronic: life-threatening illness in immunocompromised patients (i.e., HIV infection); and (3) diarrhea with malnutrition in young children in developing countries. Transmission of *cryptosporidium* occurs via spread from an infected person or animal or from a fecal-contaminated food or water source.[54] The pathogenesis of *cryptosporidium* infection involves ingestion of oocysts, excyst to sporozoites in the small bowel lumen, and invasion of the epithelial cells. Clinically, this may result in an asymptomatic carrier state, mild diarrhea, or severe enteritis. The illness usually resolves without therapy in 10–14 days in immunologically healthy people, yet excretion of oocysts can continue for prolonged periods.[55] In immunocompromised AIDS patients, a number of other clinical manifestations have been described, including cholecystitis, cholangitis, hepatitis, pancreatitis, and respiratory tract involvement. Biliary tract involvement most commonly with acalculous cholecystitis or

sclerosing cholangitis affects 10–30% of these patients with underlying AIDS.[56] The diagnosis of cryptosporidiosis is made by microscopic identification of the oocysts in stool or tissue, via microscopy, histopathology, ELISA, and PCR. Immunocompetent hosts generally recover within 2 weeks without antimicrobial therapy, only requiring simple supportive treatment. Treatment with nitazoxanide has been shown to speed clinical improvement and clear posttreatment *cryptosporidium* oocysts from stool samples.[57,58] This is recommended for persisting symptoms and in the pediatric age group. For HIV-infected patients, it is essential to initiate appropriate HAART treatment. In addition, nitazoxanide is recommended when CD4 counts are less than 100 cells/μL. Prognosis in this latter group is poor, particularly if the immune system cannot recover with HAART therapy. Ultimately, the majority of patients develop chronic disease with 10% acquiring a fulminant form with a corresponding high mortality rate.[59]

Giardiasis

Giardia lamblia is a flagellated protozoan gastrointestinal parasite that is commonly encountered in the United States. This is a common cause of water-borne and food-borne diarrhea encountered in day-care center outbreaks, internationally adopted children, and diarrhea in international travelers. Similar to *cryptosporidium*, after ingestion, the *Giardia* cysts excyst in the upper small bowel and release trophozoites which absorb to the mucosal surface of the jejunum, but do not invade the epithelium (Figure 34-5). Infection persists as the trophozoites revert to cysts in the large intestine. The mechanism how this leads to diarrhea and malabsorption is poorly understood; however, alterations in epithelial structure occur which may play a factor. Interesting to the surgeon,
FIGURE 34-5. Duodenal giardiasis. Pale pink organisms are identified in the lumen. No architectural distortion or inflammation is seen. (Courtesy of Jeanette R. Burgess, MD).

hypochlorhydria is a risk factor for infection, particularly after gastrectomy or in patients on acid suppressive medications. Transmission occurs via person-to-person (infectious cysts in stool), in uncooked foods, and contaminated water supplies (common in hikers and bikers who drink from mountain lakes).[60] The clinical presentation of infection varies greatly, ranging from asymptomatic infection in up to 60% to a self-limited acute or long-lasting chronic infection.[61] Classic symptoms of an acute infection include a prolonged 2- to 4-week course of diarrhea along with weight loss.[62] Chronic infection can occur in up to 30–50% of symptomatic patients, resulting in loose stools, significant malabsorption, weight loss, and fatigue. In addition, malabsorption may lead to approximately 40% of patients developing lactose intolerance. As this may take many weeks to normalize, confusion may occur in differentiating lactose intolerance symptoms with recurrence after treatment. Proper identification involves stool samples for ova and parasite (O and P), which reveals trophozoites and cysts in 50–70% of cases with a single specimen, and approximately 90% after three specimens.[63] Immunoassays with antibodies directed against either cyst or trophozoite antigens can confirm the diagnosis. Most asymptomatic patients do not require treatment, while all symptomatic patients are given antimicrobial therapy. Metronidazole is the first-line therapy in the United States, resulting in resolution of infection in 80–95% of cases. While not commonly use, other options include tinidazole, quinacrine, albendazole, and nitazoxanide.

Trypanosomiasis

Trypanasoma cruzi is the organism responsible for Chagas' disease or trypanosomiasis. Chagas' disease is transmitted via the bite of the reduvid bug, also known as the "kissing bug." Chagas' disease occurs primarily in central Brazil, but also is found in nonendemic areas where it may be acquired by blood transfusion, congenital transmission, or organ transplantation.[64] Clinical syndromes present in two stages – acute and chronic. Most patients infected with *T. cruzi* are asymptomatic during the acute stage of infection, while others develop a wide range of symptoms including fever, swollen face or eyelids (Romana's sign), peripheral edema, conjunctivitis, hepatosplenomegaly, lymphadenopathy, and less commonly, myocarditis and meningoencephalitis.[65] Organ damage during the acute phase is due to both high-grade parasitemia and direct tissue parasitism, mainly in the gastrointestinal tract, central nervous system, and heart. Approximately 50% of infected individuals develop chronic disease, typically following a long period of clinical latency called the "indeterminate form," which lasts for years to decades. This may ultimately lead to cardiomyopathy, megaesophagus, and megacolon. Involvement of the colon results in abnormal basal colonic motility and an impaired relaxation response in the anal sphincter.[66] The colonic wall becomes thickened and dilated, most commonly at the sigmoid colon. Patients develop constipation, which can be severe, resulting in impaction of desiccated feces. The atonic colon occurs as result of denervation in both the submucosal (Meissner) and myenteric (Auerbach) plexuses. In the chronic form, parasites often cannot be detected circulating in the blood or visualized in biopsies of involved organs; as such, the diagnosis is made on linking clinical symptoms with a presence of an endemic area along with supportive radiological findings. Treatment of colonic complications includes fiber supplementation, enemas, and often, frequent disimpaction. Severe complications such as toxic megacolon and volvulus usually require either endoscopic treatment or surgical intervention. All patients with acute infection and all immunosuppressed individuals should be treated medically as well. The two main agents that are used are nifurtimox and benznidazole, although both have extensive side effect profiles that impact compliance. Finally, it is controversial whether patients in the indeterminate phase or late stage benefit of antiparasitic therapy and thus should be determined on a case-by-case basis.[67]

Ascariasis

Ascaris lumbricoides is one of the most common helminthic human infections worldwide, infecting an estimated 25% of the world population. Infection is more prevalent in children, tropical climates, and areas with poor sanitation. This is impacted by the fact that ova can survive in the environment for years and asymptomatic infected patients can shed ova for years.[68] Transmission typically occurs via ingestion of contaminated water or food. The life cycle entails the ova hatching in the small intestine and releasing larvae, which penetrate the intestinal wall and migrate hematogenously or via lymphatics. These larvae mature in the lungs, migrate up the bronchial tree, and are swallowed back into the GI tract. The mature worms are generally found in the jejunum, although they can live anywhere from esophagus to rectum. Adult worms live 1–2 years, and while not replicating in the host, one person can carry anywhere from 100 to 1,000 worms, depending on egg exposure. Although most patients are asymptomatic, large worm loads are responsible for the development of symptoms. Additionally, symptoms have been attributed to the immunologic response to the foreign body, luminal obstruction, or nutritional deficiencies. For the colorectal surgeon, a mechanical intestinal obstruction can occur from a mass conglomeration of worms, particularly at the ileocecal valve and in the pediatric population.[69] Worm migration into the biliary tree can cause biliary tract infections and strictures. Diagnosis is typically made by stool microscopy. One should note that the worms' eggs are not seen in the stool early in infection cycle or if the infecting worms are all male. Peripheral eosinophilia can be seen, particularly during the pulmonary infection stage.[70] Imaging including plain films, contrast studies, and CT scans often detect worm, either in the GI or biliary tracts. The mainstays

for treatment are mebendazole and albendazole, typically administered as a single dose.[71] However, because they are teratogens, pyrantel pamoate is given during pregnancy. As these therapies are directed against the adult worm, as opposed to the larvae, patients should be rechecked in 2–3 months to rule out reinfection, which is unfortunately seen in up to 80% of individuals.[68]

Schistosomiasis

Schistosomiasis is caused by infection with parasitic blood flukes/trematode known as *schistosomes*. Infection is very common, manifests in an array of clinical presentations, and can result in significant illness. Several species exist and occur in geographic patterns. Their lifecycle is complex, beginning with infection via contaminated fresh water and subsequent hematogenous spread, where they survive for many years.[72] Most of the adult worms feed off circulating blood products, but do not cause disease. Rather, the eggs invade tissues, release toxins, and provoke an immune response.[73] In the bowel, granulomatous inflammation around the invading eggs can result in intestinal schistosomiasis characterized by ulceration and scarring.[74] A similar granulomatous fibrosing reaction causes injury in the biliary tract and urinary tract. Acute infection includes dermatitis and Katayama fever, which resembles serum sickness. Severity of chronic infection is related to the number of eggs trapped in tissues, their anatomic distribution, and the duration and intensity of infection.[75] This includes intestinal, hepatic, urinary, spinal cord, cerebral or cerebellar, and pulmonary schistosomiasis. Regarding intestinal schistosomiasis, most patients present with intermittent abdominal pain, poor appetite, and diarrhea. Intestinal polyps, ulcers, and strictures can also arise due to granulomatous inflammation surrounding eggs that are deposited in the bowel wall. The diagnosis is made by microscopy with egg identification, serology, or radiological findings in the appropriate clinical scenario. Rectal biopsy may also reveal the presence of eggs in the mucosa or submucosa. All infected patients should be treated, regardless of symptomatology, as the adult worms can live for years.[76] Praziquantel paralyzes worms by altering permeability of calcium channels, causing the worms dislodge from the intestines, and are ultimately passed by peristalsis. Cure rates exceed 85%, with even treatment failures still decreasing the intensity of infection in those not cured.[77]

Strongyloidiasis

Strongyloides stercoralis infection results in a wide range of clinical presentations, from a peripheral eosinophilia to septic shock, depending on host immune status. Cases are seen in the southeastern Appalachian region of the United States and in tropical endemic regions. Contact with contaminated soil allows the filariform larvae to penetrate the skin and spread hematogenously to the lungs, where they penetrate the alveolae, travel up the tracheobronchial tree, and are swallowed, similar to *Ascaris*. These larvae mature into adult worms and penetrate the mucosa of the duodenum and jejunum. Uniquely, the adult Strongyloides worms can produce rhabditiform larvae, which mature into filariform larvae within the gastrointestinal tract. These filariform larvae can then penetrate the perianal skin or colonic mucosa to complete the cycle. This maturation results in autoinfection and maintenance of parasitism.[78] As a result of this autoinfection, disease can persist for many years. Clinical manifestations include peripheral eosinophilia, cutaneous rashes (entry site most commonly sole of foot), gastrointestinal disturbances including duodenitis, enterocolitis, malabsorption, pulmonary, and hyperinfection syndrome that involve massive hematogenous dissemination (particularly in the immunosuppressed host) to the lungs, liver, heart, central nervous system, and endocrine glands.[79] The diagnosis of strongyloidiasis is made either by detecting rhabditiform larvae in the stool or via serologic testing. Ivermectin is the treatment of choice for strongyloidiasis, while albendazole is a less reliable option.[80]

Trichuriasis

Trichuriasis is a common intestinal helminthic infection, seen particularly in warm, moist climates.[81] *Trichuris trichiura* is also called "whipworm" because the adult worm is shaped like a whip. Eggs are ingested orally and release larvae that mature into adult worms in the intestinal tract where they attach to the bowel mucosa (Figure 34-6). Most infections are asymptomatic, although heavy worm loads can result in diarrhea with blood, mucous, and rectal prolapse, in which case the adult worms are visible on the prolapsed rectal mucosa. The diagnosis is made by seeing the characteristic barrel-shaped eggs harvested from stool samples, or visualizing the
FIGURE 34-6. Characteristic microscopic appearance of *T. trichiura* (whipworm) egg.

adult worms endoscopically (Figure 34-7). Mebendazole is the treatment of choice, administered in a dose of 100 mg twice daily for 3 days.[82]

Enterobiasis

Enterobius is a common nematode that is found worldwide. Otherwise known as "pinworm," infection occurs most frequently in school children aged 5–10 years. The adults live in the human gastrointestinal tract mainly in the cecum and appendix, and migrate out through the rectum onto the perianal skin at night to deposit eggs. As these larvae mature over the next 6 h, they cause local symptoms of pruritis ani secondary to an inflammatory reaction to the adult worms and eggs on the perianal skin. Scratching actually aids the worms by promoting reinfection and spread via oral ingestion. Rarely, with high worm burden, eosinophilic enterocolitis can develop.[83] Rarely, the adult worm can migrate locally and cause vulvovaginitis, salpingitis, oophoritis, or cervical granulomas.[84] The diagnosis of enterobiasis is best made using a "scotch tape" test, as adhesive tape will capture the eggs. These can be visualized under a microscope with their characteristic "bean-shaped" appearance. Adult pinworms may also be visualized endoscopically. Both mebendazole and albendazole are equally efficacious in curing 95% of patients, either with a single dose or repeated dose 1 week later aimed at treating reinfection.[85] Pyrantel pamoate is recommended for symptomatic pinworm infections in pregnant women again to the teratogenic effects of the former two

medications. Due to the likelihood of reinfection, all family members should be treated along with washing of all sheets and clothes.

Anisakiasis

Anisakis is a roundworm that uses marine mammals as their natural hosts. Infection is most commonly encountered in Japan and areas where raw fish is ingested. The larvae enter the intestinal mucosa where they die, resulting in an inflammatory reaction and abscess formation. Patients usually present with relatively acute onset of epigastric or abdominal pain, nausea, and vomiting and subsequent bloody diarrhea. Intestinal complications include obstruction and perforation, along with eosinophilic enterocolitis. When the ileocecal region is involved, patients may be misdiagnosed with appendicitis.[86] Allergic reactions ranging from mild urticaria to anaphylactic shock can also occur. Diagnosis is made by visualizing the worm at the base of intestinal ulcerations, contrast studies with worm-like filling defects, or via serologic testing. Worms can be spontaneously regurgitated or removed endoscopically. Surgical treatment is typically reserved for complications such as perforation or obstruction.

Tapeworm

A number of adult tapeworms parasitize the intestinal tract of humans. They are classified as hermaphroditic flatworm parasites, and consist of a head, neck, and segmented body. Infection is acquired through the ingestion of raw or inadequately cooked infected flesh of the intermediate host. The clinical symptoms of all tapeworm species are variable, and include abdominal discomfort, nausea, vomiting, cutaneous sensitivity, headache, and malaise. Yet, most humans who carry an adult tapeworm are asymptomatic. *Diphyllobothrium latum* is the fish tapeworm that results from the ingestion of raw fish. The worm produces megaloblastic anemia due to vitamin B12 deficiency and fatigue. *Taenia solium* is the pork tapeworm acquired by eating inadequately cooked pork. Cysticercosis occurs when humans ingest the egg of *T. solium* and may present with a variety of neurological symptoms. *Taenia saginata* is the organisms responsible for beef tapeworm, which is found throughout the world and can achieve many meters in length. Patients may intermittently pass proglottids either with their stool (*T. solium*) or spontaneously (*T. saginata*). Often these are noted in the toilet bowel or patients may feel the spontaneous movement of proglottids through the anus. Segments occasionally enter the appendix, common bile duct, or pancreatic duct and cause obstruction. Finding the ova in fecal samples makes the diagnosis of tapeworm infection. Treatment for all tapeworms is with either niclosamide or praziquantel. Until all eggs and scolex portions of the tapeworm are eliminated, infection can reoccur; therefore, stools should be re-evaluated at 1–3 months following therapy.

Fungal Enteritis/Colitis

Fungal colidites may occur, but are highly unusual in an immunologically normal patient. This is separate from *Candida* colonization in healthy adults, found in 30–50% of oropharyngeal cultures and in 40–65% of normal fecal flora.[87] Clinical settings in which true fungal infection must be considered include human immunodeficiency virus (HIV) infections, immunocompromised states such as postsplenectomy, transplant patients, chronic liver disease, chronic steroid therapy, as well as in debilitated patients being treated with broad spectrum antibiotics. The major pathogens in this category include *Candida* species, *Histoplasma capsulatum*, and *Cryptococcus neoformans*. Outside the United States, other fungi may predominate such as is seen with *Penicilium marneffei* in Southeast Asia.

Candida

Certain conditions can promote the involvement of the lower GI tract by *Candida* species, including age (i.e., extremes of infancy and elderly), HIV infection, neoplasms, diabetes, endocrinopathies, and localized lesions of the GI tract.[88] Despite the high physiologic concentration of *Candida* species, infection does not occur under normal circumstances due to the innate defense mechanisms. *Candida* colitis is found predominantly in patients in the intensive care unit. Most commonly, the infection is systemic involving septicemia, the pulmonary tract, the urinary tract as well as the gastrointestinal tract. Colonic involvement may be diffused with resulting diarrhea, fever, and abdominal pain. Endoscopic findings include small creamy-white, curd-like patches on the surface of edematous, and inflamed mucosa. Perforation may occur with resultant peritonitis or fistulization – portending a poor prognosis. Stool cultures coupled with endoscopic biopsies are diagnostic when typical spores, yeast, or pseudomycelia are demonstrated. Medical treatment is first-line therapy in the absence of peritonitis. Mild candidiasis may only require oral nystatin 500,000–1,000,000 units four times daily. Yet, typically sicker patients need diflucan or ketoconazole 200–400 mg daily. For extremely ill patients or those with multiresistant disease, amphotericin B (0.3–0.6 mg/kg) or caspofungin (50 mg daily) can be administered intravenously. Surgical intervention may be required in the face of free perforation or clinical findings of peritonitis. Despite aggressive surgical intervention, mortality is very high due to the severity of the associated conditions.

Histoplasmosis

H. capsulatum is found endemically throughout the Midwestern United States. While principally being a pathogen of the reticuloendothelial system, like other fungal infections, it can cause systemic infection in the immunocompromised host. Pulmonary disease is most common, yet ileocolitis does occur as a granulomatous process causing bleeding, ulceration, stricture formation, and perforation.[89] Endoscopic examination can be confusing as the lesions may appear to resemble adenocarcinoma or inflammatory bowel disease. Skip areas, pseudopolyps, ulcerations, and plaque-like lesions may be seen, although biopsies will reveal intracellular budding yeasts within the mucosa when this organism is present.[89] Serologic tests and fungal cultures may also confirm the diagnosis. While perforation is rare, emergent surgery with resection of the grossly affected tissue and proximal diversion may be necessary. As these patients are often critically ill, intravenous amphotericin B may be indicated in severe cases, while ketoconazole has been used effectively in more mild disease and long-term to prevent relapse.

Cryptococcus

Cryptococcosis most commonly affects the central nervous system when *C. neoformans* is acquired via inhalation of soil contaminated with this encapsulated yeast. Isolated gastrointestinal infection is rare outside of immunocompromised patients. Colitis with perforation can occur spontaneously or following endoscopic biopsy, therefore, surgical intervention is generally reserved to manage life-threatening complications. A high index of suspicion must be maintained when patients present with symptoms of colitis and a concomitant history of immune suppressive therapy or infection with HIV. Early medical therapy provides the best means of avoiding surgery in these very ill patients. Diagnosis is confirmed by biopsy of infected mucosa demonstrating encapsulated budding yeasts or via stool culture. Similar to other fungal infections, ketoconazole is effective in mild disease forms, while amphotericin B is standard therapy in severely ill or immunocompromised patients.

AIDS Diarrhea

Diarrhea in the AIDS or HIV-positive patient can be the result of many causes, but is often a source of significant morbidity. Chronic diarrhea is defined as that persisting for more than 4 weeks. This was a much more prevalent symptom prior to the use of highly active antiretroviral therapy (HAART). It should be noted that diarrheal disease in HIV-infected individuals is frequently caused by infectious agents, but may also be due to medications or infiltrative diseases such as lymphoma, Kaposi's sarcoma, or GI tract infection of the HIV itself.[90] The specific infectious pathogen varies with the degree of immunocompromise in the host; therefore, it is important to ascertain the most recent CD4 cell count.[91] HIV-infected patients are often prescribed antibiotics, therefore *Clostridium difficile* or small bowel overgrowth syndrome is also potential diagnostic considerations. Diarrhea may also be a result of small or large bowel involvement. Symptoms may provide insight

into location, with large volume, watery stools and associated bloating, cramping, and weight loss seen most typically with small bowel involvement. On the other hand, hematochezia, tenesmus, and lower abdominal cramps are more likely seen with colon involvement. Diagnostic work-up is broad-based, with the goal of finding a treatable source of infection. Stool studies including ova and parasites, *C. difficile* toxin assay, and bacterial culture, and with blood cultures, and endoscopy may all be required. In addition, upper endoscopy with small bowel biopsy is helpful in diagnosing opportunistic organisms such as *Cryptosporidium*, *Microsporidium*, *Histoplasmosis*, *Mycobacterium avium* complex, or lymphoma. Colonoscopy with biopsy can reveal *CMV* or *Kaposi* sarcoma. Malabsorption of nutrients can lead to even further significant malnutrition, which remains a strong predictor of morbidity and mortality in the setting of HIV. Treatment should be tailored to the specific organism, while empiric treatment with a quinolone and metronidazole after a negative diagnostic workup remains controversial. This antibiotic regimen is able to cover the most common causes of AIDS diarrhea including small bowel overgrowth, culture-negative *Campylobacter*, or *Giardia*; yet, may lead to development of resistant organisms. Surgery is reserved for acute abdominal emergencies and in of itself carries a substantial mortality.[92]

Clostridium difficile

C. difficile (CD) is a gram-positive rod bacterium that resides naturally within the human colon. Following antibiotic treatment, alterations of the normal colonic flora occur that allow preexisting colonization of CD to overgrow, become pathologic, and result in *C. difficile* or pseudomembranous colitis.[93] Symptoms of the disease may vary on a spectrum ranging from abdominal pain, distention and diarrhea, to outright sepsis with toxic megacolon requiring colectomy. In extreme cases, the process is nonreversible, resulting in hemodynamic instability and death. Although the bacteria are present in stool cultures of approximately 3% of normal healthy adults and up to 16–35% of hospitalized patients, increasing rates are now reported following exposure to antibiotics in asymptomatic carriers as well as those with severe underlying disease.[94,95] Overall, reported cases of CD colitis in the USA rose 200% between 2000 and 2005.[96] Similar alarming trends in CD colitis occurrence following pre-operative prophylactic antibiotics was illustrated in a large cohort study from a tertiary care hospital in Quebec showing an increase from 0.7 cases per 1,000 from 1999 to 2002 to 14.9 cases per 1,000 from 2003 to 2005.[97] This recent rise in the rate of CD colitis in hospitalized patients is even more concerning in light of reports of the increased virulence of particular strains, and has led to a greater concern about this disease worldwide. One such strain, known as B1/NAP/027, has shown capacity for hypersporulation, increased resistance to fluoroquinolones, a 16- to 23-fold increase in toxin production, and a severe disease pattern leading more frequently to fulminant CD colitis.[98–100]

Certain conditions are required to allow proliferation of bacteria such as *C. difficile*. In the most frequent mechanism, normal intraluminal homeostasis of gastrointestinal flora is altered via antibiotic-mediated destruction. While any single antibiotic can cause the change in this bacterial milieu leading to the pathologic state, certain drugs such as penicillin, clindamycin, fluoroquinolones, and third-generation cephalosporins are traditionally more commonly associated with development of CD colitis.[101] However, all antibiotics have been associated with *C. difficile* infection and recurrence, even those most often used for treatment of the infection.[102–104] In addition, pre-operative bowel preparations may alter this normal balance of colonic flora, leading to conditions amenable for secondary CD infection. Other risk factors reported to be associated with the development of *C. difficile* infection include concomitant multiple antibiotic use, advanced age, high gastrointestinal output, and prior GI surgery.[105]

Despite the underlying cause, this transformation in the typical bacterial environment allows the normally inhibited bacteria to flourish. The pathogenesis of CD infection relates to two major toxins that are released by the bacteria. The first, toxin A, acts as a chemoattractant for neutrophils and causes inflammation and fluid secretion of the colonic mucosa. Toxin A also causes the release of PGE2, which activates the Fas–Fas ligand system causing enterocyte and colonocyte apoptosis.[106] Additionally, both toxins A and B activate inflammatory cytokine release from monocytes, further inciting this inflammatory cascade.[107] Continued toxin production leads to connective tissue degradation causing colitis, watery diarrhea, and a pseudomembrane formation that can clinically result in a wide spectrum of enteric disease ranging from asymptomatic bacterial growth or bowel thickening and dilation, to sepsis and death.

Clinically, *C. difficile* colitis results in copious gastrointestinal output reflective of the natural history of the underlying disease process, and is present in 90–95% of cases. In fact, *C. difficile* is presently the leading cause of hospital-acquired diarrhea. This profuse diarrhea is often accompanied by low-grade fevers, abdominal pain, and often-significant leukocytosis. Varying degrees of abdominal tenderness may also be present, though in many patients the abdominal examination is unremarkable. A small percentage of patients go on to develop fulminant colitis with high fever, severe abdominal pain, and have diffuse peritonitis on abdominal examination. While hypotension, oliguria, sepsis, and toxic megacolon may be seen in this critically ill stage, the diarrhea may be paradoxically absent when the disease reaches its peak.[108]

While many clinicians prefer to initiate treatment empirically, the clinical diagnosis is often confirmed in the laboratory by sending stool for *C. difficile* cytotoxin and antigen assays. Several combinations currently in practice are based upon both the antigen and toxin assays, with antigenic positivity representing a marker for presence of the bacterium, while presence of the toxin is thought to signify clinically relevant intestinal disease. Similarly, stool cultures of the bacterium do not distinguish between carriers and those with

acute infection. Diagnosis may also be made clinically by endoscopic examination and/or biopsy with the characteristic presence of pseudomembranes, inflammatory mucosal changes, and erythema (Figure 34-8).[109] Yet, the mucosal findings vary with the severity of the disease. In those with mild or moderate disease, endoscopy most often reveals normal mucosa or nonspecific inflammatory changes. On the other hand, severe disease often demonstrates the classic pseudomembranes appearing as round, punctate yellow or whitish lesions (Figure 34-9). Although the finding of pseudomembranes suggests the diagnosis of pseudomembranous colitis, biopsy of these lesions is recommended to definitively establish the diagnosis.[110]
FIGURE 34-8. Low power view of pseudomembranous colitis. A thick pseudomembrane adheres to the colonic mucosa. (Courtesy of Jeanette R. Burgess, MD).
FIGURE 34-9. Classic pseudomembranous appearance of *C. difficile* on endoscopy.

Proper timing of therapy has been examined extensively in recent publications, due to failure of traditional medical management as a result of more virulent disease. Thus early identification and initiation of therapy along with recognition of a worsening course are paramount. Furthermore, small studies have demonstrated a cost savings approach through the implementation of empiric treatment alone when given a classical history.[111–113] However, a full evaluation for confirmatory diagnosis when encountering this clinical constellation is still recommended, especially those with recalcitrant symptoms. Attempts to verify the diagnosis of *C. difficile* colitis through laboratory evaluation may be performed while therapy is being instituted.

Once diagnosed, the most important initial intervention is to stop the inciting antibiotic or switch to alternative antibiotics with similar spectrum of antimicrobial properties. In cases of *Clostridial* infection of the colon, this will cause remission of the disease in 20–25% of patients without additional treatment. Vigorous fluid resuscitation and electrolyte replacement are often necessary in patients with high-volume watery diarrhea, as this may precipitate systemic cardiovascular, renal, and metabolic morbidity. Additionally, patients should be placed on contact precautions to prevent spread to other patients. The most effective and commonly used antibiotics against *C. difficile* are metronidazole and vancomycin, with cure rates of 76 and 97%, and recurrence in 14 and 15%, respectively.[114] The initial antibiotic chosen is often metronidazole, in part due its cost-effectiveness and that of contact isolation, but also as an attempt to prevent vancomycin-resistant *Enterococci* with extended use of the latter. This is despite higher cure rates with vancomycin. Additionally, metronidazole may be used intravenously in patients who are unable to have oral intake, as it is excreted through the hepatobiliary system. In patients with *C. difficile* infection of the distal colon and rectum, ileostomies, or even those with prior restorative proctocolectomies, metronidazole and vancomycin enemas may also be effective for treatment as primary therapy or as an adjunct – especially in cases that are refractory to or cannot take oral metronidazole.[115] Other agents that may be useful are teicoplanin and fusidic acid with clinical cure rates of 96 and 93%, respectively.[116,117] Bacitracin, when rarely used, has been shown to be as effective treatment as vancomycin when 20,000–25,000 units are used four times daily for 7 days.[118] Anion exchange resins have also been used successfully to treat *C. difficile* infection. Cholestyramine and colestipol act via binding to the *C. difficile* toxin in the lumen, thereby limiting the damage caused by the toxins. It is important to note that these agents have not proved to be as reliable as antimicrobials, and are therefore not recommended for use as sole treatment except in cases of mild infection. Furthermore, there are reports that these resins may bind to antimicrobials in the intestinal lumen when given concomitantly with the antibiotics, and additional consideration should be given to proper timing of medications.[119]

The medical treatment of *C. difficile* is recommended for a minimum of 10 days.[112] In most patients, significant improvement will often be witnessed within 2–5 days of initiation of therapy. Repeat stool assays are unnecessary if there is clinical response, as the assay may be positive for weeks in up to 50% of patients.[120] When possible, patients with a history of *C. difficile* should attempt to avoid the previously associated antibiotic as the use may precipitate recurrent disease. Furthermore, all patients with a history of *C. difficile* infection should have an annotation in their chart of the associated antibiotic to help avoid the peri-operative use and potential recurrence.

Indications for surgical management of CD colitis have been well documented, including severe disease refractory to medical management and the development of life-threatening complications such as perforation or toxic megacolon. Clinical signs that should trigger progression toward operative intervention include peritonitis and persistent hemodynamic instability.[121] Some authors advocate early colectomy for those who fail initial treatment with antibiotics. While mortality rates remain high among patients who undergo surgical treatment for complications of CD colitis, data suggests total abdominal colectomy with end ileostomy before onset of multisystem organ failure resulting from CD colitis is associated with improved morbidity and mortality.[122] Rarely, colectomy with primary ileorectal anastomosis with proximal diversion may be considered; however, bowel wall thickening, tenuous anastomosis, and hemodynamic instability often preclude this technique and are generally discouraged. Despite improvements in early recognition, implementation of therapy, and postoperative care, mortality rates following emergent colectomy for fulminant colitis has been reported to be 35–57%.[123,124]

Recurrence of *C. difficile* infection is not uncommon, occurring in 13–28% of patients, and is associated with multiple patient and therapeutic factors.[125] Reported factors include an inadequate immune response to the *C. difficile* toxin and a persistent disruption in the normal colonic flora. Other variables include advanced age, continuation of other antibiotics, and prolonged inpatient length of hospital stay.[126] When recurrence takes place, most authors suggest a second and longer course of antimicrobials for patients who have a symptomatic relapse. Current recommendations involve the first recurrence to be treated with the same agent as used for the initial occurrence; though with severe clinical disease vancomycin has been associated with better outcomes. Some authors recommend an additional course of cholestyramine or colestipol after the antimicrobials. There is also additional data suggesting probiotics may lessen the rate of subsequent recurrence, although the bulk of the current literature does not currently support their use.[127] Recurrent infection is often as responsive to antimicrobial treatment as are primary infections. Unfortunately, up to one-third of patients who relapse once will have further subsequent recurrences. Therefore, any patient with an unexplained abdominal illness who in the recent past has either been in the hospital or has received antibiotics should be suspected to have a *C. difficile* infection, even in the absence of diarrhea.[128]

A large body of literature also exists documenting poor outcomes associated with CD infections in hospitalized patients, even in the absence of surgery. Unfortunately, as depicted, surgery for fulminant colitis also portends a poor prognosis, thus leaving the clinician with a difficult conundrum. This is likely to only get worse, as population-based series have reported rising prevalence, mortality, and need for colectomy following development of CD colitis.[129] Even more concerning, the evolution of CD resistance to first-line therapy such as metronidazole, and higher recurrence rates suggest development of this disease may carry even greater morbid outcomes than previously reported. Finally, although many patient-related and peri-operative factors may play a role in eventual outcome, postoperative mortality following the development of severe CD colitis is highest when respiratory failure, renal failure, or vasopressor requirements occur.[111–113,130]

Ischemic Colitis

Gangrenous alterations to the colon have been recognized for over 100 years, yet it was not until the 1950s that the full spectrum of colonic changes from lack of blood flow was reported. These phenomena were initially described following high ligation of the inferior mesenteric artery during abdominal aortic aneurysm repair as well as with colectomy for carcinoma.[131,132] After performing a series of clinical and experimental animal studies, Boley first reported in 1963 that colonic ischemia was a reversible process secondary to vascular occlusion.[133] The actual term "ischemic colitis" was coined by Marston and colleagues after depicting its three stages of evolution (transient ischemia, late ischemic stricture, and gangrene) along with the natural history of the disease in 1966.[134] The original reports of ischemic colitis detailed the high mortality rate associated with this condition; which unfortunately, have not shown much improvement through the years. Currently, ischemic colitis is the most common form of gastrointestinal ischemia, accounting for 50–60% of all cases, approximately 1 in 2,000 hospital admissions, and as such, necessitates physician familiarity.[135]

The causes of ischemic colitis are numerous, though the exact etiology of the initial insult is rarely elucidated – particularly as this disease is most often witnessed in elderly, debilitated patients with multiple contributing co-morbidities. The differential diagnosis remains vast, with inflammatory and infectious colitis manifesting similarly, and making the true incidence of ischemic colitis unknown. Regardless of its etiology, patient outcome rests on the severity, extent, and rapidity of the ischemic insult, and is strongly influenced by prompt diagnosis and appropriate clinical management. Although the colon and rectum derive their blood supply from branches of three major vessels [superior mesenteric

artery (SMA), the inferior mesenteric artery (IMA), and the paired internal iliac arteries], it is the extensive collateral circulation that allows this ischemic process to be avoided in many cases. The two main collateral routes are via the marginal artery of Drummond that parallels the colon and gives rise to the vasa recta, and the meandering mesenteric artery (or Arc of Riolan) which, while not always present, can represent another potential connection between the SMA and IMA systems. In addition, the IMA and internal iliac arteries communicate via the superior and middle hemorrhoidal arteries and the left colic branch off the IMA contributes to overlap the transverse colon that is supplied mostly by branches of the SMA.

In its most basic terms, ischemic colitis occurs when blood flow is interrupted or diminished, and supply does not equal colonic demand. Ischemic colitis may also be divided into two groups based on etiology: occlusive or non-occlusive. Occlusive ischemia can result from either arterial inflow or venous outflow obstruction, although the latter is very rare.[136] Most commonly, ischemia is not associated with occlusion of any of the major abdominal vessels, as the aforementioned collateral circulation of the colon is able to compensate. Nonocclusive ischemia occurs following a precipitating event such as hypotension, medication-induced vasoconstriction, shock, cardiac failure, hemorrhage, or sepsis that results in a low-flow state. Patients with nonocclusive ischemia may have preexisting vascular abnormalities that contribute to a worsening phenotypical manifestation.[137] Yet, with any source of inadequate flow, the earliest manifestation is witnessed at the mucosal level, furthest away from the vasa recta, and creates a secondary disruption of the mucosal barrier that can potentially lead to bacterial translocation and sepsis.[141,142] When occurring in the context of major vascular repair, the pathogenesis may be unique in that an isolated interruption of inferior mesenteric artery blood flow may be the sole underlying cause in many cases.[138] Other factors that have been shown to have a higher association with the development of colonic ischemia are increased intraoperative blood loss, hypotension, and prior pelvic radiation.[139,140] As radiation damage is both cumulative over time and progressive, this may be a precipitating factor not only in early disease, but also with chronic changes such as colonic stricture.

Although any area of the colon may be affected by inadequate flow, the watershed areas of the rectosigmoid (Sudeck's point) and splenic flexure (Griffith's point) are commonly involved due to frequent incomplete anastomoses of the marginal artery in those locations. The next most common area afflicted is the cecum, secondary to low blood flow in the terminal branches of the ileocolic artery combined with varying competency of the right colic artery.[141–143] Longo and colleagues[144] found a much higher rate of right colonic involvement than most other studies, with 46% of their 47 patients having this portion affected.

The diagnosis of ischemic colitis remains somewhat of a challenge, especially in its mild form, as the majority of symptoms are often self-limited and nonspecific. As such, the diagnosis is aided by the combination of early and repeated clinical evaluations, radiological studies, and colonoscopic visualization. Complete history and physical examination, focusing on the abdomen and evaluation for peritoneal signs is of utmost importance. Most commonly, patients present with abdominal pain, fever, distension, and diarrhea.[142] Sudden onset of crampy abdominal pain is present in two-thirds of all patients.[137] While generally poorly localized, ischemia arising in the left colon and rectum tends to be referred to the left lower quadrant and flank areas, while ischemia arising in the transverse and right colon refers symptoms to the central abdomen.[136] This pain is soon followed by an urge to defecate and subsequent passage of either bright red blood or maroon blood mixed with stool, typically within 24 h of onset. Occasionally the patient may also have nonbloody stools, depending on the location, degree, and extent of the colon affected. Abdominal examination may show widely variable findings ranging from mild localized tenderness to diffuse peritonitis. Rectal examination may be completely normal or demonstrate blood ranging from bright red to melena.

Laboratory examination is often noteworthy for a leukocytosis and metabolic acidosis. Occasionally, electrolyte and renal abnormalities may be present secondary to lack of oral intake combined with volume loss from diarrhea. Serum lactate levels may be elevated, though generalized systemic hypoperfusion or tissue hypoxia may also cause this, and is therefore not a specific marker. Unfortunately, no biochemical marker exists to date that is reliable in identifying colonic ischemia. Reports of measuring serum levels of D-lactate (a stereoisomer of lactate) have shown some promise. In healthy individuals, the serum levels are negligible,[145] whereas with colonic ischemic injury, mucosal permeability will increase, allowing D-lactate to enter the portal and systemic circulation. Elevated D-lactate was found to have a sensitivity of 82–90% and a specificity of 77–87% in predicting early colonic ischemia in small series.[145–147] What remains clear is that identifying patients at the onset of their clinical course entails a high index of suspicion.

Colonoscopy remains the most sensitive and specific study available for diagnosis of ischemic colitis. Ischemia has a wide extent of changes and characteristics when viewed endoscopically (Table 34-1). In early ischemia, the mucosa appears pale and edematous with interspersed areas of hyperemia.[148] As the ischemic process progresses, evidence of submucosal edema and hemorrhage can be seen as bluish-black

TABLE 34-1. Endoscopic findings of ischemic colitis

Stage	Endoscopic findings
Acute	Hyperemia, edema, friable mucosa, superficial ulcerations, petechial hemorrhage, gangrene[a]
Subacute	Edema, exudate, ulceration
Chronic	Stricture, mass, segmental involvement

[a]Irreversible damage characterized by gray, green, or black appearance.

blebs or nodules protruding into the lumen of the bowel.[136] These lesions create the characteristic thumbprinting sign on radiographic studies, which often disappear within days as the submucosal hemorrhages are either resorbed or evacuated into the colon when the overlying mucosa ulcerates and sloughs.[135] Occasionally, extensive areas of gray-green or black mucosa and submucosa are identified that can signify transmural infarction.[142] Endoscopy also allows the examiner to sample the colonic mucosa for pathologic assessment to help differentiate inflammatory, infectious, and ischemic etiologies. However, biopsy is hardly ever useful and is more likely to demonstrate either nonspecific ischemic or inflammatory changes, and rarely shows the ghost cells that are classic for ischemia.[142] The decision to pursue colonoscopy should be undertaken with caution, as air insufflation may result in distention of the bowel to pressures greater than 30 mmHg, diminishing colonic blood flow and may actually worsen the colonic ischemia.[144] In addition, the ischemic wall of the colon is fragile and at risk of perforating with the application of even minimal force, so any examination should proceed with great vigilance. The classic pattern of rectal and distal sigmoid sparing along with varying degrees of mucosally based changes more proximal is quite helpful in this select patient population.[149] In this light, endoscopy is used more to corroborate the clinical examination.

Other radiological tests may provide additional insight as to the diagnosis or the degree of insult to the bowel. Plain radiographs have limited use in the diagnosis of colonic ischemia. In approximately 20% of patients, specific signs of colonic ischemia may be present, including thumbprinting and rarely pneumatosis coli, a sign of advanced disease.[150] However, the majority of plain films are nonspecific, showing only dilation and/or air-fluid levels. The main utility in obtaining plain radiographs is to rule out visceral perforation and the presence of pneumoperitoneum. On the other hand, computed tomographic (CT) imaging has been used much more frequently to diagnose ischemic colitis, with associated changes in the bowel wall more often offering clues to the diagnosis (Figure 34-10).[151] By providing the ability to evaluate the bowel as well as the surrounding tissue, a diagnosis is aided by findings such as wall thickening, mesenteric fat stranding, mucosal enhancement, intramural air, dilatation, or even more ominous signs such as portal venous gas. It can also be a very useful test in ruling out other diagnoses.[152] In general, angiography does not help in patients with acute ischemic changes, although it may be occasionally useful in the patient who has previously undergone reimplantation of the inferior mesenteric artery to evaluate for patency or collateral circulation. Findings on air contrast or barium/air contrast enemas can be predictive of ischemic colitis, but often they do not exclude other forms of colitis such as inflammatory bowel disease or pseudomembranous colitis.[136] In the acute setting their use is extremely limited, and normally should be avoided. The risk of worsening the ischemic process with over-distention of the colon leading

FIGURE 34-10. CT image of splenic flexure ischemic colitis demonstrating bowel wall thickening and peri-colonic fat stranding.

to perforation clearly outweighs the potential benefits.[137] Finally, color Doppler and duplex ultrasound have been used to determine whether an arterial signal or color Doppler flow can be detected. When absent, ischemia should be a strong consideration and inflammatory sources virtually excluded. However, only 50% of patients with ischemia demonstrated this finding, and in general the sensitivity does not allow it to be a reliable primary diagnostic tool as patients may have preexisting thrombus independent of the acute event.[153]

The mainstay of therapy for ischemic colitis remains supportive therapy with adequate fluid hydration and blood pressure support. As most patients present with only mucosal ischemia, their clinical course is often relatively benign. Intravenous fluids should be started and the patient placed at bowel rest. Cardiac function and oxygen delivery should be optimized and, if possible, any medications that are known to cause mesenteric vasoconstriction should be discontinued. If an ileus is present or the colon is markedly dilated, a nasogastric and/or rectal tube should be placed, although rectal tubes are generally discouraged in this setting and only be used with great caution.[154] Vasopressor support is controversial as it is also a contributing factor. Although low flow states and sepsis may require improvement in blood pressure, due to the vasoconstriction of the splanchnic vessels, vasopressors may amplify the ischemic process, worsening the already low-flow situation. Should pressor support be necessary, beta-adrenergic agonists that also improve cardiac output are preferred, while making every attempt to avoid alpha-agonists when possible. Additionally, broad spectrum antibiotics have been shown to decrease bacterial translocation and morbidity, and should be empirically added.[155–157]

With rare exceptions, all patients with evidence of bowel infarction or perforation require surgical therapy and exploration should rapidly follow. Surgical options generally fall into

two categories: bowel resection and vascular reconstruction. Typically when patients require operative intervention, the surgeon must first determine bowel viability. Caution however must ensue, as often times the serosal appearance of the bowel does not accurately reflect the degree of ischemic changes to the entire bowel wall in cases with less than full thickness injury and frank necrosis. Intraoperatively, several different methods have been described to provide surgeons with additional useful information regarding blood flow. The surgeon must balance the need to avoid leaving behind necrotic bowel with the potential morbidity of overzealous resection leading to short bowel syndrome, although the intraoperative judgment of the well-trained surgeon remains one of the most important factors. Palpation of mesenteric pulses, detecting Doppler signals on the antimesenteric portion of the bowel wall, and Wood's lamp evaluation of the bowel wall following administration of fluorescein dye intravenously are all described techniques to help separate perfused from nonperfused bowel. Yet, in most cases, surgical resection involves a total abdominal colectomy with end ileostomy. Although primary anastomosis after a subtotal or partial colectomy with a proximal diversion may be considered in isolated hemodynamically stable patients with healthy bowel margins, this is almost uniformly a poor choice. Regardless of the approach, patients treated operatively in the acute setting have mortality rates as high as 40%, particularly when they carry other diagnoses such as atherosclerosis or chronic renal failure.[158] Surgeons have classically mandated a second look operation in 12–48 h regardless of the patient's clinical condition to evaluate the need for further resection and aid in being less aggressive at resecting potentially viable bowel at the initial surgery.[159] Yet, all clearly nonviable bowel needs to be resected at the initial operation, as mortality rates of 50–89% have been reported for patients requiring surgical resection of infarcted bowel at the second operation.[141]

Vascular repair involves first determining the patency of the vessel supplying the at risk portion of the colon. In addition, determining whether there is antegrade flow to the iliac vessels that may provide potential pelvic collaterals is crucial. Although the technical aspects of vascular reconstruction are beyond the scope of this chapter, options for dealing with the inferior mesenteric artery or other major visceral vessel include resection of the base of the vessel along with a small cuff of aortic wall (Carrell patch) and reimplanting it in the aorta or graft, patch angioplasty of the stenotic opening, bypass grafting, or endarterectomy of the atherosclerotic plaque.[160–162]

In most cases of ischemic colitis, the signs and symptoms of disease disappear within 24–48 h. More severe initial ischemic insults may result in necrosis of the overlying mucosa resulting in a future stenosis or stricture of the colon. A follow-up colonoscopy is advisable to either confirm complete resolution or to document the development of a stricture and/or persistent colitis. Another 20–30% of patients will go on to develop chronic colitis from irreversible ischemic injury, manifested by persistent diarrhea, rectal bleeding, and/or weight loss.[163] If suspected, this too will likely require surgical intervention. Recurrent episodes of attacks in otherwise asymptomatic patients are felt to be a result of unhealed areas of segmental colitis and should also be considered for elective resection. Other patients may develop chronic visceral ischemia. This is manifested by abdominal pain, especially with eating as a result of supply not equaling demand, and leads to relative bowel ischemia. Ultimately this may result in food fear and weight loss. Complete visceral artery revascularization of celiac, superior mesenteric, and inferior mesenteric arteries is often required to alleviate symptoms.[160] For this to be a success, requires a well-developed pattern of collateral circulation for the IMA system and should be evaluated prior to considering this option.

Finally, ischemic proctosigmoiditis is a rare condition affecting approximately 3% of patients with colorectal ischemia.[164] Excellent collateral blood supply almost always precludes this as an isolated entity, and it usually occurs in conjunction with more proximal colonic involvement. It is important to differentiate isolated ischemic proctosigmoiditis from inflammatory bowel disease, as the use of steroids may adversely affect those patients with ischemic proctosigmoiditis. Theories to its etiology include hemodynamic disturbance superimposed on atherosclerotic narrowing of the aorto-iliac vessels.[164] Most cases can be managed conservatively, as with ischemic colitis, and only rarely is proctectomy required.

Radiation Colitis

Radiation therapy is a frequent and successful modality used in the primary and adjuvant treatment of many malignancies including gynecological, anal, rectal, and prostate cancer. Despite this, radiation therapy is not without its hazards, due in part to a known dose-dependent relationship with cell death. Toxicity is focused on surrounding organs – especially the distal colon and rectum.[165,166] Other gastrointestinal sites may also be affected, particularly the terminal ileum in patients with prior adhesions that fixate the bowel in the pelvis.

Radiation therapy causes changes via two major mechanisms: (1) direct damage to DNA and (2) production of oxygen-free radicals.[167] Although the maximal radiation dose tolerance levels for the colon and rectum average 6,000–8,000 cGY, varying doses given over shorter intervals are associated with complication rates of 25–50%.[168] In the acute phase, changes within the bowel occur during the course of radiotherapy, though may become apparent over the course of several weeks and up to 6 months. In this setting, rapidly dividing crypt cells are most sensitive to radiation damage, and patients will experience atrophy of the villi, degeneration of the mucosal lining, diarrhea, mucous discharge, tenesmus, bleeding, and even incontinence.[169]

Chronic radiation injury appears most often at 6–12 months following radiation, and is secondary to a progressive fibrosis of the microvasculature (i.e., obliterative arteritis). This endothelial thickening in the small blood vessels eventually leads to thrombosis or reduced flow leading to ischemia. Clinically, this may manifest in a wide spectrum of findings including nonhealing ulcerations and telangiectasias of the bowel wall (Figure 34-11), fistulas and sepsis, as well as more common findings of thickening, stricture, and obstruction.[168,170–172] Additionally, there are reported higher rates of secondary colorectal cancer.

The method of delivery also impacts the types of symptoms. With external beam radiation therapy (EBRT), common complaints include pain, bleeding, tenesmus, incontinence, and an increase in stool frequency.[165] These may be further divided by the Radiation Therapy Oncology Group (RTOG) classification system (Table 34-2).[165] While the majority of symptoms are self-limiting, overall
FIGURE 34-11. Endoscopic view of radiation colitis.

rates remain high, ranging from 41 to 57% for acute grade 2 symptoms, and 1–5% for acute grade 3 symptoms. Late grade 2 symptoms have also shown wide variability from 95 to 33%, while late grade 3 symptoms are reported in 0–6%.[173,174] Radiation may also be given via brachytherapy (BT) for certain malignancies such as prostate cancer, in which radioactive seeds are directly implanted. Radiation toxicity differs slightly with BT, as the majority of colorectal side effects are from local effects on the anterior rectal wall, as opposed to the field effects of EBRT.[175] As such, more concentrated effects have resulted in rates of 4–24% for rectal bleeding following this modality.[176,177] An additional potential complication of BT is the development of a rectal–urethral fistula, with reported incidences of 0.2–1%.[175,178] Patients classically present with recurrent urinary tract infections, pneumaturia, or fecaluria – symptoms which should prompt physicians to embark on a thorough work-up to exclude its presence in those patients with prior radiation therapy. Finally, anal stenosis with bleeding and obstructive symptoms has been described.[179]

Although the vast majority of patients may be adequately treated with oral or topical medicines alone, some will require endoscopic or surgical therapy for complications. In patients with hemorrhagic proctitis, multiple different techniques have been described to include electrocautery, mesalamine, steroid, and carafate enemas.[180] Sucralfate has been associated with improved clinical response rate over anti-inflammatory agents, and may show further improved rates when used concomitantly with metronidazole.[181] Second-line therapy includes the use of Nd YAG and Argon lasers through an endoscope, as well as instillation of topical 4% formalin, which has demonstrated successful cessation of bleeding in up to 70–90%.[182,183] Finally, resistant bleeding or ulcerations may require hyperbaric oxygen therapy, which has demonstrated good clinical results in small case series of refractory disease.[184] The protocol commonly employed treats the whole body for 60 min at two atmospheres of 100% O_2 for 30 days. Prostaglandin E_1 can be co-administered for its vasodilatory properties.

TABLE 34-2. Acute and late complications according to the RTOG and RTOG/EORTC morbidity scales for radiation toxicity

	Grade 2	Grade 3	Grade 4
Acute GI toxicity	Diarrhea requiring medications, rectal pain requiring analgesics, *rectal bleeding requiring topical medications*	Diarrhea requiring parenteral support, severe mucous, or bloody discharge requiring pads, abdominal distension, *bleeding requiring multiple cauteries, or surgery*	Obstruction, fistula, or perforation. Abdominal pain or tenesmus requiring decompression or diversion
Late GI toxicity (>12 weeks)	Moderate diarrhea, intermittent, severe cramping; bowel movements >5 per day. Frequent bleeding, requiring single cautery treatment and/or transfusion	Watery diarrhea, obstruction requiring surgery; bleeding requiring surgery or ≥2 cauteries and/or transfusions	Necrosis, perforation, abdominal pain or tenesmus requiring decompression or diversion

Patients with significant diarrhea may undergo a trial of antimotility agents such as loperamide or octreotide, as well as be encouraged to take in a low residual diet.[185] Focus is also on prevention of injury, with some evidence suggesting both 5-aminosalicylates and probiotics may be effective; though reduction of radiation dose and size of the field remains the most important factor in this effort.[186] In addition, cessation of radiation, even if temporarily, will often allow most patients to resolve the acute changes. For those with extensive bowel disease in which oral intake is severely limited, nutrition therapy via total parental nutrition may be required for support or in preparation for surgery.

In general, operative indications for radiation-induced toxicities fall into one of a few categories: refractory disease (i.e., bleeding, nonhealing ulcer), septic complications (i.e., fistula, perineal sepsis), bowel obstruction or stricture, and secondary malignancies. A study of 5,719 patients undergoing EBRT or BT found a 0.2% incidence of surgical therapy for late recto-urethral fistulae and intractable bleeding.[178] Other series have reported a much higher rate of surgical therapy at 1–6%, with the vast majority of these secondary to small bowel obstruction from small bowel radiation.[187] Fistulizing complications are best managed conservatively, when possible. When not possible, the type of surgery will depend on fistula origin (i.e., proximal vs. distal) as well as the secondarily involved organ. Rectovaginal fistulas have been reported in up to 18% at 3 years following radiation therapy for advanced gynecological malignancy and often require diversion or nonirradiated tissue flaps (i.e., gracillus or Martius).[187]

Embarking on surgical therapy should not be taken lightly, as simply entering the abdomen following radiation may be wrought with hazard. Surgeons must balance limited adhesiolysis in the face of matted bowel loops with that of adequate exposure of the offending source. Though not ideal, proximal diversion for more distal lesions plays a prominent role. In the case of radiation-induced intestinal stenosis or obstruction, the same surgical considerations apply. Where feasible, resection and anastomosis to normal appearing bowel is preferred. Meticulous technique must be emphasized as operative management of small bowel radiation injury has mortality rates of 5–38%, with approximately one-third of patients developing postoperative complications such as recurrent obstruction, fistula, and anastomotic leak.[188–190] Other radiation-induced complications have a much lower rate of surgical therapy requirement. In general, only rarely will RTOG acute grade 3 or higher toxicity result in recalcitrant bleeding that requires operative evaluation for control. Though limited data, good results have been reported in small series for pull-through operations for severe proctitis.[191] Nonhealing ulcers may require resection, diversion, or biopsy for diagnosis. Finally, secondary malignancies need to have appropriate evaluation and staging with standard oncological resection performed in the absence of widely metastatic disease.

Microscopic Colitis: Collagenous and Lymphocytic Colitis

Distinct from other forms of more overt colitis, microscopic colitis is an inflammatory condition of the colon that is responsible for up to 20% of patients referred for colonoscopy with nonbloody chronic diarrhea.[192] Though clinically similar, microscopic colitis encompasses both lymphocytic and collagenous colitis, with roughly half of patients in each group.[193] Also shared by these two subtypes is the lack of a known underlying etiology, despite an estimated incidence of 4–10 per 100,000 people.[194,195] The hallmark of each, however, is the characteristic histological changes identified in the setting of normal colonic mucosa on endoscopy within the context of what can be profound chronic diarrhea.

The majority of patients are older than 50 years of age at disease onset, with a female predominance (especially in collagenous colitis).[195–197] Common associations include bile acid malabsorption, underlying autoimmune conditions, smoking, and a postulated infectious etiology – largely in part to its improvement following treatment with antibiotics.[197–200] In addition, several medications have been described as having a frequent association with microscopic colitis including acarbose, acetylsalicylic acid, lansoprazole, chronic nonsteroidal anti-inflammatory drugs (NSAIDs) use, ranitidine, sertraline, and ticlopidine, among others.[201] Yet, despite it being a described entity since Lindstrom[202] and several common associations, no identifiable underlying cause has been identified.

Like many of these "benign" colorectal diseases, patients may present across a spectrum of courses, from mild abdominal pain and diarrhea, to severe volume depletion, electrolyte abnormalities and protein-losing enteropathy. The vast majority of patients experience crampy abdominal pain, 3–20 loose bowel movements per day, and weight loss. Although described, fever, vomiting, and gastrointestinal bleeding suggest an alternative diagnosis such as infectious or inflammatory bowel disease, and should be evaluated appropriately.

In addition to a thorough history and physical examination, the mainstay of diagnosis is endoscopy with multiple colonic mucosal biopsies. Clinically the mucosa of the colon appears normal, thus random biopsies are required for diagnosis. Focal directed biopsies are taken of any specific abnormalities, though more indicative of concomitant disease or other pathology. Both collagenous colitis and lymphocytic colitis demonstrate a lymphocytic proliferation and infiltration of the lamina propria and epithelium of the bowel wall. In fact, the histologic criteria for lymphocytic colitis require more than 10 lymphocytes per 100 epithelial cells in the colon, with a normal colon having less than 5 per 100 cells (Figure 34-12). What distinguishes collagenous colitis is the presence of marked thickening of subepithelial collagen layer (Figure 34-13).[203] In addition, while lymphocytic colitis tends to occur evenly throughout the colon and
FIGURE 34-12. Lymphocytic colitis. A significant increase in the intraepithelial lymphocyte is present particularly in the surface epithelium.
FIGURE 34-13. Collagenous colitis. Note the thick band of pink collagen beneath the surface epithelium (H and E stain).

rectum, collagenous colitis is characterized more in a random patchy distribution microscopically.[204] Although the vast majority (>95%) of patients have disease in the left colon, up to 10% will have isolated right-sided disease; therefore, full colonoscopy with multiple random biopsies is generally recommended.[198,205]

Because the disease is still relatively unknown and uncommon, treatment options are based on a paucity of high-quality evidence. As such, therapy is often empiric, directed at controlling symptoms, attempting to decrease inflammation, and individualized. A thorough medication history is imperative, as a simple trial of stopping the more commonly associated medications (especially NSAIDs), where possible, may result in improved symptoms. In addition, dietary modifications with elimination of caffeine, dairy, alcohol, and artificial sweeteners may also provide signifi-

cant improvements in symptom control. Chronic loose stools are the hallmark for each of these diseases, thus antidiarrheal therapy with loperamide and diphenoxylate/atropine are effective first-line therapeutic agents. Although there is only a small number of series to support their use, their high safety profile, inexpensiveness, and effectiveness make these excellent initial choices for patients with mild or moderate diarrhea.[200,206] Similarly, in a small study of 12 patients, bismuth subsalicylate has been reported to cause resolution of diarrhea in 92% of patients and histological improvement in 75% following an 8-week course of eight tablets per day, and is often used for patients with more mild disease.[207] With the known association of bile-acid malabsorption, bile-acid binding agents such as cholesytramine have shown response rates of 59–92%, and are particularly useful in those patients in whom symptoms of microscopic colitis arise after cholecystectomy.[197,208] Budesonide has the best evidence to support its use for these patients. With its decreased systemic absorption, dosages of 9 mg daily for 6 weeks have demonstrated clinical and histological improvement and resolution in the majority of patients with collagenous colitis.[209] It is generally recommended that budesonide is used for patients with more severe or resistant disease, and may be effective in helping with initial remission prior to changing to one of the less toxic medications above for long-term therapy. In patients with recalcitrant disease, medications ranging from immunomodulator and anti-inflammatory drugs such as 5-aminosalicylic acid products, steroids, azathioprine, 6-mercaptopurine, and methotrexate to probiotics and even octreotide have been described with each demonstrating some success.[201] Surgery has been described mostly in case reports for severe disease when all medical options have failed. The most common described surgical option is a diverting ileostomy with excellent control of symptoms.[210,211] Unfortunately, the vast majority of patients develop recurrence of disease following stoma closure. In extreme settings, colectomy with or without restoration of continence has been described,[212,213] although the paucity of evidence precludes definitive recommendations for this approach – especially in light of the response rates to medical therapy.

Eosinophilic Colitis

Rarer than the two subtypes of microscopic colitis, eosinophilic gastrointestinal disease (EGD) was described much earlier by Kaijser.[214] Eosinophilic colitis, one component of EGD, is the least commonly affected site. All subtypes of EGD are characterized by eosinophilic infiltration of the involved tissues and elevated eosinophil counts in peripheral blood.[215] Unlike its more proximal counterparts that tend to mainly affect pediatric aged population, eosinophilic colitis has a bimodal age distribution affecting neonates as well as young adults, with equal gender distribution.[215] Patients most frequently present with nonspecific symptoms include

abdominal pain, nausea, vomiting, diarrhea, and weight loss. Depending on the degree of colon wall involvement, symptoms can range from diarrhea, malabsorption, and protein-losing enteropathy with mucosal disease to bowel thickening and obstruction with involvement of the deeper layers of the bowel wall. In extreme form, serosal involvement leads to an eosinophilic ascites that may detect eosinophils in up to 90% on paracentesis.[216] Similar to microscopic colitis, the underlying etiology is largely unknown. Several authors have suggested a connection with food allergies with cow's milk and soy protein being the most common, as well as a history of allergies or atopy in 75%.[215] The diagnosis of eosinophilic colitis is generally made by the trilogy of peripheral eosinophilia (5–35%), gastrointestinal symptoms, and greater than 20 eosinophils per high power field on histological examination of endoscopic biopsies – all with no other defined source for the eosinophiliic manifestations.[217] Colonoscopic findings may range from normal in appearance to diffuse edema, but commonly demonstrates patchy areas of edema and punctate erythema.[218] The differential diagnosis includes infectious etiologies such as tuberculosis or parasite infestations, allergic enteropathies, collagen vascular disorders, and Crohn's colitis. Multiple medications have also been associated with this condition to include gold, NSAIDs, rifampin, and tacrolimus.[219–221] Not surprisingly, the majority of treatment recommendations are based on case reports and anecdotal experience. Most importantly, a thorough history and physical examination should be performed to identify potential other sources for the clinical picture (i.e., parasitic or drug-induced). That aside, corticosteroids are the first-line therapy for eosinophilic colitis, with up to 90% of patients demonstrating some response within 2 weeks.[222,223] Surgery has a role only for management of complications, such as intussusception, obstruction, hemorrhage, or perforation, or in difficult cases where a diagnosis is in question.[224,225]

Gastrointestinal Manifestations of Vasculitis and Connective Tissue Disorders

Although rare, vasculitis can also involve the gastrointestinal tract, commonly resulting in mesenteric ischemia. Patients generally present with abdominal pain, nausea, vomiting, diarrhea, and gastrointestinal bleeding. Symptoms can present acutely with bowel necrosis, massive bleeding, perforation, or chronically with stricture-related obstruction.

Polyarteritis Nodosa

Polyarteritis nodosa (PAN) is a focal segmental vasculitis that affects small and medium-sized arteries. Antigen–antibody complexes are deposited in the vessel walls, causing local inflammation and eventual necrosis ("fibroid necrosis") that result in stenosis, thrombosis, aneurismal dilatation,

and rupture. The organs supplied by these vessels may have impaired perfusion, resulting in ulcerations, infarcts, or ischemic atrophy.[226] It is felt to be associated with hepatitis B virus (HBV) in approximately 7% of cases. Overall, gastrointestinal involvement occurs in 14–65% of patients with PAN, and is a major cause of morbidity and mortality in this cohort.[227] Most patients have concomitant systemic symptoms, such as hypertension, renal insufficiency, neurological dysfunction, myalgias, and cutaneous disease. The small bowel and gallbladder are the most commonly affected areas in the GI tract, although liver, biliary tract, pancreas, and colonic ischemia may occur as well. Clinical presentation depends on whether ischemia is transmural, varying from postprandial abdominal pain and weight loss or superficial ulcerations to perforation with peritonitis. The Churg–Strauss syndrome is a variant of PAN, where GI involvement caused by eosinophilic infiltration causes abdominal pain, bloody stools, and diarrhea. Arteriography is a primary modality used to diagnose PAN, revealing focal and segmental saccular aneurysms or stenosis, particularly at areas of bifurcation. Tissue biopsy may confirm the diagnosis, and common biopsy sites include sural nerve, muscle, and skin lesions that may be present. The mainstay of treatment is 1 year of corticosteroid therapy, resulting in remission in 50% of cases. Cyclophosphamide for 6 months of duration can be added to improve response rates and to reduce the incidence of relapse. Untreated, the prognosis in PAN is poor, mostly secondary to renal failure and mesenteric, cardiac, or cerebral infarction. One-year and 5-year survival rates in this setting are approximately 50 and 13%, respectively.[228] While gastrointestinal involvement portends a poor overall prognosis, aggressive treatment has improved survival to approximately 80% at 5 years.[229]

Henoch-Schonlein Purpura

Henoch-Schönlein purpura (HSP), the most common systemic vasculitis in childhood, is a small vessel inflammatory disease that classically results in lower extremity purpura, arthritis, and hematuria. The gastrointestinal tract is affected in up to 50% of patients.[230] Although a variety of infectious and chemical triggers have been proposed, the underlying cause of HSP remains unknown. IgA deposits in the arterial wall result in extravasation of erythrocytes and infiltration of tissue with neutrophils, creating the picture of leukocytoclastic vasculitis. In the small intestinal villi, this eventually leads to necrosis. Abdominal pain, associated with nausea, vomiting, or bleeding, occurs in 51–74% of patients.[231] While the small intestine is the most frequently involved site in the GI tract, the colon can also demonstrate petechiae, hyperemia, ecchymotic lesions resembling the rash, and aphthoid ulcers. Intussusception, typically due to a lead point of intramural hemorrhage, is the most common surgical complication of HSP in childhood.[232] In adults, advanced presentation can include GI hemorrhage, necrosis, and stricture/obstruction. Diagnostic tools include ultrasound, CT scan, upper and

lower endoscopy, and video capsule endoscopy. The ideal method of diagnosis is to identify leukocytoclastic vasculitis with IgA on tissue biopsy (whether from the skin, kidney, or GI tract) coupled with classic clinical manifestations. The natural history of the disease is spontaneous resolution, and as such, the role of medical treatment remains unclear. Analgesics (acetaminophen or NSAIDs) and H2-blockers appear to help with symptoms, while the use of corticosteroids is controversial. Over 80% of patients recover within 2 weeks; however, a generally milder and shorter recurrence takes place in one-third of patients most often within 4 months of the initial presentation.

Systemic Lupus Erythematosis

Systemic lupus erythematosis (SLE) is a chronic multisystem inflammatory disease of unknown cause that can affect any organ system of the body, following a relapsing and remitting course. Disturbances within the immune system result in the formation of immune complexes in the microvasculature leading to complement activation and inflammation. Patients with SLE can develop a small- and medium-sized vessel vasculitis that involves the GI tract in approximately 25–40% of patients.[233] Similar to Crohn's disease, SLE can affect any portion of the GI tract. Confusing the situation, abdominal pain may be secondary to any of the concomitant disorders that are associated with lupus such as infection, peritonitis, peptic ulcer disease, mesenteric vasculitis with intestinal infarction, and pancreatitis. The development of abdominal pain is often intermittent and insidious in onset, typically associated with nausea, vomiting, fever, and diarrhea. However, patients may also present acutely with mesenteric vasculitis and infarction in a septic picture. Diagnosis generally involves CT scan, though arteriography may prove helpful. More invasive testing including endoscopy or laparoscopy may be employed. Treatment options include broad-spectrum intravenous antibiotics and systemic corticosteroids, with the possible addition of other immunosuppressives. As steroids may mask the physical examination findings of evolving peritonitis and visceral perforation, surgeons should maintain a high index of suspicion for other signs or worsening physiology. Surgical intervention is indicated for failure to respond to aggressive resuscitation or signs of perforation.

Patients with SLE peritoneal inflammation can also present with an acute abdomen with abdominal ascites. When paracentesis reveals a transudate (excluding infection) a trial of steroids may be considered, though often require operative exploration. SLE-related intestinal pseudo-obstruction may occur as a result of impaired intestinal motility, likely due to a dysfunction of the visceral smooth muscle or the enteric nervous system.[234] Early treatment with high-dose corticosteroids is efficacious, while other treatment options include immunosuppressive medications (azathioprine, cyclosporin A, and cyclophosphamide) along with promotility agents. Finally, while rare, patients with lupus may develop a protein-losing enteropathy, which responds well to steroids.

Behcet's Disease

Behcet's disease is a chronic, relapsing, inflammatory disease mainly affecting young men in the Middle East and women in Japan and Korea.[235] Classically, it causes painful oral and genital apthous ulcerations, uveitis, arthritis, and skin lesions. Yet, 15–60% may also experience gastrointestinal manifestations, with 10–20% developing neurological changes, and up to one-third acquiring vascular abnormalities. This vasculitis is unique as it involves blood vessels of all sizes – small, medium, and large – and affects both the arterial and venous systems. Behcet's disease typically has a waxing and waning course characterized by exacerbations and remissions. From a GI perspective, patients present with anorexia, nausea, abdominal pain, diarrhea, and bleeding. Ulcerations may be superficial or transmural, and are most often seen in the terminal ileum, cecum, and ascending colon. Endoscopically, these ulcerations appear round and deep with discrete margins. When located in the ileocecal location (96%), they are often single (67%), and tend to be larger than 1 cm (76%).[236] It is often difficult to distinguish between Bechet's and inflammatory bowel disease, due to the similarity in intestinal symptoms including GI ulcerations, inflammatory masses, anorectal pathology, and rectovaginal fistulas. In addition, both have extra-intestinal symptoms such as oral ulceration, erythema nodosum, uveitis, and arthritis. While nonspecific serum markers of inflammation may be elevated, there are no pathognomonic laboratory tests in Behcet's disease. Therefore, the diagnosis is often one of the exclusion, and made purely on the basis of the clinical spectrum. Treatment is dictated both by the type of organ system involved and by the severity of disease. Due to a paucity of reliable data, medical options remain controversial, though most often include corticosteroids and a variety of immunosuppressive medications. For those patients with GI involvement, treatment typically involves corticosteroids plus azathioprine, while several reports have demonstrated success with infliximab.[237] Surgery is generally reserved for the management of complications. There is some controversy on the proper resection margins on the bowel, with some authors advocating wide surgical margins, while others recommending removal of only the grossly involved disease.[238] Intestinal anastomosis is normally discouraged as anastomotic leaks, reperforation, and fistulization are common.[239] Long-term, the rate of recurrence after surgery has been reported to be 40–56%, and typically occurs at the anastomotic site.[240]

Scleroderma

Systemic sclerosis (scleroderma) is a multisystem fibrotic disease secondary to alterations of the microvasculature, the autonomic nervous system, and the immune system. Neurohumoral mediators, cytokines, and physical agents such as cold temperature and trauma mediate these alterations in small vessel function. Ultimately, this results in smooth muscle atrophy and gut wall fibrosis. Nearly 90% of patients with systemic

sclerosis have GI involvement. While the entire GI tract can be affected, esophageal disease is the most common site.[241] In the small bowel, mucosal villous structure is normal, but collagen deposits around Brunner's glands, leading to periglandular sclerosis. Patients develop malabsorption as a result of intestinal stasis, bowel dilation, and bacterial overgrowth – often resulting in malnutrition. More rare complications include pseudo-obstruction, small bowel perforation, pneumatosis intestinalis, and small bowel volvulus. Bacterial overgrowth can be treated with yogurt and cyclical, chronic oral antibiotics. Pseudo-obstruction and small bowel dysmotility are challenging to treat. Typically, prokinetic agents are not helpful, though daily balanced electrolyte solutions containing polyethylene glycol (PEG) may be beneficial. Octreotide therapy (50 μg/day, subcutaneously), by inducing phase III-like migrating motor complexes, may offer some improvement, although experience of this treatment is still limited.[242] Patients with advanced intestinal failure require total parenteral nutrition, either on a temporary or long-term basis. Surgical resection is rarely beneficial due to the diffuse nature of GI involvement and risk for short bowel syndrome with extended resections. Dietary changes including lactose and fiber avoidance, intake of medium chain triglycerides, and supplementation with vitamins, calcium, and iron have all demonstrated varying results. Anorectal and colonic disease occur in 10–50% of patients with systemic sclerosis. Collagen is deposited in the mucosa and submucosa, while the muscularis externa undergoes atrophy. Wide-mouthed diverticuli can be visible protruding through the weakened wall on the antimesenteric border. Clinically, both constipation, due to dysmotility and pseudo-obstruction, and fecal incontinence are common problems. Disordered defecation often results in fecal incontinence as a consequence of decreased internal anal sphincter pressures, reduced rectal compliance, and an absent or diminished rectoanal inhibitory reflex.[243] Constipation can be managed with bulking agents or PEG, although this may paradoxically worsen proximal dysmotility. For patients with fecal incontinence, treatment options include sphincter muscle training by biofeedback, sacral nerve stimulation, and proximal diversion with a stoma.[244]

Miscellaneous Colitis

As depicted, inflammation of the colon and rectum can result from a vast number of underlying pathologic processes, but also may occur following iatrogenic and rare sources. Included in this mixed bag are colitides from diversion, immunosuppression, medications, toxins, and autoimmune conditions. In this final section, we briefly review a few of the more unusual, though not entirely uncommon, causes of colitis.

Diversion Colitis

Fecal diversion is performed for a variety of reasons, with the ultimate purpose to prevent the fecal stream from reaching the distal segment of large intestine to prevent complications including perineal infection, fecal incontinence, fistula, stricture, or anastomotic protection/leak. Yet, while diversion in these situations is often critically important, it may result in clinically evident disease, particularly following extended periods in which the colorectal mucosa is devoid of fecal matter. The defunctionalized colon and rectum develops a nonspecific inflammation that is felt to be secondary to a lack of short chain fatty acids – the primary colonocyte nutrient.[245] While this is the leading theory, the lack of consistent findings on endoscopy and histological examination has led to alternative hypotheses including infection and ischemia.[246,247] Patients most often present with symptoms of abdominal and/or pelvic pain, tenesmus, bright red blood per rectum, and mucus discharge. Endoscopy commonly reveals erythema, friable mucosa, contact bleeding, and mucus plugs (Figure 34-14). In extreme cases, severe bleeding occurs due to gross ulceration.[248] It is often difficult to differentiate the clinical appearance from inflammatory bowel disease.[249] While the temporal relationship with stoma construction may help with the diagnosis, symptoms normally occur months, and in rare reported cases, 17 years following diversion.[246] Most often patients are asymptomatic and do not require treatment. For those patients with a temporary stoma, resolution of symptoms is the norm once intestinal continuity is restored, while failure to improve should prompt an evaluation for other underlying pathology.[250,251] In symptomatic patients in whom the diversion is permanent or not ready for stomal reversal, treatment regimens including 5-aminosalicylate, sucralfate, and steroid enemas have demonstrated moderate success for symptom control.[252] In addition, there is good evidence that twice-daily irrigation of short-chain fatty acid enemas for 2–4 weeks or even longer will lead to resolution of symptoms.[253,254] It is also critically important for even asymptomatic patients

FIGURE 34-14. Diversion colitis. Notice the erythematous, friable mucosa.

with long-term diversion to undergo periodic endoscopic and digital examination for screening and surveillance of colorectal cancer and polyps.

Neutropenic Enterocolitis

Neutropenic enteroclotis, or typhlitis, is a potentially fatal complication of cytotoxic chemotherapy for malignancy, most commonly seen with leukemia or lymphoma.[255] Additionally, immunosuppressed patients from other causes such as following transplantation, aplastic anemia, or AIDS may present with a similar clinical picture. While the exact pathogenesis is unknown, leading proposed mechanisms include alterations of normal bowel flora, weakened immunologic defenses, mucosal injury, and development of more virulent GI pathogens.[256] One consistent factor is the presence of neutropenia, with most patients having absolute neutrophil counts less than 500/mm^3. The process has a predilection for the terminal ileum and cecum, although any segment of the bowel can be involved. During the course of chemotherapy, patients often present with watery diarrhea, vomiting, fever, and abdominal pain, while more severe forms result in perforation and sepsis.[257] Computed tomography is the most widely used method of diagnosis, with characteristic right-sided colonic and ileal wall thickening with or without adjacent fat stranding and free fluid.[258] Pneumatosis has been reported in up to 21% of patients.[259] Due to the patients' underlying condition, the mainstay of therapy remains nothing per os, intravenous fluid resuscitation, broad-spectrum antibiotics, and continued supportive care. Consideration may be given for parenteral nutrition, although in most cases the clinical condition improves as the neutropenia resolves. Patients should be frequently examined for signs of worsening examination or peritonitis. Surgical therapy is generally reserved for patients with signs of nonviable bowel, perforation, or sepsis.[260–262] When surgery is required, consideration is normally given for resection of the involved bowel with the formation of a proximal stoma (i.e., ileostomy).

Disinfectant Colitis

With the prominent role that endoscopy possesses in gastrointestinal screening and treatment, the potential for development of significant contact irritation and subsequent colitis exists. Endoscopic disinfectants commonly use hydrogen peroxide bases or glutaraldehyde formulations for cleaning in part due to their broad spectrum of action against acid and alcohol resistant bacilli, hydrophilic viruses, and spores. While the scopes are thoroughly rinsed and cleansed as a part of the sterilization process, residual formulation or response analogous to contact dermatitis may provoke a change in the mucosa that has been referred to as pseudolipomatosis.[263] This remains somewhat of a controversial topic, as the exact mechanism of this is unknown, as well as whether the irritation results from the bowel preparation, mechanical trauma

from the scope itself, or another source. The lesion plaque resembling pseudomembranous colitis, and often appears on withdrawal of the scope in regions which appeared relatively normal on introduction. Patients may have a variety of nonspecific complaints ranging from mild cramping abdominal pain to fever, bloody diarrhea, and significant tenderness starting approximately 24–48 h following endoscopy. The vast majority of patients will have complete symptom resolution without need for therapy, though a paucity of data exists pertaining to this topic, owing to its relatively rare entity.[264] Consideration should be given to appropriate evaluation that often includes history and physical examination, as well as laboratory evaluation to include stool studies to exclude other sources of colitis. In more advanced cases, radiographic evaluation with plain films and CT scan to exclude perforation, and/or repeat endoscopy to determine severity and extent of the process as well as biopsy with histological examination may be required. Most importantly, prevention of this entity may be aided with diligent rinsing and forced-air drying of the endoscopes, along with proper maintenance and routine use of automatic disinfecting machines whenever possible.[265]

Corrosive Colitis

Specific formulations, such as previously described glutaraldehyde and formalin preparations that are used in a variety of medical capacities may result in an iatrogenic corrosive colitis. In addition, self-induced agents per rectum such as household bleach, coffee enemas, colas, and other potentially hazardous liquids and gels may result in varying degrees of bowel wall injury. In the former, changes may occur in the setting of mucosal contact with residual cleaning solutions during endoscopy or rectal instillation to treat diffuse bleeding from radiation proctitis. In the latter, underlying motives such as autoeroticism or attempts at "cleaning" the rectum have been described.[266] Similar to disinfectant colitis, most patients develop a self-limiting symptom complex of abdominal pain, mucous discharge, diarrhea, and rectal bleeding within hours to a few days depending on the extent of exposure and chemical composition of the offending corrosive agent. Treatment typically remains supportive with bowel rest, intravenous fluids, and occasional topical medications (i.e., mesalamine, steroids) as needed, though anecdotal reports of full thickness rectal injury and need for diversion and/or proctectomy with severe cases.[264,267–269] Depending on the degree of injury, patients may also develop symptoms of tenesmus, chronic rectal pain, and even stricture formation long-term that may require therapy.[266]

NSAIDs and Salicylate-Induced Colitis

Many nonsteroidal and salicylate derivatives are used in various ways for the treatment of a number of disease processes. As in the setting of peptic ulcer disease, chronic (or

even short-term) NSAID use has been postulated to play a role in the pathogenesis of chronic colitis or colonic ulcer formation.[270] The degree to which they play a role remains undetermined. This is especially interesting in light of the information regarding a potential chemoprotective effect of long-term use of NSAIDS against development of colorectal neoplasia.[271] These drugs have also been associated with causing a reactivation of previously quiescent inflammatory bowel disease (especially ulcerative colitis) via lowering levels of prostaglandins by dual inhibition of the cyclooxygenase (COX) enzymes.[272,273] Relapse may occur in up to 30% of patients and commonly occurs within 10–14 days of NSAID consumption.[274] However, the available data remains very mixed on this topic. Presenting symptoms are often diarrhea, rectal bleeding, and abdominal pain, coupled with a history of NSAID usage. Endoscopic findings include patchy erythema, ulcerations, and in many cases the colonic mucosa appearance will mimic inflammatory or idiopathic colitis. Treatment involves discontinuing NSAID and salicylate use as well as administering topical or steroid preparations – especially in those patients with underlying IBD. Though most patients will have resolution of the symptoms, recurrence is frequent and chronic colitis may require surgery.[275]

Toxic Epidermal Necrolysis

Toxic epidermal necrolysis (TEN), also known as Stevens–Johnson syndrome, is a severe dermatological disease that is characterized by extensive epidermal and mucocutaneous necrosis and exfoliation. Whereas the primary manifestation is the appearance of an erythematous confluent eruption that rapidly evolves into necrosis and exfoliation of the skin at the dermal–epidermal junction, it is also been occasionally associated with disseminated mucosal erosions throughout the gastrointestinal tract.[276] Although this has an unknown etiology, this process appears to be immune-complex mediated and often occurs as an idiosyncratic reaction to a drug or chemical agent. The disease has an extremely high mortality rate and manifests with sepsis, gastrointestinal hemorrhage, diarrhea, high fevers, leukopenia, fluid/electrolyte imbalance, and renal insufficiency.[277,278] The ulceration is not limited to the colon, with diffuse ulceration anywhere from mouth to anus. Radiographically, the colon may appear stenotic or even "lead-pipe" like, similar to chronic ulcerative colitis. Endoscopically, the colon may resemble severe ulcerative or pseudomembranous colitis, however, biopsies show extensive necrosis and lymphocytic infiltration without crypt abscesses or neutrophils and pathologically the muscular layers remain intact. The mucosal sloughing of the bowel may result in melena or intestinal perforation.[70] Patients are critically ill and require aggressive surgical resection along with multisystem intensive care support including extensive skin care that is often only available in burn units.

Conclusion

The wide array of pathology affecting the colon and rectum presents some of the most challenging diagnostic and therapeutic situations. Though each is unique in their own way, varying in extent, severity, and outcome, they share many common bonds. Clinicians should stay abreast of these conditions and possess a well thought out algorithm to evaluate patients presenting with these similar constellation of symptoms.

Advanced Laparoscopic Colorectal Surgery

Tonia Young-Fadok

Introduction

Since the first edition of this textbook, advances in laparo-scopic colorectal surgery have been made in the arenas of education, research, and practice. In education, the vast majority of, if not all, trainees now finishing colorectal surgery fellowships have learned laparoscopic techniques. All laparoscopic colorectal procedures continue to be considered advanced procedures and are considered as such in this chapter. In the research arena, a multicenter randomized controlled trial is in progress evaluating the safety and other outcomes of laparoscopic resection of rectal cancer. In clinical practice, single-incision laparoscopic surgery has sparked interest in making these procedures even less invasive, and there is at least intellectual and experimental interest in natural orifice transluminal endoscopic surgery (NOTES) even though this approach has not yet made its way into practice. This chapter will review these issues and provide an assessment of the use of laparoscopic techniques for the common disease processes seen by colorectal surgeons.

Learning Curve

There continues to be relatively slow adoption of laparoscopic colectomy into the surgeon's practice. Laparoscopic colorectal surgery faces certain challenges which distinguish it from other minimally invasive procedures. In comparison to laparoscopic cholecystectomy, the performance of laparoscopic colectomy requires working in multiple quadrants of the abdomen. This requires a better understanding of depth perception and proprioception. A coordinated team consisting of a surgeon, an assistant, and often a cameraperson is required. All three must work together along with the nursing and anesthesia teams. All of these add to the complexity of the procedure and this results in the need to perform a number of cases before the surgeon and surgical team become proficient. Numerous previous studies have evaluated the "learning curve" of laparoscopic colectomy, although the actual definition of learning curve remains somewhat nebulous.[1–3]

Although earlier studies estimated the learning curve for laparoscopic colectomy to be at least 20 cases, several publications have suggested the learning curve is greater than this.[4] The initial randomized trials of laparoscopic resection for colon cancer demonstrate this, with a fall in conversion rates over the course of the trials. In a prospective randomized study of colorectal cancer in the United Kingdom, the "CLASICC" trial, surgeons had to perform at least 20 laparoscopic resections before they were allowed to enter the study.[5] The study began in July 1996 and was completed in July 2002. Despite the surgeon's prior experience, the rate of conversion dropped from 38 to 16% over the course of the study, suggesting that a minimum of 20 cases may not be enough to reach the plateau of the "learning curve." In the COLOR trial from Europe,[6] a prospective randomized study for colon cancer that required a prerequisite experience in laparoscopic colon resection before surgeons could enter patients in to the study, surgeon and hospital volume were directly related to a number of operative and postoperative outcomes. The median operative time for high-volume (>10 cases/year) hospitals was 188 min compared to 241 min for low volume (<5 cases/year) hospitals, and likewise conversion rates were 9% vs. 24% for the two groups. High-volume groups also had more lymph nodes in the resected specimens, fewer complications, and shortened hospital stay. These studies suggest that the learning curve is clearly greater than 20 cases and surgeons need to perform a minimum yearly number of procedures to maintain their skills.

A major achievement has been the introduction of laparoscopic training into most, if not all, of the accredited colorectal fellowships, so that graduates of these programs have laparoscopic skills. There are three groups of surgeons among whom laparoscopic approaches remain slow to permeate: colorectal surgeons who finished training prior to the introduction of laparoscopic cholecystectomy; general surgeons who perform few colorectal procedures; and residents graduating from general surgery programs with no

laparoscopic colorectal training. Regarding the first group, it is challenging for established colorectal surgeons to assimilate laparoscopic procedures into their practice, when they are not familiar with the basics of laparoscopy. This is reflected in the data obtained from board-certified colorectal surgeons who are taking recertification examinations: only 30% perform laparoscopy which indicates that less than 30% of cases being performed by recertifying colorectal surgeons are being performed by this approach as even experienced laparoscopic colorectal surgeons acknowledge that some cases must be performed open.

For general surgeons, the difficulty with the broad application of laparoscopic colectomy is that most general surgeons perform far fewer than 50 segmental colon resections per year. In a review of 2,434 general surgeons who were taking the recertification examination of the American Board of Surgery, all of whom supplied their operative lists from the previous year, most surgeons performed fewer than 20 colon resections in 1 year.[7] In fact, the mean number of colon resections performed was 11. Even at the 90th percentile, only 23 colectomies were performed in a single year. If the average surgeon performs 11 resections and approximately half are eligible for a laparoscopic approach, assuming a learning curve of even just 20 cases, it would take a surgeon 4 years to feel comfortable performing laparoscopic colectomy, and many would argue that so few cases per year is not sufficient to build up one's skill level. Most surgeons (and their patients!) cannot afford to go through such a learning curve. Either the learning curve will need to be shortened, as some have suggested may be possible by the use of hand-assisted laparoscopic techniques, or the performance of laparoscopic colectomy may be limited to surgeons who perform a greater number of colon resections per year.

Conversion

Rates of conversion vary widely in the literature, from 0% to as high as 48%, depending on multiple factors such as date of publication, disease process, patient factors and of course, surgeon experience and ability. Most series report the need to convert in 5–25% of cases. While surgical proficiency would likely decrease the need to convert, this is counterbalanced by the surgeon's desire to perform more complex cases.[2] Several patient and disease-related factors such as obesity, prior abdominal surgery (a marker for adhesions), acuity of inflammation (i.e., abscess and fistula formation), tumor bulk or contiguous involvement, and disease location, may also affect the rate of conversion. Obesity, defined as a body mass index greater than 30 kg/m^2, was once considered a relative contraindication to a laparoscopic approach. For a surgeon early in his/her learning curve, it should remain a relative contraindication. However, once more experience is gained by the surgeon, several reports have demonstrated that obesity itself is not a contraindication to a minimally

invasive approach.[8–10] For inflammatory conditions such as Crohn's disease and diverticulitis, the presence of an abscess or fistula may result in the need for conversion in up to 50% of cases,[11,12] with reports from experienced centers suggesting a conversion rate of 25–35% for enteric fistulae.[13–15] The presence of a fistula or small abscess is not a contraindication to a minimally invasive approach but should alert the surgeon to consider a variation in operative approach if obstacles cannot be overcome. Conversion from a laparoscopic to open resection should *not* be viewed as a failure of the surgeon but as a sign of mature surgical judgment. Based on preoperative studies, it is difficult to predict which cases cannot be completed laparoscopically.

More crucial than the rate of conversion may be the time spent prior to conversion. Delayed conversion, occurring only after a complication has occurred, may in some cases reflect poor judgment or little experience. An initial laparoscopic survey may quickly identify a complex process, allowing a speedy alteration in the operative plan. If the approach is expeditiously changed, additional time and costs may be avoided. Early reports suggested worse outcomes for patients who required conversion, but later studies suggest that if conversion is made early, the outcome of converted cases is similar to patients undergoing conventional surgery.[16,17] The goal is to perform a preemptive conversion; once it is determined the case cannot be completed laparoscopically, rather than a reactive conversion to a complication which occurred due to adverse conditions which the surgeon could have avoided.

Outcomes

This section is an overview and summary of the types of outcomes measured for laparoscopic colectomy; disease-specific outcomes are provided in the next section and in the accompanying tables. In comparison with conventional colectomy, benefits of laparoscopic colectomy may include shorter duration of postoperative ileus, less postoperative pain and concomitant reduction in the need for analgesics, earlier tolerance of diet, shortened hospital stay, earlier resumption of normal activities, improved cosmetic results, and possibly preservation of immune function. This is offset by a prolongation in operative time, the cost of laparoscopic equipment, and the learning curve of these technically challenging procedures. When reporting the outcomes of laparoscopic colectomy, there is, however, a natural selection bias when comparing conventional and laparoscopic cases. More complex cases are generally not suitable for a laparoscopic approach and therefore are performed "open." Also, in many series the results of the successfully completed laparoscopic cases are compared to both conventional cases and the cases converted from a laparoscopic to conventional procedure. Few studies, with the exception of the larger prospective randomized studies, leave the "converted" cases

in the laparoscopic group as part of the "intention to treat" laparoscopic group. This clearly introduces selection bias.

The vast majority of studies reporting outcomes of laparoscopic vs. open colectomy are retrospective case–control studies or even just case series. Although some postoperative outcomes are available from randomized trials, most of the well-performed randomized trials are designed to answer important oncologic issues such as safety and survival in cancer patients, and postoperative outcomes have been of secondary interest. Conclusions regarding outcomes, therefore, often come from the repetitiveness of the results rather than the superiority of study design. For any one study, the evidence is weak, but collectively, due to the reproducibility of results by a large number of institutions, even with different operative techniques and postoperative management parameters, the preponderance of evidence favors a minimally invasive approach with respect to postoperative outcomes. Also, the prospective randomized studies which are available corroborate the findings demonstrated in nonrandomized studies.

Operative Time

Most comparative studies provide information regarding operative times. The definition of the operative time may vary with each series, and there may be different groups of surgeons performing the laparoscopic and conventional procedures. Most studies demonstrate a longer operative time associated with a laparoscopic procedure. In prospective randomized trials, the procedure was roughly 40–60 min longer in the laparoscopic groups. As the surgeon and team gain experience with laparoscopic colectomy, operating times do reliably fall, but rarely does it return to the comparable time for a conventional approach.

Return of Bowel Activity and Resumption of Diet

Reduction in postoperative ileus is one of the proposed major advantages of minimally invasive surgery. Most studies comparing open and laparoscopic colectomy have shown a statistically significant reduction in the time to passage of flatus and stool. Most series demonstrate a 1–2-day advantage for the laparoscopic group. Whether the reduction of ileus relates to less bowel manipulation, or less intestinal exposure to air and desiccation, or some other factor during minimally invasive surgery, remains unknown.

In clinical studies, it is difficult to eliminate the biases of the physician and the higher expectations of the patient undergoing laparoscopic surgery. Psychological conditioning of the patient preoperatively may interfere with an objective assessment of bowel activity postoperatively. To answer this question formally, both human and animal studies have evaluated the return of gastrointestinal motility. Both canine and porcine models have confirmed an earlier return of intestinal myoelectric activity following laparoscopic resection.[18,19] A study in dogs demonstrated an earlier return to preoperative motility, utilizing radionucleotide techniques in animals subjected to laparoscopic resection.[20] These studies clearly demonstrate a more rapid return of bowel activity without the subjective bias which may be introduced in clinical studies.

With shorter postoperative ileus, tolerance of both liquids and solid food is sooner following laparoscopic resection. The time to resumption of diet varies from 2 to 7 days (depending, interestingly, on the country in which the study was performed, reflecting accepted local practices), but in the majority of comparative studies this is 1–2 days sooner than in patients undergoing conventional surgery. Again, the physician and patient are usually not blinded, which may alter patient expectations. The overwhelming reproducible data reported in both retrospective and prospective studies of laparoscopic procedures, however, does favor a shorter period of postoperative ileus and earlier tolerance of liquid and solid diet.

Postoperative Pain and Recover of Pulmonary Function

A variety of assessments have demonstrated a significant reduction in pain following minimally invasive surgery: some studies utilize an analog pain scale, while others measure narcotic requirements. Physician bias and psychological conditioning of the patients may interfere with the evaluation of postoperative pain. There are also cultural variations in the response to pain. Three of the early prospective randomized trials evaluated pain postoperatively and all three found a reduction in narcotic requirements in patients undergoing laparoscopic colectomy.[21–23] In the COST study,[24,25] the need both for intravenous and oral analgesics was less in patients undergoing laparoscopic resection. Numerous other nonrandomized studies have shown a reduction in postoperative pain and narcotic usage.

Closely related to the severity and duration of postoperative pain is the return of pulmonary function. Adequate pain management allows the patient to inspire more deeply. Following conventional abdominal surgery, suppression of pulmonary function is a well-known sequela. Several studies of laparoscopic colectomy have evaluated the return of pulmonary function. In a randomized trial of patients undergoing surgery for colon cancer from the Cleveland Clinic, preoperative and postoperative spirometry was performed every 12 h in 55 patients in the laparoscopic group and 54 patients in the conventional group.[21] An 80% recovery of baseline forced vital capacity (FVC) and forced expiratory volume in 1 s (FEV_1) was measured in each patient. The median recovery for the laparoscopic group was 3 days which was half the recovery (6 days) seen in the conventional group. A similarly designed study by Schwenk et al.[23] confirmed these results. Although subject to bias, the results of comparative

studies suggest a quicker recovery of pulmonary function and reduction in postoperative pain in patients subjected to laparoscopic colectomy.

Length of Stay

More rapid resolution of ileus, earlier resumption of diet and reduced postoperative pain results in a shortened length of stay after laparoscopic resection compared with traditional procedures. Recovery after open operation has also been shortened by fast-track practices, but this is not consistent throughout the literature. In the absence of minimally invasive techniques, it would seem unlikely that the length of stay could be further reduced. In most studies, the length of hospitalization is 1–6 days less for the laparoscopic group. In an attempt to minimize the differences between a conventional midline incision and a laparoscopic incision, Fleshman et al.[25] compared the outcomes of 35 patients whose surgery was performed through a minilaparotomy (12 cm, mean incision length) to 54 laparoscopic patients. Outcome was similar for both groups with a mean day of discharge of 6.9 days (range 3–15 days) for the minilaparotomy group and 6.0 days for the laparoscopic group (range 1–15 days). However, when the results of successfully completed laparoscopic cases (75%) where compared, the results favored the laparoscopic group (5.3 days, range 1–14 days). Therefore, despite an attempt to minimize the incision, the overall length of stay was still longer in the minilaparotomy group.

While psychological conditioning of the patient cannot be avoided and likely has a desirable effect, the benefits of minimally invasive procedures on the overall length of stay cannot be discounted. The benefit, however, is more likely a 1–2-day advantage only. The more recent introduction of fast-track clinical pathways in conventional and laparoscopic surgery has also narrowed the gap, but laparoscopy still appears to confer advantages.[26,27]

Quality of Life and Return to Work

If laparoscopic colectomy results in less postoperative pain and earlier return to normal activities, one would anticipate that quality of life after a laparoscopic procedure should be improved compared with conventional procedures. Few studies, however, have objectively examined the patient's assessment of recovery. In a nonrandomized study, Psaila et al.[28] evaluated the recovery of hand grip strength and quality of life utilizing an SF-36 symptom score 2 and 4 months postoperatively. Hand grip strength, as a measure of protein loss, recovered more rapidly after laparoscopic surgery. In six of eight areas the SF-36 questionnaire showed less impairment of health following laparoscopic colectomy. By 4 months postoperatively, this trend persisted but to a lesser degree. In the COST study, quality of life was evaluated by three complementary viewpoints: patient self-reported symptoms, patient self-reported functional status, and a third more objective measurement scale of compliance to treatment referred to as Q-TWiST (quality-adjusted time without symptoms of disease and toxicity of treatment).[24,29] Due to a high conversion rate of 25% in the initial study report, and the "intention to treat" design of the study, there were no significant differences between the conventional and laparoscopic groups with the exception of a global rating score at 2 weeks. In every category, however, patients who had a laparoscopically completed procedure were improved compared with open procedures and with laparoscopic patients who required a conversion to open surgery, although this did not achieve significance. The results of the CLASICC trial found similar results.[5]

Few studies have assessed the ability of patients undergoing laparoscopic colectomy to return to work. With less postoperative pain and reduced narcotic usage one would presume that patients undergoing a minimally invasive approach would return more quickly to normal activities and employment compared with patients undergoing conventional resection. In a nonrandomized study, patients undergoing laparoscopy returned to full activities and work sooner than matched patients undergoing conventional resection (mean – 4.2 weeks vs. 10.5 weeks, 3.8 weeks vs. 7.5 weeks, respectively ($P < 0.01$ for all)).[30]

Hospital Costs

A theoretical disadvantage of laparoscopy is higher operative costs related to longer operative times and disposable equipment. Whether the total cost of the hospitalization (operative and hospital costs) is higher following laparoscopic colectomy is debatable. A case control study from the Mayo Clinic looked at total costs following laparoscopic and open ileocolic resection for Crohn's disease.[31] Sixty-six patients underwent laparoscopic ($n = 33$) or conventional ($n = 33$) ileocolic resection during the same time period (10/95 to 7/99) and were well matched. Patients in the laparoscopic group had less postoperative pain, tolerated a regular diet sooner by 1–2 days and had a shorter length of stay (4.0 days vs. 7.0 days). In their cost analysis, despite higher operative cost, the overall mean costs were $3,273 less in the laparoscopic group. The procedures were performed by different groups of surgeons at the institution, and while the surgeon may have introduced bias, this study was undertaken during the current era of cost containment. Other studies by Dupree et al.[32] and Shore et al.[33] have confirmed these findings with a mean reduction of $438 in costs and $7,465 in hospital charges, respectively, in patients undergoing laparoscopic compared to conventional ileocolic resection. The results are similar for elective sigmoid diverticular resection with a mean cost savings of $700–$800[34,35] (and there are additional examples in the disease-specific section). Increased operative times and equipment expenditures appear to be offset by a shorter hospital stay.

Disease-Specific Outcomes

Crohn's Disease

Laparoscopy in the setting of inflammatory bowel disease has its own unique challenges. In Crohn's disease, there may be inflammatory changes, difficulty in assessing bowel involvement, and associated abscess and fistulous disease.[11] In the patient with Crohn's colitis, the challenges are also technical owing to the difficulty in performing laparoscopic total colectomy.

Crohn's disease of the terminal ileum seems an ideal model for a minimally invasive approach. The disease is usually limited to one area of the abdomen and only mobilization and vascular pedicle ligation are required laparoscopically, with resection and anastomosis performed extracorporeally. Patients with Crohn's are typically young and interested in a procedure that minimizes scars. Additionally, since many of these patients require reoperation over their lifetime, a minimally invasive approach is appealing. Early reports of laparoscopic ileocolic resection showed it to be feasible and safe but were typically small nonrandomized uncontrolled studies. More recent studies (Table 35-1) demonstrate a more extensive experience.[36–55] The majority of studies, however, are retrospective case control series. Most series report the rate of conversion from 10 to 20% with the mix of complex cases (abscess, fistula, or reoperative surgery) ranging from 40 to 50%.

As expected, outcomes of laparoscopic ileocolic resection for Crohn's disease mirror those seen in other studies of laparoscopic colectomy for benign and malignant disease. In comparative studies (Table 35-1), laparoscopic ileocolic resection is associated with earlier return of bowel function and tolerance of oral diet. The quicker resolution of ileus, earlier resumption of diet, and reduced postoperative pain results in a shorter length of stay for patients after laparoscopic resection compared with traditional procedures. Milsom et al.[43] reported a prospective randomized trial comparing conventional and laparoscopic ileocolic resection for refractory Crohn's disease. Sixty patients were randomized to either conventional or laparoscopic resection after an initial diagnostic laparoscopy to assess feasibility of a laparoscopic resection. The results favor a laparoscopic approach with regards to pulmonary function, morbidity, and length of stay. There were no apparent short-term disadvantages. All patients had oral intake withheld for 3 days to evaluate nutritional parameters. This impacted on the timing of dietary intake and was likely responsible for a delay in discharge in some patients. The total length of stay in this randomized study was 1 day shorter in the laparoscopic group (5 days vs. 6 days) but did not reach statistical significance. Had dietary intake not been withheld, a shortened length of stay of the laparoscopic group might have achieved significance.

Without tactile sensation, one of the concerns of laparoscopic surgery in the patient with Crohn's is missing an isolated proximal ileal lesion. Many patients following ileocolic resection, whether open or laparoscopic, will develop a symptomatic recurrence proximal to the ileocolic anastomosis, but whether patients undergoing a laparoscopic procedure will present more frequently as a result of unrecognized proximal disease remains unclear. There are, however, several studies that have reported recurrence rates following laparoscopic ileocolic resection. In one study, the long-term follow-up results (mean 39 months) of 32 patients over 7 years who underwent a laparoscopic ileocolic resection were compared to 29 patients undergoing open resection.[46] The rate of Crohn's recurrence was high but similar in both groups (48% laparoscopic, 44% conventional) as was the disease-free interval (24 months). In another review of long-term outcome, Bergamaschi et al.[47] reported the results of 39 laparoscopic and 53 conventional ileocolic resections with a 5-year follow-up. Recurrent disease was determined by patient symptoms and confirmed both radiographically and endoscopically in 27% of patients undergoing a laparoscopic procedure and in 29% of patients with a conventional resection. Interestingly, the incidence of small bowel obstruction was significantly less in the laparoscopic group (11% vs. 35%, $P = 0.02$). This was thought to be due to less adhesion formation following a laparoscopic procedure. Laparoscopic ileocolic resection does not appear to offer any advantage over conventional resection with regard to symptomatic recurrence, but it also did not lead to a higher rate of recurrence or discovery of a missed lesion. There are two options for evaluating the small bowel to evaluate for proximal lesions: the bowel can be run from ligament of Treitz to the ileocecal valve using a "hand-over-hand" instrument evaluation; alternatively, if a specimen is being removed, the small bowel can be evaluated manually as it can usually be exteriorized through a small periumbilical incision.

Laparoscopic ileocolic resection for Crohn's disease appears to be safe and feasible and offers the advantages seen in other reports of laparoscopic colorectal procedures. For the inexperienced laparoscopist, the initial uncomplicated terminal ileal resection is an ideal procedure in which to gain laparoscopic experience. An initial laparoscopic survey should be performed, with a low threshold to convert to open if a complex case beyond the skill of the surgeon is encountered.

Ulcerative Colitis

There are a few small prospective randomized studies of laparoscopic proctocolectomy for ulcerative colitis[56,57] but the vast majority of reports are prospective and retrospective case control studies and noncomparative reports (Tables 35-2A and 35-2B).[58–76] Several reasons likely account for the slow adoption of laparoscopic proctocolectomy including the steep learning curve for even segmental colectomy, the technical challenges of transverse colon resection, and unfavorable early reports of laparoscopic total colectomy. The

earliest attempts at laparoscopic proctocolectomy showed longer operative time, higher blood loss, and longer hospital stay than matched open procedures, with no apparent benefit, thus discouraging this approach.[77,78] However, with advances in technology and experience gained with segmental resection, many groups have re-evaluated the role of laparoscopic total colectomy and proctocolectomy for inflammatory bowel disease.

Recent reports demonstrate that laparoscopic total colectomy and proctocolectomy with and without ileal pouch-anal anastomosis is technically feasible and shares the same advantages as seen with segmental colonic resection. Laparoscopic proctocolectomy has been performed in the elective setting, but several groups have performed laparoscopic total colectomy on an urgent basis for the patient with non-resolving acute colitis. These procedures, however, are still not recommended for the patient with toxic colitis.

One important potential benefit of a laparoscopic approach in this group of patients is a reduction in adhesions. A large multicenter randomized trial of an adhesion barrier (glycerol hyaluronate/carboxymethylcellulose bioresorbable (GHA/CMC) adhesion barrier) used the two-stage operation model in ulcerative colitis to evaluate adhesions.[79] At the second stage, i.e., ileostomy closure, laparoscopic evaluation of abdominal adhesions was performed. In the control group, without the use of the barrier, 90% of patients had adhesions to the anterior abdominal wall, compared with 67% in the study arm. Indar et al.[80] showed in a series of 34 patients (21 female) that after a laparoscopic approach to the first stage, only 32% of patients had adhesions to the anterior abdominal wall, and these were all flimsy, i.e., no dense adhesions. Also, in the 21 female patients, 15 (71%) had no adhesions to the adnexae, and in the six patients with pelvic adhesions, none had both adnexae affected. This has potential significance in the maintenance of fertility in young female patients, for whom pelvic adhesions are considered to be the most likely cause of reduced fecundity after operative intervention for ulcerative colitis.

Diverticulitis

Laparoscopic sigmoid resection remains the leading indication for minimally invasive colon resection for benign disease. The surgery is hampered by both the fibrotic changes associated with elective resection of recurrent disease and the inflammatory changes associated with acute disease. As surgeons acquire their laparoscopic skills, more complex cases involving abscess and fistulous communications have been successfully completed laparoscopically. There are now a large number of studies evaluating laparoscopic surgery for diverticulitis (Tables 35-3A and 35-3B).[81–98] These are both large case series and nonrandomized comparative studies with open resection. Most series report an operative time of 2–3 h with a conversion rate of 10–20% for larger series. The largest series of diverticular resection comes from a German multi-institutional study of 1,545 patients accumulated over 7 years at 52 institutions.[87] The study demonstrated a low morbidity and mortality with an overall conversion rate of 6.1%. As experience increased the percentage of complex cases increased without significantly altering the morbidity or rate of conversion. High-volume centers performed more of the complex cases with a similar conversion rate to the low volume centers which performed less complex cases.

Nearly all comparative studies of laparoscopic to open sigmoid resection demonstrate a benefit for the laparoscopic approach including a shorter duration of ileus, shortened length of stay, but as in other studies, with a longer operative time. Early reports suggested a higher overall cost associated with a laparoscopic approach for diverticular resection; however, more recent studies have demonstrated a cost saving with the laparoscopic approach. This cost reduction has been noted not only in the USA, but also in European countries. It should be noted that these are generally the elective uncomplicated cases with fewer patients presenting with abscess or fistula formation. For more complex cases, where the operative times are longer and the rate of conversion is higher, the cost savings benefit of a laparoscopic approach may be lost.

This highlights the importance of case selection when considering a laparoscopic approach. Less experienced surgeons should consider an early conversion of complicated diverticular resection or potentially an alteration in the approach to a hybrid approach where the difficult pelvic dissection can be guided by the hand laparoscopically or by conventional means through the open wound.[99,100]

One of the more recent areas of interest – and concomitant controversy – involves the use of laparoscopic lavage and placement of drains for purulent peritonitis secondary to perforated diverticulitis. Following early sporadic reports, one of the earliest large series was from Winters' group in Dublin. Myers et al.[101] reported the results of a prospective multi-institutional study of 100 patients. Patients with perforated diverticulitis causing generalized peritonitis underwent attempted laparoscopic peritoneal lavage. The Hinchey grading system was used to record the degree of peritonitis. The median age was 62.5 years, with a male:female ratio of 2:1. Eight patients with grade 4 (feculent) diverticulitis were converted to open Hartmann's procedure. Laparoscopic lavage was performed in the other 92 patients, with morbidity and mortality rates of 4 and 3%, respectively. Two patients developed a pelvic abscess postoperatively, requiring intervention. Only two patients presented with recurrent diverticulitis at a median follow-up of 36 months. The authors concluded that laparoscopic management of perforated diverticulitis with generalized (purulent) peritonitis is feasible, with a low recurrence risk in the short term.

Franklin et al.[102] reported 40 patients undergoing laparoscopic lavage and placement of drains in complicated diverticulitis and diverticulitis without fecal peritonitis. The average operative time was 62 min and there were no conversions. Just over 50% underwent elective interval sigmoid colectomy, and none of the remaining patients required surgical intervention after 96 months follow-up. The authors note that this approach avoids a colostomy, allows elective interval sigmoidectomy, and was associated with minimal morbidity. They went as far as to state that the approach should be considered the standard of care. Alamili et al.[103]

performed a review of the literature which included eight studies, none randomized, reporting 213 patients with acute complicated diverticulitis managed by laparoscopic lavage. Mean age was 59 years and most patients had Hinchey stage III disease. Conversion to laparotomy occurred on 6 patients (3%) and the complication rate was 10%. Mean hospital stay was 9 days. After mean follow-up of 38 months, 38% underwent elective sigmoid resection. Potential benefits were acknowledged, but larger studies were recommended.

Rectal Prolapse

Full-thickness rectal prolapse repaired by an abdominal fixation procedure is potentially an ideal procedure for a laparoscopic approach since there is no specimen to remove or anastomosis to create. Early reports were primarily technical descriptions of the procedure.[104–109] A large number of studies have evaluated not only laparoscopic fixation procedures but also the combination of sigmoid resection and rectopexy for the treatment of rectal prolapse (Table 35-4).[110–125] The magnified view into the pelvis with the laparoscope provides unparalleled visualization of the pelvic floor and the relative laxity of the rectal fixation to the presacral area is beneficial to performance of a laparoscopic procedure. This likely is the reason for the relatively low rate of conversion (<10%) for a laparoscopic rectopexy or resection and rectopexy in comparison to other laparoscopic colorectal procedures. The mobilization of the rectum for rectal prolapse is an ideal procedure in which to learn the laparoscopic technique of rectal mobilization which may then be applied to other procedures such as laparoscopic proctocolectomy or total mesorectal excision for rectal cancer.

In addition to case series results there have been several nonrandomized comparative studies of laparoscopic vs. conventional rectopexy and resection rectopexy.[114,115,121] These studies showed a longer operative time of 45–60 min with the laparoscopic procedures but with a shortened length of stay of 2–3 days. Functional results following surgery were similar in laparoscopic and conventional groups, with the majority of patients reporting an improvement in incontinence and constipation. Solomon also reported a prospective randomized study of 40 patients with full-thickness rectal prolapse.[120] This was a well-designed study with the use of blinded observers, and a standardized clinical pathway for both groups. As expected, the mean surgical time was 153 min in the laparoscopic group compared to 102 min in the open group ($P<0.01$). In the laparoscopic group, however, 75% of patients followed the clinical pathways as compared to only 37% of patients in the conventional group. The mean length of stay was also less (3.9 days vs. 6.6 days, $P<0.01$) with 19/20 patients in the laparoscopic group discharged by postoperative day 5 as compared to 9/19 patients in the conventional group. There were no differences in postoperative pain scores but total intravenous narcotic usage was less in the laparoscopic group. Functional outcomes of surgery were equivalent, and there were no recurrences of prolapse in either group with a short mean follow-up of 24 months. While the study is small in size, the outcomes mirror the results of other prospective randomized studies of laparoscopic surgery for other diseases and procedures. A later cost analysis of this study demonstrated an overall mean cost savings of ₤357 per patient in the laparoscopic group.[126]

One of the major issues when discussing surgery for rectal prolapse is the rate of recurrent prolapse. For an abdominal approach the risk of recurrence should be less than 5–10% over 5 years. Unfortunately, the majority of reports on laparoscopic surgery for rectal prolapse have limited follow-up (less than 3 years). The reported rate of recurrence ranges from 0 to 6% in these studies (Table 35-4). Recently, however, there have been two studies with a mean follow-up of 5 years.[122,124] In a study of 42 patients by D'Hoore et al.,[122] with a mean follow-up of 61 months, the rate of recurrent prolapse was 4.8%. In the largest study of laparoscopic surgery for rectal prolapse by Ashari et al.[124], with 117 patients over a 10 year period and a mean follow-up of 62 months, the rate of recurrent full-thickness prolapse was only 2.5%. The study, however, noted an 18% rate of mucosal prolapse, which is somewhat concerning. Further long-term follow-up of these patients is needed to ensure that the rate of recurrence remains acceptable. If the rate of recurrent prolapse is confirmed to occur at a rate equal to conventional surgery, a minimally invasive approach to rectal prolapse appears to be an ideal operation for surgeons with laparoscopic skills.

One of the concerns regarding rates of recurrent prolapse is reflected in a study comparing three techniques for rectopexy: open (OR), laparoscopic (LR), and robotic rectopexy (RR).[127] All consecutive patients who underwent a rectopexy over a 7-year period were enrolled in the study. Eighty-two patients (71 females, mean age 56.4 years) underwent a rectopexy for rectal prolapse. Nine patients (11%) had a recurrence; one (2%) after OR, four (27%) after LR, and four (20%) after RR. RR showed significantly higher recurrence rates when controlled for age and follow-up time compared to OR ($P=0.027$), while LR showed near-significant higher rates ($P=0.059$). It was concluded that LR and RR were adequate procedures but have a higher risk of recurrence. A RCT was proposed to assess the definitive role of robotic assistance in laparoscopic surgery in rectopexy. This study raises concerns regarding the completeness of rectal mobilization whether performed laparoscopically or with robotic assistance. While there is much interest in utilizing the rather spectacular technical abilities of the robot, the device does not compensate for lack of advanced laparoscopic surgical skills.

Colorectal Cancer

It is estimated that more than 106,100 new cases of colon cancer (52,010 in males and 54,090 in females) and 40,870 new cases of rectal cancer (23,580 males, 17,290 females)

Robot-assisted vs. conventional laparoscopic rectopexy for rectal prolapse: a comparative study on costs and time. Dis Colon Rectum 2007;50:1825–30.)[125]

were diagnosed in the USA in 2009.[128] Despite the fact that colon and rectal cancer together comprise the second most frequent cause of cancer death, the commonest source of cancer statistics[128] does not break out the mortality rates for each cancer type, resulting in 49,920 deaths for the combined groups (25,240 males, 24,680 females).

Prior to 2004, fewer than 5% of resections for colon and rectal cancer were being performed laparoscopically. There are no good sources for estimating current figures although approximately 30% of candidates for recertification for the American Board of Colon and Rectal Surgery (ABCRS) denote that they perform "some" laparoscopy. Early in the history of laparoscopic resection of colorectal cancer there was controversy related to the phenomenon of cancer implants at incision sites. Data from randomized controlled trials, however, have laid to rest these controversial aspects of the minimally invasive approach. The percentage of colon cancer cases performed laparoscopically is expected to increase, as more surgeons become familiar with these techniques, and especially as young surgeons graduate from colorectal fellowships with advanced laparoscopic skills. The issue of laparoscopic resection for rectal cancer is still unresolved. The American College of Surgeons Oncology Group (ACSOG) is sponsoring the ongoing study of laparoscopic vs. open resection for rectal cancer for advanced rectal neoplasms requiring preoperative chemoradiation.

Outcomes for Colon Cancer

After the initial success of minimally invasive techniques for cholecystectomy, reports of laparoscopic colon resections soon appeared.[129] Sadly, the specter of wound implants, or recurrence of cancer in the laparoscopic incisions, followed shortly thereafter.[130] In retrospect, it appears that as surgeons attempted to bring the benefits of minimally invasive techniques to their patients, some were performing operations for colon cancer that did not fulfill accepted oncologic principles, i.e., short-cuts were being taken with the extent of resection. Subsequent larger series by experienced surgeons showed that wound implants were not an inevitable accompaniment of the laparoscopic approach,[131] but the damage was done. From 1994 to 2004, there was essentially a moratorium on laparoscopic resection for colon cancer, with national surgical societies, such as The American Society of Colon and Rectal Surgeons (ASCRS) and the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) calling for these procedures to be performed only under the auspices of randomized controlled trials or with other means of careful prospective data collection.[132] These concerns prompted an unprecedented number of randomized controlled trials[5,6,21–24,133–136] and a new field of tumor and immunology investigation as they pertain to the pneumoperitoneum.

Lacy and colleagues[134] published the first large single-center randomized controlled trial in 2002. With median follow-up of 39 months, he and his colleagues reported higher cancer-related survival for the laparoscopic arm. Specifically, he showed no difference between arms for stage II cancers, but an improved survival for the laparoscopic approach in stage III cancers where the outcome was similar to that of stage II patients.

This was followed in 2004 by the results of the large multicenter COST study group.[29] With almost 900 patients randomized either to the open or the laparoscopic arm of the study, no differences were found in overall survival nor disease-free survival. Further reassurance was provided in finding that there were only two wound recurrences in the laparoscopic group, and one in the open arm.

The "CLASICC" trial from the United Kingdom included both colon and rectal cancers. The findings were similar, except for a rather spectacularly high rate of conversion, at 29%.[5] Those results were updated more recently in 2007.[135] Concerning issues from that trial were the very high conversion rate, the rate of positive radial margins in patients undergoing resection for rectal cancer (in both the laparoscopic *and* the open arms), and the 20% reduction in survival in patients undergoing abdominoperineal resection compared with low anterior resection. This raises very realistic concerns regarding technical issues.

The COLOR (COlon cancer Laparoscopic or Open Resection) trial was performed as a multicenter randomized trial at 37 centers throughout Europe.[6] The study accrued patients from 1997 to 2003 and there were several interim reports regarding accrual and outcomes compared with operative volumes, but the long-term oncologic outcomes were not reported until 2009, and even then only 3 year outcomes were reported.[136]

The results of these four trials are summarized in Table 35-5. Interestingly, all four studies reported the overall survival rates and disease-free survival rates for the entire study, but none actually reported the stage-specific rates. The values in the table have been obtained manually by extracting the data from graphs presented within the manuscript, and thus may have an error of 1–3% depending on the accuracy of reproduction and the thickness of the lines used within the graph.

The results of these trials (Table 35-5) have demonstrated that similar oncologic resections can be achieved by experienced surgeons performing laparoscopic colon resections. After publication of the COST study results, ASCRS and SAGES co-published an approved statement, that laparoscopic colectomy for cancer appeared to produce similar oncologic outcomes, but emphasized that these procedures should only be attempted by surgeons experienced with laparoscopic techniques.[137]

Outcomes for Rectal Cancer

Surgical resection of rectal cancer has the potential to achieve a curative result. Total mesorectal excision (TME) is currently the standard of care, minimizing the risk of local recurrence and providing accurate information regarding

staging, that affects prognosis and subsequent therapy. The surgical integrity and pathologic staging of the resection is the most important prognostic factor in preventing recurrent rectal cancer. Laparoscopic resection of rectal cancer must achieve at least equivalent oncologic results in comparison with open laparotomy and TME prior to becoming an established means of resection.

Early prospective studies, from experienced surgeons, suggested that laparoscopic resection did not worsen survival or disease control in patients with rectal cancer compared with open resection.[138–141] There were limited early data available from randomized controlled trials. An early study by Leung et al.[142] evaluated laparoscopic vs. open resection for rectosigmoid cancer, so this was not a trial of TME. A total of 403 patients were accrued between 1993 and 2002, 203 in the laparoscopic arm and 200 open. The probability of survival at 5 years for the laparoscopic and open resection groups were 76.1 and 72.9%, respectively. Five-year disease-free survival rates were 75.3 and 78.3%, respectively. The operative time for the laparoscopic group was significantly longer, whereas postoperative recovery was significantly better than for the open resection group. These benefits, however, were at the expense of higher direct cost. Reassuringly, the distal margin, the number of lymph nodes found in the resected specimen, overall morbidity, and operative mortality did not differ between groups.

The first randomized trial to provide outcomes for rectal cancer was not reassuring at all.[4,135] The CLASICC randomized controlled trial in the UK differed from its contemporaneous trials (COST, COLOR) in that patients with both colon cancer and rectal cancer were included. The study enrolled 268 patients to the open arm, of which 128 (48%) had rectal cancer, and 526 patients to the laparoscopic arm, of whom 253 (48%) had rectal cancer. The conversion rate for the study overall was 29%, with a 25% conversion rate for colon cancer and 34% for rectal cancer. The conversion rate dropped by year of the study, from 38% in year 1 to 16% in year 6 of the study. Operative time was longer for the laparoscopic rectal resections (180 min vs. 135 min), time to bowel movement shorter (5 days vs. 6 days), time to regular diet the same (6 days), and hospital stay shorter (11 days vs. 13 days). It was noted that the rate of positive circumferential resection margins (CRM) was the same between the two groups, but a closer look at the data is very disturbing. The CRM was positive in 14% of open patients and 16% of laparoscopic patients ($P=0.8$). Admittedly, these are not significantly different but the fact they are not different is not reassuring as the rate in the open group is hardly acceptable! In the low anterior resection group, it was noted that there was a nonsignificant trend toward a higher positive CRM rate in the laparoscopic group (12% vs. 6%, $P=0.19$). It was noted that no difference was seen in CRM positivity in the abdominoperineal group, but again the actual figures are far from reassuring with a 20% (10/49) positive rate in the open group vs. 26% (7/27) in the laparoscopic group.

Thus although the reports of the randomized controlled trials for colon cancer were reassuring, the CLASICC trial raised concerns regarding the application of laparoscopic techniques for rectal cancer. The fact that there were also high rates of CRM positivity in the open cases raised the issue of technical competence in the CLASICC trial, and deflected some of the attention away from the laparoscopic technique itself. Fortunately, overall, there were no differences in the long-term outcomes in the follow-up report of oncologic outcomes.[135] There was no statistically significant difference in 3-year overall survival for patients undergoing anterior resection (AR) or abdominal perineal resection (APR) in either technique group (AR-open 66.7%, laparoscopic 74.6%; APR-open 57.7%, laparoscopic 65.2%.) The higher positivity of the circumferential resection margin reported after laparoscopic anterior resection did not translate into an increased incidence of local recurrence. There was no difference in 3-year local recurrence rates after anterior resection of rectal cancer (7% open, 7.8% laparoscopic) or abdominoperineal resection of rectal cancer (21% open, 15% laparoscopic).

Numerous single-institution prospective case series have since supported the safety and efficacy of laparoscopic resection of rectal cancer in experienced centers and experienced hands.[143–147] Ng et al.[148] reported short-term outcomes and long-term survival in a large single-institution series of 579 patients undergoing laparoscopic resection for rectosigmoid and rectal cancer. Rectosigmoid and upper rectal cancers (12–18 cm from the anal verge), both undergoing low anterior resection, were grouped together for the subsequent analysis. Patients with tumors in the mid-rectum (7–12 cm from the anal verge) underwent sphincter-preserving TME. Patients with low-rectal tumors (<7 cm from the anal verge) underwent either TME or APR. Over a 15-year period, there were 316 laparoscopic anterior resections, 152 sphincter-preserving TME, and 92 laparoscopic APRs. Median follow-up was 56 months. Overall, early and late operative morbidity rates were 18.8 and 9.7%, respectively. The anastomotic leak rate was 3.5% ($n=20$). Conversion occurred in 31 patients (5.4%). Port site recurrence was seen in 0.4% of patients (1 laparoscopic anterior resection, 1 laparoscopic TME) and locoregional recurrence in 7.4% of patients. Microscopic resection margin involvement was identified in 6 laparoscopic TME and in 2 laparoscopic APR. Overall 5- and 10-year survival rates were 70 and 45.5%, and cancer-specific 5- and 10-year survival rates were 75 and 56%, respectively. Of note, patients in the anterior resection group were not stratified by tumor location, so the number of patients with rectosigmoid vs. upper rectal cancer is unclear. The authors concluded that laparoscopic resection for rectal cancer is safe and offers long-term oncologic outcomes equivalent to those of open resection.

In a retrospective study of 421 patients comparing outcome between open (310 patients) and laparoscopic (111) resection for stage II and stage III rectal cancer, Law et al.[149]

reported 5-year actuarial survival rates of 71.1% vs. 59.3% in the laparoscopic vs. open arms, respectively ($P=0.029$), after a median follow-up of 34 months. There was no difference in local recurrence. Laparoscopic resection was associated with decreased blood loss (200 ml vs. 350 ml, $P<0.001$) and shorter hospital stay (7 days vs. 9 days, $P<0.001$). The conversion rate was 12.5%. On multivariate analysis, laparoscopic resection was an independent factor associated with improved survival ($P=0.03$, hazards ratio 0.558 [95% confidence interval, 0.339–0.969]). There was, however, no breakdown of the number of stage II vs. stage III rectal cancer patients. The study concluded that compared to open resection, laparoscopic resection for locally advanced rectal cancer is associated with more favorable overall survival.

Thus in these large retrospective and prospective single-institution studies, the data consistently demonstrate improved early postoperative outcomes with no negative impact on oncologic outcomes, and even improved oncologic outcomes in some series. Interestingly, the potential for improved TME specimens has been demonstrated in an elegant study by Gouvas et al.[150] in 39 open and 33 laparoscopic proctectomies.

A more recent single-institution randomized controlled trial was reported by Lujan et al.[151] After neoadjuvant chemoradiation, 204 patients with mid- and low-rectal cancer were randomized to open (103) or laparoscopic resection (101). Sphincter preservation rates were not different, 78.6 and 76.2% in the open and laparoscopic group, respectively. Complication rates and involvement of CRM rates were similar, but the lymph node retrieval rates were greater in the laparoscopic group (mean 13.6 vs. 11.6). There were no differences in oncologic outcomes in terms of local recurrence, disease-free, or overall survival.

Concerns still remained regarding the applicability of laparoscopic techniques for rectal cancer outside highly specialized, high-volume institutions. For this reason, there are several multicenter randomized trials in various stages of accrual. In the USA, a prospective, multicenter randomized trial was established to determine the feasibility, reproducibility, and oncologic applicability of minimally invasive techniques in the resection of rectal cancer.[152] This study is currently accruing patients under the auspices of the ACOSOG Study AZ6051.[153] The primary objective of the trial is to test the hypothesis that laparoscopic resection of rectal cancer is not inferior to open resection. Outcomes being measured are based on a composite primary endpoint of oncologic factors which are considered to indicate a safe and feasible operation. These parameters are circumferential margin >1 mm; distal resected margin >2 cm (or >1 cm with clear frozen section in the low rectum); and completeness of TME, defined by careful evaluation by an experienced pathologist. Secondary objectives are to assess patient-related benefit of laparoscopic-assisted vs. open rectal resection (blood loss, length of stay, pain medicine utilization); to assess disease-free survival and local pelvic recurrence at

2 years; and to assess quality of life, sexual function, bowel and stoma function.

The UK MRC CLASICC trial[5,135] is close to reporting its mature 5-year data. The Japan Clinical Oncology Group Study JCOG 0404,[154] which has been evaluating laparoscopic surgery for colorectal cancer, was activated in October 2004 and is also close to reporting its long-term data. At present, the European Colon Cancer Laparoscopic or Open Resection (COLOR) II trial COLOR II is a randomized, international, multicenter study comparing the outcomes of laparoscopic and conventional resection of rectal carcinoma with curative intent.[155] Prior to its start, a feasibility study is to be performed with the objective of controlling for quality of laparoscopic TME. The primary endpoint is locoregional recurrence at 3 years. Secondary endpoints are recurrence-free and overall survival at 3, 5, and 7 years, rate of distant metastases, port site and wound site recurrences, microscopic evaluation of the resected specimen, 8 week morbidity and mortality, quality of life, and cost.

Given limited prospective data, laparoscopic resection for rectal cancer remains investigational in the USA.[156] Although it is performed in some specialist centers by experienced surgeons, open surgical resection is still the standard of care in most hands, and the role of laparoscopy is yet to be confirmed. Studies consistently show improved short-term outcomes, such as quicker recovery times, shorter hospital stays, and reduced analgesic requirements, but these are at the price of longer operative times and higher overall costs. Careful patient and tumor selection are essential. Mature 5-year data are pending from the MRC CLASICC and the JCOG 0404 trials. The European COLOR II trial and the ACOSOG-Z6051 trial, specifically comparing outcomes of laparoscopic-assisted and open resection for rectal cancer, are under way but far from reporting results.

Laparoscopic Resection of Colon and Rectal Cancer

The following description regarding the safe performance of laparoscopic resection for curable colon and rectal cancer is based on current literature and experience. The attention to technical detail is in response to the early concerns regarding oncologic outcomes. It is predicated on the understanding that patients with curable colon and rectal cancer are treated by experienced surgeons whose minimally invasive skills fulfill the Credentialing Recommendations endorsed jointly by ASCRS and SAGES.[137]

General Considerations

Following detection of a colon or rectal cancer, routine evaluation incorporates preoperative staging, assessment of resectability, and determination of the patient's operative risk. As part of this assessment, a laparoscopic approach

may be contemplated. There are several factors to consider, primarily in terms of gauging the difficulty of the procedure and the likelihood of being able to perform it laparoscopically. The site of the tumor is important, as right and sigmoid colectomy are generally less technically demanding than, for example, low anterior resection. Documented extensive adhesions may preclude a minimally invasive approach, although laparoscopic resection is frequently possible in patients who have had prior abdominal operations. Obesity, and particularly the distribution of abdominal fat, may preclude laparoscopic resection, especially in the case of a rectal cancer in an obese male patient with a narrow pelvis. The patient should be informed of both laparoscopic and open alternatives, and the possible need for conversion. Above all, the surgeon must have adequate experience prior to embarking on resection for a potentially curable malignancy. Patients are increasingly sophisticated regarding their health care, and the surgeon must be prepared to answer questions about experience with the procedure.

Tumor Localization

The entire colon and rectum should be evaluated to eliminate synchronous lesions.[157,158] This is usually achieved with colonoscopy, but this has limitations in terms of localization, particularly if a minimally invasive approach is being considered. Colonoscopy is most accurate for localization of a tumor in the rectum and cecum only. Lesions elsewhere in the colon may be inaccurately localized by colonoscopy in up to 14% of cases.[159] A laparoscopic approach requires accurate localization of the tumor to a specific segment of the colon, as even a known cancer may not be visualized from the serosal aspect of the bowel during laparoscopy. The wrong segment of colon may be removed if accurate localization has not been performed.[160]

A variety of other options are available to localize a lesion including, preoperative colonoscopic marking with ink tattoo or metallic clips, barium enema, or intraoperative endoscopy. The area adjacent to a cancer or polyp may be marked either by endoscopic clips or submucosal India ink injection. If clips are placed, immediate abdominal X-rays films should be taken; otherwise, intraoperative imaging with laparoscopic ultrasound or fluoroscopy is necessary to localize the clip's location. This procedure is not commonly employed since it requires an experienced radiologist and/or endoscopist. Preoperative endoscopic tattooing is a common method of tumor localization.[161,162] India ink is a nonabsorbable marker which has been reported in more than 600 cases for tumor localization since 1975. The ink is injected into the submucosa in three or four quadrants around the lesion, or 2 cm distal to the lesion if the tumor is in the distal colon and distal margins are potentially an issue (typically, 0.5 cc per site). During diagnostic laparoscopy the ink marking can be identified even at the flexures or transverse colon. India ink injection appears to be safe with few reported complications.

Intraoperative endoscopy is hampered by persistent bowel distention, prolongation of operative times, and need for equipment and endoscopist intraoperatively. More recent studies have evaluated CO_2 colonoscopy which allows for more rapid absorption of the intracolonic gas which may facilitate its use during laparoscopic procedures.[163]

Preoperative Staging

Guidelines are available for standard practices in preoperative assessment for open resection of colon or rectal cancer.[164,165] There are additional considerations with a laparoscopic approach to ensure accurate staging of the liver. In patients with colorectal cancer the liver should be thoroughly evaluated either using computed tomography with intravenous contrast, ultrasound, or magnetic resonance imaging. Due to limitation in tactile sensation associated with laparoscopy, these studies should be performed preoperatively. Alternatively, intraoperative laparoscopic ultrasonography offers the ability to fully evaluate the liver at the time of colorectal resection. Several studies have confirmed the feasibility and efficacy of laparoscopic ultrasound in the evaluation of liver metastasis from colorectal cancer.[166–168] Preoperative CT or US was a requirement of the COST randomized controlled trial.[29] No excess of stage IV disease was noted in the laparoscopic arm, suggesting that routine preoperative evaluation of the liver was equivalent in terms of oncologic outcome to palpation of the liver intraoperatively in the open arm of the study.

These considerations do not apply to rectal cancer, where staging CT scan and transanal rectal US should be routine.[165,169] Preoperative CT of the abdomen and pelvis or hepatic US are routinely utilized in planning resection of rectal cancer, as the results may markedly alter the need for neoadjuvant therapy and the timing of the operative approach.

Perioperative Preparation

Perioperative guidelines address the use of outpatient bowel preparation, prophylactic antibiotics, blood cross matching and thromboembolism prophylaxis.[164] None of these aspects of patient care are affected by a laparoscopic approach, although some surgeons prefer to modify the bowel preparation. Despite lack of clear evidence of benefit from meta-analysis[170] and randomized controlled trials,[171–175] a mechanical bowel preparation is commonly used in North America. Aside from the aesthetic aspects, an empty colon facilitates manipulation of the bowel with laparoscopic instruments. Use of large volume mechanical bowel preparations may occasionally leave fluid-filled loops of small bowel that are more difficult to handle with laparoscopic instruments. A smaller volume preparation may be used or the large volume preparation may be followed by use of laxatives such as bisacodyl to reduce the volume of residual fluid. Some surgeons use 2- to 3-day periods of preparation rather than the

usual 24 h, especially if a completely laparoscopic approach and intracorporeal anastomosis is contemplated.[176]

Operative Issues

Certain operative principles pertain specifically either to the colon or to the rectum. Other issues are relevant to both.

Operative Techniques: Colon

Oncologic principles must not be compromised by a laparoscopic resection for colon cancer. Guidelines for colon cancer surgery outline recommendations for: proximal and distal resection margins (based upon the area supplied by the named feeding arterial vessel); mesenteric lymphadenectomy containing a minimum of 12 lymph nodes; and ligation of the primary feeding vessel at its base.[177] The randomized trials of laparoscopic colectomy adhered to these standard principles[5,29,134,136] and showed no significant difference in bowel margins, lymph nodes harvested, and, in the COST study, perpendicular length of the mesentery (a guide to the length of the vascular pedicle).[29] Inability to achieve these aims laparoscopically should prompt conversion to an open procedure.

These principles guide which steps of a procedure performed for cancer may be completed intracorporeally or extracorporeally. In the individual with a normal body mass index (BMI) undergoing right colectomy, it may be possible to divide the origin of the ileocolic pedicle extracorporeally using a small periumbilical extraction incision which overlies the base of the pedicle, and achieve an oncologically correct proximal ligation; intracorporeal ligation is obviously also an acceptable approach. In patients with BMI > 25, this ligation should be performed intracorporeally to ensure the base of the pedicle is ligated. Intracorporeal ligation is required for proximal division of all other vessels unless a larger incision such as used for hand-assisted devices permits access via the incision to the origin of the vascular pedicle.

Operative Techniques: Rectum

Similar guidelines exist for oncologically appropriate open rectal cancer surgery, with levels of evidence and grades of recommendation.[165,169] These include a distal margin of 1–2 cm, removal of the blood supply and lymphatics up to the origin of the superior rectal artery (or inferior mesenteric artery if indicated), and appropriate mesorectal excision with radial clearance. Again, these principles of adequate clearance of the primary tumor and supporting tissues should not be compromised by a laparoscopic approach.

There is little data from randomized trials evaluating laparoscopic resection of rectal cancer.[5,142,151] Current opinion among laparoscopic experts is that the principles outlined apply equally to laparoscopic as to open procedures. Prospective and retrospective case series[138–141,143–149,178–181] indicate that laparoscopic rectal resection is possible in selected patients. Compared with colonic resection, additional technical challenges are associated with operating within the confines of the pelvis. Multiple factors affect feasibility of an oncologically adequate laparoscopic resection for rectal cancer: tumor factors such as bulkiness, proximal or distal location; and patient factors, e.g., width of the pelvis, obesity, presence of a bulky uterus, and obscuration of tissue planes by prior radiation. Inability to perform an appropriate resection should prompt conversion.

Contiguous Organ Attachment

En bloc resection is recommended for locally advanced adherent colorectal tumors.[177] A bulky tumor invasive into an adjacent organ may be detected by preoperative imaging, such as CT scan, and guide the recommendation for an open resection. A known T4 colonic cancer will prompt an open approach in the vast majority of cases,[177] although some experienced surgeons may complete en bloc resection of involved small bowel or abdominal wall laparoscopically. If a T4 lesion is discovered intraoperatively, conversion is indicated unless the surgeon is capable of performing en bloc resection.

Prevention of Wound Implants

Port site recurrences, or wound implants, have been reported at both extraction site and trocar site incisions.[130,182] This unanticipated phenomenon has prompted extensive investigation. Current consensus is that wound implants should be kept at a rate less than 1% by correct oncologic technique and experience.

In vitro and in vivo animal models, not clinical practice, have generated most recommendations for avoidance of wound implants. Avoidance of the pneumoperitoneum and alternative gases has been evaluated. Gasless laparoscopy has shown decrease in port site metastases,[183,184] and no effect.[185,186] Tumor growth may be proportional to insufflation pressure.[187] Carbon dioxide is associated with increased tumor implantation and growth,[188] but is clinically the safest and most widely used gas. Helium decreases tumor implants but is not easily adapted to the clinical setting.[189–191] Wound excision may either decrease[192] or increase[193] the rate of tumor implants.

Some experimental results are easily adapted to the clinical setting. The significance of aerosolization of tumor implants is controverisal,[194,195] but as evacuation of the pneumoperitoneum via the ports rather than via the incision is easily performed; some experts advocate this practice.[196] Gas leakage along loosely fixed trocars (the "chimney effect") may be associated with increased cancer wound implantation[197] so some surgeons fix the trocars to prevent slippage. Irrigation of the abdominal cavity and/or trocar site incisions with a variety of substances (e.g., povidone-iodine, heparin, methotrexate, cyclophosphamide, taurolidine, and 5-fluoro-uracil) has decreased wound implants in animal models.[68,186,190,198–212]

An expert panel convened by the European Association of Endoscopic Surgery (EAES) reported that half the members irrigated the port sites and all members protected the extraction site and/or extracted the specimen in a bag. [196]

The most important development in the issue of wound implants is experience and the refinement of laparoscopic techniques and equipment that permit a true oncologic resection to be performed. Early reports of implant rates of 2–21% [130,182] have not been reproduced in large retrospective series by experienced surgeons, who reported rates of 1% or less. [131] This is similar to the incisional recurrence rate for open colorectal cancer resection. [204] The multicenter randomized trial from the COST study group reported tumor recurrence in the surgical wounds in 2 of 435 laparoscopic cases (0.5%) and in 1 of 428 patients in the open colectomy group (0.2%, $P = 0.50$). [29] Lacy, in a single-center randomized trial, reported 1 implant in 111 patients for a rate of 0.9%. [134] The COST study required all surgeons to have performed at least 20 colorectal resections prior to participation in the trial. [29] The member surgeons at Lacy's institution had extensive experience. In the clinical setting, the experience of the surgeon is considered the most important factor in the prevention of implants.

Training and Credentialing in Laparoscopic Colorectal Surgery

In terms of technical complexity, laparoscopic colon and especially rectal operations are considered toward the higher end of the spectrum. Adequate resection mandates mobilization of a large structure, arranging ports to facilitate dissection in several quadrants of the abdomen, ligation of large blood vessels, extraction of a bulky specimen, and creation of a safe anastomosis. Oncologic resections have the additional requirements of adequate distal and proximal margins, wide lymphadenectomy, ligation of the origin of the primary feeding vessel, and safe handling of the bowel.

Early studies estimated the learning curve for laparoscopic colectomy to be 20–50 cases. [1–3] The randomized, controlled multicenter COST study on laparoscopic vs. open colectomy for colon cancer required each participating surgeon to have performed 20 cases. [24] This was also seen in the CLASICC trial. [5] This figure became the basis of the Approved Statement from the ASCRS and endorsed by SAGES following the publication of the results of the COST study. [137] Since the results of this trial showed that the oncologic outcomes for laparoscopic colectomy were equivalent to those of open colectomy, the statement took the unusual step of defining a specific number of cases based on the study entry criteria. The following is the approved statement:

> Laparoscopic colectomy for curable cancer results in equivalent cancer related survival to open colectomy when performed by experienced surgeons. Adherence to standard cancer resection

techniques including but not limited to complete exploration of the abdomen, adequate proximal and distal margins, ligation of the major vessels at their respective origins, containment and careful tissue handling, and en bloc resection with negative tumor margins using the laparoscopic approach will result in acceptable outcomes. Based upon the COST trial, [29] prerequisite experience should include at least 20 laparoscopic colorectal resections with anastomosis for benign disease or metastatic colon cancer before using the technique to treat curable cancer. Hospitals may base credentialing for laparoscopic colectomy for cancer on experience gained by formal graduate medical educational training or advanced laparoscopic experience, participation in hands-on training courses and outcomes. [137]

The issue of defining numbers for credentialing purposes is a source of considerable controversy. [205] National surgical societies have traditionally avoided specifying required case numbers in credentialing guidelines, trying to balance the needs of their member surgeons with the safety of patients. The learning curve for laparoscopic colectomy likely varies depending on the actual procedure (as the term "laparoscopic colectomy" in this case encompasses a wide variety of procedures, from simple right colectomy to advanced proctocolectomy and J-pouch), the underlying pathologic diagnosis, and the prior laparoscopic experience of the surgeon coupled with innate skill. The COST study, however, provides a basis for specifying a minimum experience. For perspective, a resident completing a General Surgery Residency Program in 2003 and entering practice had performed a mean of 120 cases on the large intestine (mode 106, Residency Review Committee for Surgery, Reporting Period 2002–2003). Of these, an average of 50 cases required resection and anastomosis. Thus the guideline for 20 laparoscopic cases is not excessive or unreasonable in terms of attaining comparable experience prior to independent practice.

Alternative Approaches

Hand-Assisted Laparoscopy

Hand-assisted laparoscopic colectomy has been advocated as an alternative to straight laparoscopic techniques. The reintroduction of the hand back into the abdomen during laparoscopy may overcome some of the technical challenges associated with laparoscopic colectomy. Since an extraction site is required for specimen removal, supporters of a hand-assisted approach believe the hand should be placed through that wound to facilitate dissection and mobilization of the colon. Current hand-assist devices provide for hand exchanges without loss of pneumoperitoneum, allowing surgeons to perform procedures without disruption, unlike earlier versions. Opponents point out that the incision required for the hand-assist device, although smaller than for laparotomy, is still approximately twice the length of the incision required for a straight laparoscopic procedure.

There have been a number of randomized and nonrandomized studies which have evaluated hand-assisted laparoscopic

colectomy.[68,206–215] In 1995, Ou[206] reported his initial experience in 12 patients undergoing colectomy by hand-assisted methods and compared it to 12 patients undergoing a conventional open method. He demonstrated that the hand-assisted procedures required on average 135 min as compared to 100 min for the standard open method. Length of stay was reduced in the hand-assisted group with an average of 5.6 days as compared to 8.3 days for open patients. Randomized trials by the HALS Study Group[209,210] and Targarona[211] have demonstrated that hand-assisted colectomy provides similar functional results to straight laparoscopic resection with fewer conversions. In a randomized study by Kang et al.[213], comparing hand-assisted vs. open colon resection, the hand-assisted approach resulted in shortened postoperative ileus, shortened length of stay, and smaller incision size with no difference in operative time or complications. Differing results were seen in another randomized study by Maartense et al.[214], which compared the results of open proctocolectomy with ileoanal pouch construction to a hand-assisted approach. In this study, there was no difference in length of stay (>10 days) and longer operative times in the hand-assisted group. The majority of patients, however, were not diverted at the time of procedure which likely impacted the results of the operation. In a study of straight laparoscopic proctocolectomy with ileoanal pouch, patients who were not diverted had a prolonged hospitalization in comparison to those who were diverted.[58] The long length of stay in the Maartense[214] study may relate to the avoidance of proximal fecal diversion and likely influenced their results and conclusions.

Nonrandomized studies have shown benefit to the hand-assisted approach in comparison to a straight laparoscopic technique, but most have a limited number of any single procedure. A study by Chang, however, did report on a large series of laparoscopic and hand-assisted sigmoid resection.[99] The results of 85 straight laparoscopic sigmoid resections were compared to 66 hand-assisted procedures. The patients shared similar demographics including a mean body mass index of 29 kg/m^2. The rate of conversion was significantly less in the hand-assisted group (0% vs. 13%, $P<0.01$) with a shortened mean operative time (189 min vs. 205 min). The mean size of the extraction was larger in the hand-assisted group (8 cm vs. 6 cm, $P<0.01$) but there was no difference in return of bowel function (mean, 2.5 days vs. 2.8 days) or the median length of stay (4 days).

One of the more challenging colorectal procedures is proctocolectomy and ileal pouch-anal anastomosis. While a few groups perform this procedure routinely, the procedures remain technically challenging with operative times in the 3–5 h range. In an effort to reduce operative times, hand-assisted techniques have been evaluated.[56,66,68] In a small comparative study, Rivadeneira et al.[66] compared the effectiveness of hand-assisted laparoscopic approach to a conventional laparoscopic method in patients undergoing laparoscopic proctocolectomy. Both groups (10 hand-assisted [HAL] vs. 13 standard laparoscopy [SL]) were well matched, with no

differences in age, sex, ASA level, operative indication, steroid usage, or diagnosis. The results demonstrated no differences in incision size (mean 8 cm), operative blood loss, rate of conversion (HAL 10% vs. SL 0%), or complications (HAL 40% vs. SL 31%). The operative times progressively decreased in the hand-assisted group (mean 247 min) while remaining constant in the laparoscopic group (mean 300 min, $P<0.05$) over the period of study. This reduction in operative times has also been demonstrated in a multicenter randomized study of laparoscopic vs. hand-assisted sigmoid and total colectomy, with significantly shorter operative times in the hand-assisted group (175 min vs. 208 min in the sigmoid colectomy group, and 127 min vs. 184 min for total colectomy).[56] Another recent study by Nakajima showed similar advantages of hand-assisted total colectomy for ulcerative colitis.[68] Interestingly, the opposite was found in a case–control study from Mayo Clinic comparing 100 laparoscopic IPAA with 200 open cases.[71] Operative time for the laparoscopic group as a whole was 333 min vs. 230 min in the open group. Within the laparoscopic group, however, 75 cases were performed with a true laparoscopic approach primarily by one surgeon, and compared with 25 hand-assisted cases performed by four surgeons. The hand-assisted cases actually took longer, 372 min vs. 320 min in the true laparoscopic group, and hospital stay was a day longer (5 days vs. 4 days).

Proponents of the hand-assisted approach suggest that by returning the hand back to the abdomen, one of the potential advantages is that surgeons with less advanced laparoscopic skills may be able to perform these complex procedures more easily. In the study by Chang et al.,[99] colorectal surgeons without a large laparoscopic experience participated in 27% of hand-assisted resections compared to only 16% ($P<0.05$) of the straight laparoscopic procedures. In a similar study, comparing 85 straight laparoscopic total colectomy procedures to 45 hand-assisted operations, less experienced surgeons were able to perform 22.2% of the hand-assisted procedures and only 10.6% of the straight laparoscopic operations.[215] One interpretation is that a hand-assisted laparoscopic colectomy may be easier to adopt than a straight laparoscopic approach; an alternative interpretation is that these rates of adoption are unacceptable even with the device and perhaps such surgeons should not be attempting laparoscopic procedures.

Robotic Colorectal Surgery

The robotic device allows for precise control of movement, restoration of all the "degrees of freedom" provided by the human wrist, magnification and three-dimensional images. The most convincing application to date has been in the field of urology, where the device has allowed for intracorporeal suturing of the bladder to urethra anastomosis. Even this has been challenged recently.[216]

In the field of colorectal surgery, the use of the device remains controversial. It is hard to justify its use in

colectomies. Even those who have used it for right and left colectomy have demonstrated increased operative times and increased costs.[217] It may potentially have a greater role in the resection of rectal cancer. Baik et al.[218] reported a series of 56 robotic vs. 57 laparoscopic low anterior resections for rectal cancer. The operative times were similar (190 min vs. 191 min). One benefit of the robotic approach was a reduced risk of conversion (0 in the robotic group vs. 10.5% in the laparoscopic group, $P = 0.013$). The quality of the TME specimen was acceptable in both groups, but there were more complete specimens in the robotic group: the mesorectal grade was complete ($n = 52$) and nearly complete ($n = 4$) in the robotic group and complete ($n = 43$), nearly complete ($n = 12$), and incomplete ($n = 2$) in the laparoscopic group ($P = 0.033$). Choi et al.[219] in a series of 50 patients undergoing a standardized step-by-step approach, demonstrated a positive circumferential radial margin in only 1 of 50 patients (2%).

Patriti et al.[220] evaluated 66 patients with rectal cancer. Twenty-nine patients underwent robotic anterior resection (RAR) and 37 laparoscopic anterior resection (LAR). Groups were matched for age, BMI, sex ratio, ASA status, and TNM stage and were followed up for a mean time of 12 months. RAR resulted in shorter operative times when a total mesorectal excision was performed (166 min vs. 210 min; $P < 0.05$). The conversion rate was significantly lower for RAR, with 19% conversion to open rate in the LAR group, and in the robotic group only two patients were "converted" to a laparoscopic approach but with no conversions to an open approach ($P < 0.05$). Postoperative morbidity was comparable between groups. Overall survival and disease-free survival were comparable between groups; although a trend toward better disease-free survival in the RAR group was observed, the follow-up period was short. The authors concluded that RAR was a safe and feasible procedure that facilitates laparoscopic total mesorectal excision, but randomized clinical trials and longer follow-up are needed to evaluate a possible influence of the robotic approach on patient survival.

Consensus has not been reached on this approach. It is salutary to read the editorial of Cadeddu et al.[216] on robotic prostatectomy. He reflects upon the issue that marketing of the robotic device has reached such heights that opinion has "reached the level of surgical dogma among patients and physicians at the expense of objective data." The robotic device fascinates surgeons and patients alike. It is a wonderful tool. But it remains just that – a tool. Many surgeons who are currently performing advanced laparoscopic colorectal procedures have skills such that they do not require a robot. The robot may facilitate dissection in the pelvis for rectal cancer, especially for surgeons who might not otherwise be able to complete a pelvic dissection laparoscopically, but it remains to be seen if the current economic climate will continue to support expensive technology to support lack of acquisition of operative skills.

Single-Incision Colectomy

This development of single-incision colectomy is still in its seminal stages. Initial publications are primarily case reports, or press releases.[221–224] At the time of writing, there is considerable interest amongst laparoscopic aficionados regarding the potential for improved outcomes with this approach. As interest in the approach has grown, new single-port devices have been developed and several are available for use, each with their pros and cons. Reports have expanded from the original cholecystectomy,[225] to include appendectomy, sleeve gastrectomy, adrenalectomy, and colectomy. A multicenter prospective comparative study is underway to compare early results of single-incision colectomy with laparoscopic procedures. Given the difficulty of demonstrating benefits of the laparoscopic approach with laparotomy, any incremental benefits may be very difficult to confirm with current methodology, but an initial impression is that surgeons involved in this development are motivated regarding the potential benefits for their patients.

NOTES Colectomy

Natural orifice transluminal endoscopic surgery (NOTES) became a focus of intellectual and surgical creativity after the pairing of a surgeon and a gastroenterologist in India led to the release of a video of an appendectomy performed via a gastrotomy with flexible endoscopic instruments, with extraction of the specimen transorally.[226] It is now 5 years and millions of dollars of research and development money later, yet the approach is still seeking what Jeff Ponsky has referred to as the "Killer App" or the application that transcends obstacles to its use (personal communication). Although surgeons see this approach as potentially being the same quantum leap in surgical technique that laparoscopy was compared with laparotomy, there are different barriers.

There are basically three different areas of research that pertain to colorectal surgery. First, the rectum has been highlighted as a means of access to upper abdominal organs. Early procedures focused on cholecystectomy, as a common procedure, requiring limited dissection, control of a single duct and artery, and no requirement for any form of re-establishment of gastrointestinal continuity. The transgastric approach is hampered by the need for retroflexion to visualize and work on the gallbladder, need to close a gastrotomy far from the "working port" (the mouth) and limitations of the diameter of the esophagus in terms of extracting a bulky specimen. Hence, attention was redirected to using transrectal and transvaginal approaches which would permit forward-focusing of the flexible endoscopic instruments and extraction of a larger specimen. The transvaginal approach has been used primarily, as the majority of patients requiring cholecystectomy are female, and this approach affords greater confidence in the quality of the preparation. The transrectal

approach does have its merits, however, and transrectal endoscopic microsurgery (TEMS) has illustrated that this path of access can be adequately prepped.

Second, and likely least pertinent, the rectum has been used as a means of obtaining access to the peritoneal cavity with a flexible instrument that is then used to perform dissection and resection of a segment of colon. Transgastric, and bidirectional approaches with both transgastric and transrectal approaches have been described. These are *tour-de-forces* of technique but not immediately relevant to clinical practice.

The third area of research has focused on use of the TEMS device as a means of access. This makes sense that the planned anastomotic site becomes the means of access to the abdominal cavity and has implications for sigmoidorectal surgery (and also for bariatric surgery with upper endoscopy using the planned anastomotic site). Several groups have described using the TEMS device to make a circumferential incision in the rectum at the planned level of anastomosis, and then continuing the dissection in the presacral space and the left retroperitoneum [227–230] The technique does not reliably allow for mobilization of the splenic flexure, so again, applications are limited at this point with current instrumentation.

Future Considerations

It is actually quite fascinating to see how slowly laparoscopic techniques for colorectal surgery have been adopted. The procedures are likely similar in terms of technical difficulty to bariatric procedures, yet the vast majority of bariatric procedures are performed laparoscopically as opposed to less than 30% of colorectal procedures. One wonders if market forces are implicated, as many bariatric procedures are not covered by insurance and the patient pays out of pocket. Over the next few years, the field of colorectal surgery may become quite divergent, especially within the subspecialist field of minimally invasive procedures. Surgeons who have adopted hand-assisted techniques may not be able to adopt single-incision techniques, if the latter prove to have benefits. The realm of NOTES is still undetermined but there will likely be considerable cross-fertilization with the techniques and instrumentation used for single-incision procedures. Bemelman [231] phrased this upcoming period best: when fast-track protocols make it difficult to differentiate laparoscopic from open approaches, then the long-term implications of a laparoscopic approach carry far more weight than such short-term benefits as time to bowel function and time in the hospital. More important are long-term outcomes such as rates of bowel obstruction and preservation of fertility. This is an exciting time for this field, not least for our patients who will hopefully continue to benefit from the extensive efforts being expended in making these major procedures less invasive.

Polyps

Paul E. Wise

Polyps are defined as pathologic epithelial elevations of the aerodigestive and genitourinary tracts. This term serves to describe any of the types of abnormal growths identified on or involving the colonic mucosa that protrude into the bowel lumen. Polyps are of concern to clinicians due to their malignant potential depending on the histologic type of the polyp identified. The primary histologic colonic polyp types include the following: adenomas, serrated polyps (including hyperplastic polyps and sessile serrated adenomas (SSAs)), hamartomas, and inflammatory polyps. Because some of these polyps are neoplastic, they are the target of screening modalities (including colonoscopy, computed tomography (CT) colonography, etc.) to remove them prior to their malignant degeneration. Other polyp-like lesions, usually submucosal rather than mucosal in nature, such as carcinoids, leiomyomas, and lipomas will be described and discussed in Chap. 49.

Adenomas

Definition and Pathology

Adenomas are the most common neoplastic polyps identified in the colon (50–67% of all polyps) and are thought to be the precursor lesion to the majority of colorectal cancers (and therefore the target of screening programs).[1] They are by definition a low grade dysplastic lesion with the potential for progression of the dysplasia to an invasive malignancy. Grossly, these lesions can be pedunculated (mushroom-like on a stalk of submucosa lined by normal mucosa, Figure 36-1) or sessile with a broader base (Figure 36-2), can occur singly or as multiple lesions, and can vary greatly in size and extent.

Adenomas are classified as tubular, villous, or tubulovillous. The former lesions comprise approximately 75–87% of all adenomas identified in the colon and contain uniform-sized tubules and glands. As the tubules become more elongated with less stroma between glands, they assume a more villous character. For pathologists, tubular adenomas (Figure 36-3) can consist of up to 20–25% villous features and still be considered

a "tubular adenoma" while villous adenomas (5–10% of all adenomas) contain more than 50–75% villous features, making tubulovillous adenomas (8–15% of all adenomas, Figure 36-4) those polyps in between.[2,3] While the likelihood of a polyp to harbor malignancy may be impacted by this classification, the treatment for the three classes of adenomas remains the same and thus has little true clinical significance.

Adenomas are differentiated from hyperplastic polyps in that they display cellular atypia with lack of differentiation into specialized cell types. The epithelial lining will show increasing mitoses and some degree of hyperchromasia (darker hematoxylin and eosin staining) depending on the degree of dysplasia. In adenomas, because cellular proliferation is not limited to the lower half of the tubule as in normal colonic epithelium, the normal process of cellular maturation and differentiation from the base of the crypt to the surface does not occur.

Adenomas can be graded by the degree to which epithelial growth is disturbed. Mild or low grade dysplasia is characterized by tubules which are lined from top to bottom by epithelium which is morphologically similar to the normal basal proliferative zone. The nuclei are enlarged, oval, hyperchromatic, and have normal orientation. There is a slight excess of mitotic figures but the architecture is not disrupted. By definition, all adenomas show at least low grade dysplasia. In moderate dysplasia, the nuclear features are more advanced, cellular polarity is less preserved, there is nuclear stratification, and the glands are more crowded. In severe or high grade dysplasia, there are large vesicular nuclei, irregular and conspicuous nucleoli, scalloped nuclear membranes, and increased nuclear to cytoplasmic ratio. Nuclear polarity is disrupted and marked cellular pleomorphism and both numerous and aberrant mitoses are present. Structural alterations include budding and branching tubules, back-to-back arrangement of glands, and cribriform growth of epithelial cells in clusters and sheets. The terms "carcinoma *in situ*" and "intramucosal carcinoma" are often used to describe these high grade dysplastic adenomas, but these terms are potentially misleading as these lesions do not have metastatic potential.[4,5]

Presentation and Diagnosis

Most adenomas are asymptomatic and are therefore found with screening studies or incidentally diagnosed through investigations of symptoms unrelated to the adenoma. Larger adenomas may display overt hematochezia or anemia secondary to occult or overt blood loss. Adenomas in the rectum may cause rectal bleeding, mucoid discharge, tenesmus, and/or fecal urgency. Very large adenomas may rarely cause electrolyte abnormalities or diarrhea or may lead to intussusception of the colon or prolapse through the anus.

Adenomas are often multifocal and can be identified anywhere in the colon and rectum but tend to be more prevalent distally. In one large prospective study (U.S. National Polyp Study), the distribution of adenomas was as follows: cecum 8%, ascending colon 9%, hepatic flexure 5%, transverse colon 10%, splenic flexure 4%, descending colon 14%, sigmoid 43%, and rectum 8%.[3] Other studies have also documented that 24–31% of adenomas are proximal to the splenic flexure in colonoscopies in higher-risk or symptomatic patients.[3,6] In addition, when a sporadic adenoma is identified in the colon or rectum, the likelihood of a synchronous adenoma elsewhere in the colon ranges from 31 to 40%.[6,7] Therefore, when a distal adenoma is found, a complete colonic assessment is necessary because of this high rate of synchronous neoplasms.[8,9] The features of the adenomas may dictate the likelihood of synchronous lesions being found, however. Most, but not all,[10] studies of screening flexible sigmoidoscopy suggest that patients with no distal polyps, distal hyperplastic polyps, or a single small tubular adenoma have a low risk of proximal advanced adenomas (0–4%). Multiple other studies, however, support the recommendation that villous adenomas (regardless of size) and any adenoma >1 cm are important markers for the presence of advanced adenomas and even carcinoma in the proximal colon.[11]

The fact that adenomas are often asymptomatic precursor neoplasms justifies the use of screening to identify and remove these lesions before they become clinically recognizable, thus halting the adenoma to carcinoma sequence

(discussed below). In general, colorectal cancer screening has been shown to reduce mortality and be cost-effective. Screening timing and frequency is usually based on risk factors with higher-risk individuals having personal or family history of colorectal neoplasia, high-risk hereditary colorectal cancer syndromes, and/or the presence of inflammatory bowel disease (see Chap. 39).

Colonoscopy is the most accurate test for polyps, especially when compared to double contrast barium enema (DCBE) as shown by the U.S. National Polyp Study.[12] DCBE alone has been repeatedly shown to be less sensitive than colonoscopy (even for polyps >10 mm with a miss rate of 52%), offers no therapeutic benefit, and has not been shown to reduce cancer incidence or mortality. Colonoscopy, on the other hand, decreases the risk of colorectal cancer incidence by 76–90% and has been indirectly shown to reduce cancer mortality.[13] Flexible sigmoidoscopy has also been shown to lead to a decrease in distal colon cancer mortality as much as 80% (45% for all colorectal cancers) but does not show a reduction in deaths from more proximal cancers.[14] More recently, CT colonography or "virtual colonoscopy" has been supported as a potential screening modality.[1] Three meta-analyses (between 1,300 and 6,400 patients in each analysis) have shown sensitivities and specificities for detecting polyps ≥10 mm to be in the 85–95% and 95–97% ranges, respectively. Medium-sized polyps (6–9 mm) had lower sensitivities and specificities of 70–86% and 86–93%, respectively.[15,16] Newer screening modalities such as chromoendoscopy or dye-spray endoscopy, narrow band imaging, magnification endoscopy, and pill colonoscopy have not been established as effective means for surveillance or screening for all patients and are not equivalent in the hands of all providers. They are only considered adjunctive at this time by most surgical and medical societies and warrant further study. Further discussion of screening modalities and their effectiveness can be found in Chap. 39.

Epidemiology

Adenoma prevalence, the percentage of the population with one or more colorectal adenomas at a given point in time, is primarily a function of age, gender, and family history.[17] Colonoscopy-determined prevalence rates in asymptomatic, average-risk individuals ≥50 years range from 24 to 50%,[18–22] with the prevalence of advanced adenomas (≥1 cm in size, with villous features, and/or with high grade dysplasia)[23] varying from 3.4 to 9.5% depending on age and gender.[9,10,24] Prevalence rates have been shown to increase with age, even doubling between ages 50 and 60.[9,24] Higher adenoma prevalence rates have been identified in men, with a relative risk of 1.5 to 2.0 compared to age-matched women.[18,19,21,24] Interestingly, however, in one study of screening colonoscopies performed on 1,463 asymptomatic women ≥40 years old, 20.4% were diagnosed with an adenoma and 4.9% with an advanced adenoma. When these women were compared to a matched group of men (8.6% of whom had advanced adenomas on screening colonoscopy), almost 65% had their advanced adenomas in the proximal colon versus 34% of the men, suggesting that gender differences may lead to changes in adenoma location as well as overall prevalence.[8] In terms of family history risk, a multicenter screening colonoscopy study examining the risk of colorectal adenomas in a cohort of individuals with one affected first-degree relative with sporadic colorectal cancer found the odds ratio to be 1.5 for adenomas, 2.5 for large adenomas, 1.2 for small adenomas, and 2.6 for high-risk adenomas (see below).[25] The prevalence of adenomas and advanced adenomas is higher in relatives of individuals with colorectal cancer or adenoma at a young age, and in individuals with multiple relatives with cancer or adenomas.[26,27] Adenoma prevalence rates determined by colonoscopy are roughly double the rates determined by flexible sigmoidoscopy.[10,17] The prevalence of a proximal synchronous adenoma in a patient with a distal adenoma (or even hyperplastic polyps in some studies)[10] is such that proximal colonic assessment is warranted if a distal lesion is found on screening.[8,9]

The incidence of adenomas is the rate at which individuals develop colorectal adenomas over a specified time interval.[17] The incidence of adenomas at intervals ranging from 6 months to 5 years in post-polypectomy surveillance colonoscopy studies varies from 20 to 50%.[28–32] Most incident polyps are small, and a higher incidence has been associated with multiple adenomas at the index colonoscopy, larger size of the index adenoma, older age, and a family history of a parent with colorectal cancer.[13,28,33–36] The incidence rate of colorectal adenomas after a clearing colonoscopy is actually the sum of the true incidence rate of new adenoma formation plus the miss rate at the initial colonoscopy plus the recurrence rate of incompletely removed polyps.[17] Judging by repeat endoscopy, including studies with same day back-to-back colonoscopies, the miss rate for adenomas ≥1 cm is approximately 5%, for adenomas 6–9 mm it is approximately 10%, and for adenomas ≤5 mm it approaches 30%.[37–40] These high miss rates for small lesions suggest that many adenomas detected on surveillance colonoscopy are actually lesions that were missed during the index examination. Incident polyps are distributed more proximally, consistent with the observation that miss rates for adenomas are higher in the proximal colon.[37]

More important than the overall incidence rate of adenomas is the incidence rate for advanced adenomas and cancers, especially in the context of the above-described screening miss rates. The incidence rate for advanced adenomas ranges from 6 to 9%[23] and is closely related to the findings at initial colonoscopy.[41] Based on a pooled analysis of more than 9,000 patients in North America, of which 11.2% had advanced neoplasia (adenoma or cancer) on subsequent colonoscopy, a greater number of adenomas at initial colonoscopy, histologic features (villous architecture) of the excised adenoma, larger adenoma size, proximal adenoma location (odds ratio

[OR] 1.68; 95% confidence interval [CI], 1.43–1.98), and male gender (OR 1.40; 95% CI, 1.19–1.65) were all attributed to increased risk of development of advanced neoplasia.[32] Three or more polyps at the initial colonoscopy has been shown to increase the risk of subsequent advanced adenomas, and in the U.S. National Polyp Study, age >60 years plus a family history of a parent with colorectal cancer was also a predictor of incident advanced adenomas.[36,42] The cumulative incidence of advanced adenomas at 3 and 6 years of follow-up in the U.S. National Polyp Study in the highest risk group (three or more adenomas at baseline, or age ≥60 years plus a parent with colorectal cancer) were 10 and 20%, respectively.[42] The lowest risk group (only one adenoma and age <60 years at baseline) had an incidence of advanced adenomas of <1% at both 3 and 6 years of follow-up. The 5-year incidence of advanced adenomas in individuals with a previously negative colonoscopy is also <1%.[43] Similarly, post-polypectomy surveillance studies have shown that cancer incidence is also low, and in the U.S. National Polyp Study, colonoscopic surveillance was associated with a 76–90% reduction in the cancer incidence compared to reference populations.[36] The rare appearance of incident cancers at short intervals in patients who have had a clearing colonoscopy suggests that either the neoplasm was initially missed or incompletely treated (27–31% of incident cancers may be due to "ineffective" polypectomy)[44] or the cancer developed rapidly. Based on long-term follow-up from the Polyp Prevention Trial, these interval cancers are even more common in those patients with a previous history of advanced adenoma.[45] Despite the initial colonoscopy miss rates, however, modeling shows that >90% of the reduced incidence of colorectal cancer over the first 5–6 years after screening colonoscopy is the result of the initial polypectomy rather than removal of adenomas at subsequent surveillance.[46] Long-term follow-up studies are ongoing.

Adenoma to Carcinoma Sequence

The idea that an adenoma would progress into a carcinoma has been based primarily on observational epidemiologic studies, clinical studies, pathologic findings, and molecular genetic studies, and therefore the evidence, while extensive, is truly circumstantial. Given the high prevalence of sporadic adenomas in the general population but the relatively low lifetime risk of developing colorectal cancer in Western countries (6% by age 85), it appears that only a few adenomas become adenocarcinomas. While not all adenomas develop into colorectal cancer, it appears that most sporadic colorectal cancers (80–85%) develop from adenomas, although there is evidence for rare *de novo* colorectal cancer development as well as other less-rare carcinoma sequences. Adenoma size seems to be important in the likelihood for malignant degeneration, and the likelihood that a diminutive tubular adenoma will progress to become an adenocarcinoma is likely very low. In a study that analyzed 7,590 adenomatous polyps to determine risk factors for high grade dysplasia or invasion, size was the strongest predictor.[5] The percent of adenomas with high grade dysplasia or invasive cancer based on the size of the polyp was: <5 mm – 3.4%, 5–10 mm – 13.5%, and >10 mm – 38.5%. No invasive cancer was found in polyps ≤5 mm. Villous change, left-sided lesions, and age ≥60 years were also associated with advanced histologic features.[5]

One longitudinal study showed that over a 3–5-year period only 4% of 213 adenomas measuring 2–15 mm increased in size.[47] A mathematical model suggested that it takes 2–3 years for an adenoma ≤5 mm to grow to 1 cm, and another 2–5 years for the 1 cm adenoma to progress to cancer.[48] For a lesion ≥1 cm, the cancer probability is 3, 8, and 24% after 5, 10, and 20 years, respectively.[49] This supports that the transformation of adenomas to cancer is a slow process, also supported by the fact that the mean age of adenoma patients precedes the mean age of cancer patients by 7 years. Overall, the yearly rate of conversion from adenoma to carcinoma has been estimated to be 0.25%, but the risk is higher depending on size and histologic factors such as the conversion rate for polyps >1 cm (3%), for villous adenomas (17%), and for adenomas with high grade dysplasia (37%).[50] Gender does not appear to affect the rate of transition from advanced adenoma to carcinoma, but age clearly impacts malignant degeneration (ranging from 2.6% at age <60 to >5% annually at age >80 years for both men and women).[51]

On a molecular level, the "traditional" pathway from adenoma to adenocarcinoma (also known as the "loss of heterozygosity" (LOH) or "chromosomal instability" (CIN) pathway), thought to account for the development of 80–85% of sporadic colorectal cancers, was elucidated from studies on patients with familial adenomatous polyposis (FAP). The process starts with a single colorectal epithelial cell undergoing a series of genetic alterations leading to the inactivation of both copies of the tumor suppressor adenomatous polyposis coli (*APC*) gene on chromosome 5q that regulates cell growth and apoptosis.[52,53] This appears to occur very early in the process of the normal epithelial cell transitioning into adenomatous tissue or low grade dysplasia by leading to increased cell proliferation. The next alteration in the pathway is thought to occur with *k-ras*, an oncogene involved in signal transduction from the cell membrane to the nucleus. Mutation of this gene (seen in 50% of colorectal cancers) in the setting of the *APC* mutation appears to lead to exophytic growth and transition to an "intermediate" adenoma. Important to the transition from intermediate to advanced adenoma is mutation of the deleted in colon cancer (*DCC*) gene that is important for encoding an adhesion molecule and facilitating apoptosis and therefore tumor suppression.[54] The final step to the development of invasive adenocarcinoma (found in 75% of colorectal adenocarcinomas) is a mutation in the p53 gene which regulates the cell cycle after DNA injury to allow for DNA repair.[53] The accumulation of some or all of these molecular abnormalities is therefore associated with the development of invasive colorectal cancer. As noted,

however, not all colorectal cancers develop via this sequence, and alternate pathways to colorectal cancer are being increasingly recognized including pathways that may involve other polypoid lesions such as serrated polyps known as the "serrated neoplasia" pathway (see below), thought to account for the other 10–15% of sporadic colorectal cancers. This pathway is characterized by cancers showing microsatellite instability (MSI), likely due to hypermethylation of the *hMLH1* mismatch repair gene promoter leading to its inactivation, likely occurring after *BRAF* (a serine-threonine kinase involved in the *k-ras* pathway) gene mutations. These cancers are morphologically and pathologically similar to the MSI cancers that are associated with the germline mismatch repair gene mutations seen in hereditary nonpolyposis colorectal cancer (HNPCC)/Lynch syndrome (see Chap. 37).[55–57] While these cancers do appear to develop through an adenoma-carcinoma sequence, the adenomas are not considered the traditional adenomas seen in the *APC* adenoma-carcinoma sequence and are more likely the SSAs discussed below. See Chap. 38 for a more detailed review on the molecular basis of carcinogenesis.

Management

All adenomas or apparent adenomas should be completely removed for confirmation of the diagnosis and to exclude a concurrent malignancy and the potential need for further intervention. The majority of adenomas are able to be endoscopically removed by various means including "cold" (without electrocautery) or "hot" (with electrocautery) biopsy forceps or loops/snares. Removal also precludes malignant degeneration. Complications of polypectomy, primarily bleeding and perforation can be limited through the appropriate use of these standard techniques. Electrocautery is frequently used during endoscopy, but the amount of thermal injury must be balanced with the need for vascular control, as a full thickness injury to the colon wall can easily occur given that it ranges from only 1.7 to 2.2 mm in thickness.[58] Prospective assessments are lacking as to how best to approach small polyps, and therefore preferences vary between endoscopists. Because of the concern for perforations related to the use of cautery, recommendations include limiting the use of hot forceps to small polyps (<5 mm) while tenting the mucosa and somewhat deflating the colon. The majority of these smaller polyps are usually amenable to single-bite or piecemeal excision with cold forceps that will eliminate the cautery risks.[44]

Large pedunculated polyps can often be removed with snare cautery techniques (although bleeding is uncommon after removal of these). The important aspect of removal of these types of polyps is to ensure that the blood supply through a thick stalk (>1 cm), which may contain substantial vasculature, is controlled prior to the polypectomy. This maneuver is facilitated by gently closing the snare and cauterizing the base of the stalk followed by firmer closure and cutting through the stalk with cautery above the initial cauterized base. Alternatively, metal clips or endoloops can be placed at the base, or the stalk can be injected with epinephrine to provide hemostasis. The base of the stalk may be tattooed with ink or carbon agents to allow for subsequent identification (endoscopically or surgically) if the polyp has a concerning appearance for malignancy. At times, piecemeal resection of the polyp head is necessary before a large snare can even get around the polyp to reach the stalk.[44]

Larger sessile polyps (>15–20 mm) will usually require piecemeal resection with a large snare cautery. Care must be taken to ensure only inclusion of the polyp and its surrounding mucosa in the snare as accidental inclusion of adjacent folds or mucosa can potentially lead to perforation. Safe polypectomy while avoiding injury to surrounding normal tissues may also be facilitated by saline lift as described below. When performing a standard piecemeal polypectomy, starting on the proximal aspect of the polyp with or without using a spike-tip snare (allows the snare to be anchored so that pushing the sheath causes the snare loop to widen for more effective placement around the polyp) will allow for easier and more complete polyp resection. While the piecemeal technique is an effective means of removal, it requires meticulous removal of the entire polyp and capture of the pieces. This technique ensures that pathologic examination of the polyp will be complete, although the margins will be unclear when the specimen is resected in this fashion. Larger pieces might require basket retrieval, division of the larger pieces with the cold snare, or may necessitate multiple insertions and withdrawals of the colonoscope to remove them.[59] Careful coagulation of the base and edge of the polypectomy defect with the argon plasma coagulator or other electrocautery device has been shown to decrease the incidence of residual polyp.[60] It is also advisable to utilize endoscopic tattooing techniques to identify the area again for subsequent examinations of the site as well as potential surgical resection if invasive cancer is identified.[44] Both the resection area itself and the opposing colonic walls should be injected to ensure identification of the area surgically if necessary. Retroflexion can also facilitate visualization and resection of difficult polyps, primarily in the rectum and right colon. Any remaining polyp tissue should be treated with argon plasma coagulation or other coagulation techniques as noted above and has been shown to be effective in decreasing recurrence of the polyp. It has been repeatedly shown in retrospective studies that endoscopic resection of large polyps can be performed safely with low risk of perforation (rare and often treatable nonoperatively, although 5% can be fatal)[44] or bleeding (2–24%, treatable medically or endoscopically).[59] If a polyp is too large for a safe polypectomy (piecemeal or otherwise) to be performed, a conventional oncologic surgical resection should be done.

Submucosal injection of various agents has been utilized to elevate and more safely facilitate endoscopic resection of large sessile polyps in the colon and rectum by elevating the submucosa and thus increasing the distance between

the mucosa and the muscularis propria.[59] This operation not only decreases the risk of perforation but also increases the potential for complete excision. Agents that are useful include saline with or without methylene blue (to distinguish the layers) and with or without epinephrine. Other agents used to slow absorption of the fluid and prolong the elevation effect during the polypectomy include 0.5% sodium hyaluronate and 0.83% hydroxypropyl methylcellulose. Carbon/ink solutions can also be used to both tattoo the area for subsequent identification as well as elevate the polyp. The volume of the agent to use is not standardized, but injection of 1–4 mL at a time to create swelling of the submucosa, and up to 20–30 mL or greater may be needed for larger polyps. Injection distal to a polyp (along the front edge on retrograde view) may obscure the view and make polypectomy more difficult. Therefore, starting with proximal injections (far edge of the polyp) may facilitate the lateral and distal injections and thus the ability to view the polyp and allow for its subsequent removal. Failure of the polyp to elevate at the time of submucosal injection despite appropriate swelling of the submucosa ("nonlifting sign") is concerning for invasion of the polyp into the submucosa or deeper and should therefore indicate need for surgical resection.[59,61] The nonlifting sign may be falsely positive if a previous biopsy of the polyp has caused scarring in the area.

The greatest concern, of course, is whether the polyp harbors a malignancy. There are no prospective studies on how to visually identify a malignancy in a polyp, but most endoscopists seem to agree that ulceration, friability, or induration in addition to tactile clues with a biopsy forceps such as fixation or being firm suggest that there is likely an underlying malignancy and surgical resection should be favored. Biopsies may be helpful but may suffer from sampling bias. In situations where a large polyp is identified incidentally on a screening colonoscopy, a simple biopsy rather than more aggressive resection may be warranted as the patient and/or endoscopist may not be prepared for the increased complications associated with a complex polypectomy. A repeat endoscopy after further discussion and informed consent is then appropriate. If a complex polypectomy is to be performed, the patient must understand that repeat procedures may be necessary to completely remove the polyp. Of note, polyps that occupy greater than one-third the circumference of the colon, encompass two or more haustral folds, or involve a diverticulum or the base of the appendix are rarely able to be endoscopically removed.[44]

At the time of surgical resection for an endoscopically challenging polyp, intraoperative colonoscopy is a technique useful for localizing nonpalpable or softer polyps which have not been preoperatively tattooed. This technically can complicate a surgical resection, however, due to insufflation of the colon and potentially the small bowel. Use of carbon dioxide insufflation rather than room air can help in this regard based on its quick resorption and resulting colonic decompression. It has been shown to be safe even in patients with pulmonary disease.[62] Intraoperatively maneuvering the colonoscope can

also be a challenge without having the advantage of compressing the abdominal wall to provide counter pressure and limit the colon's mobility. However, the surgeon can frequently telescope the bowel over the scope itself to an area known to be proximal to the lesion and then the mass can be found during withdrawal while desufflating the colon.

Hybrid minimally invasive and endoscopic procedures have been shown to be safe with long-term success in removing large colonic polyps.[63–65] This technique utilizes intraoperative colonoscopic polypectomy in conjunction with laparoscopic confirmation of complete polypectomy while assessing for colonic perforation or uses endoscopic assistance with a laparoscopic wedge resection of the polyp. These procedures are also best performed in combination with the use of carbon dioxide as the endoscopic gas. While the endoscopist identifies the mass, the surgeon performs diagnostic laparoscopy to examine the affected area of the colon as well as the remainder of the abdomen for other pathology. Other trocars may be placed to allow for manipulation of the bowel at the same time. As the polyp is excised endoscopically (with or without lift techniques), the exterior of the bowel can be observed for perforation or near-perforation. If this occurs, or there is an area of concern, this can be repaired or oversewn laparoscopically while the polyp is removed and examined with frozen section. Any invasive cancer or concerning features may warrant immediate laparoscopic colectomy, which would be discussed with preoperatively and consented to by the patient. This may necessitate unwarranted reservation of surgical block time if a resection is not needed but would require only one general anesthetic for the patient. Rare inaccuracy of the frozen section (if the initial pathology was benign but permanent sections showed cancer or other concerning features) might necessitate a subsequent operation. Alternatively, the diagnostic laparoscopy with or without bowel repair can be completed and the final permanent (rather than frozen section) pathologic examination performed – usually taking 2–3 days – after which the patient can undergo resection if needed. An additional hybrid option involves using laparoscopic techniques to divide intrabdominal adhesions, usually in the sigmoid colon, that prevent passage of a colonoscope to the cecum.

Surveillance

Improvements in colorectal cancer incidence and mortality rates are attributed to prevention through adenoma removal with screening and surveillance endoscopy, as well as risk factor modifications and improved therapies.[1] Patients with adenomas are at increased risk for metachronous adenomas and have been shown to have a decreased incidence of subsequent cancer with follow-up surveillance. Surveillance recommendations after colonoscopic polypectomy, therefore, are based on the estimated risk of metachronous neoplasia.[66,67] After polypectomy of large (≥1 cm) or multiple adenomas (three or more) or advanced adenomas, cancer risk is increased three- to five-fold.[68] The risk of subsequent cancer

is not measurably increased in patients with only one or two small tubular adenomas.[33,69] The U.S. National Polyp Study determined that colonoscopy performed 3 years after initial polypectomy protects patients just as well as more frequent examinations.[13] Currently, no other modalities other than colonoscopy are advocated for post-polypectomy surveillance (although CT colonography has had some support as a surveillance option for patients with <1 cm adenomas who refuse or are not candidates for colonoscopy).[1] In fact, utilizing other surveillance modalities such as fecal occult blood testing (positive predictive value in surveillance of <30%) has been ineffective at best and is currently discouraged for those patients having undergone screening colonoscopy.[46]

Current recommendations for colonoscopic surveillance based on the ASCRS Practice Parameters[70] and the joint guidelines from the American Cancer Society, the U.S. Multi-Society Task Force on Colorectal Cancer, and the American College of Radiology[1,46] are as follows (see also Table 36-1): Patients with one to two <1 cm tubular adenomas should have a repeat in 5–10 years, depending on personal and family history. Patients with advanced adenomas or cancer in a completely resected polyp or patients with 3–10 adenomas all completely removed should have a repeat colonoscopy in 3 years, assuming a complete colonoscopy in a well-prepared colon. If they have more than ten polyps, or an incomplete or poorly prepared colon, they should have a repeat in <3 years. After the follow-up colonoscopy for these conditions is clear, a repeat examination every 5 years is warranted if the repeat is normal and well-prepared. Due to a high recurrence rate after endoscopic polypectomy, patients with large, sessile adenomas that are resected piecemeal should undergo repeat in 2–6 months to verify complete removal. Even when the endoscopist believes that a large polyp has been completely removed, follow-up examinations reveal residual or recurrent polyp in approximately 14–55% of patients.[44] Once complete removal is confirmed, there should be close follow-up of these patients with the frequency based on clinical judgment (usually within 1 year). Most patients with hyperplastic polyps, except those with hyperplastic polyposis, are considered average risk depending on family and personal history otherwise and should continue routine screening. Patients with a strong family history of colorectal cancer concerning for a hereditary predisposition (e.g., HNPCC/Lynch syndrome, familial polyposis, etc.) warrant more frequent surveillance (see Chap. 37). Overall surveillance recommendations after polypectomy should be individualized based on patient age and comorbidity (e.g., after removal of a small tubular adenoma, no follow-up may be indicated in elderly patients or for those with significant comorbidity).[1]

Adenoma Prevention

Because the majority of colorectal cancers are thought to develop from adenomas, prevention of the development of adenomas has been at the center of an extensive body of work trying to prevent the development of colorectal cancer. Observational studies looking at the affect of diet initially suggested that excess dietary fat and limited dietary fiber lead to increased incidence of colorectal cancer, but prospective trials on fiber supplements (e.g., Nurses Health Study) as well as dietary fat intake did not show any decrease in adenoma development. Certain foods, especially certain fruit and vegetable types, have been shown in case–controlled trials to decrease colorectal cancer risk between 13 and 40%, but long-term follow-up in large prospective trials such as the Polyp Prevention Trial and the Women's Health Initiative have shown no difference in colon cancer incidence with dietary alterations.[22] Increased body mass index, decreased physical activity levels, red meat intake,[71] smoking, and alcohol intake have all been lifestyle issues that have been associated with increased colorectal cancer risk, but alterations in these factors have not been studied in relation to the possible improvement in adenoma or colorectal cancer development.[22,57] Folate was thought to be an effective colorectal cancer preventative agent in observational trials, but prospective trials have shown weaker effects leading to

TABLE 36-1. Colonoscopy surveillance guidelines[a]

Screening colonoscopy finding	Recommended follow-up	Comments
No polyps	10 year colonoscopy or standard screening recommendations	Assumes no familial colorectal cancer history
Small distal hyperplastic polyps	10 year colonoscopy or standard screening recommendations	Assumes no hyperplastic polyposis or familial colorectal cancer history
≤2 small (<1 cm) tubular adenomas	5–10 year colonoscopy	Timing based on clinical factors (e.g., family history, patient preference, physician judgment)
3–10 adenomas or 1 adenoma >1 cm or any adenoma with villous features or high grade dysplasia	3 year colonoscopy	All lesions completely removed. If follow-up scope shows only 1–2 small tubular adenomas, repeat colonoscopy in 5 years
>10 adenomas	<3 years colonoscopy	Consider polyp syndrome
Sessile adenoma(s) removed piecemeal	2–6 months colonoscopy to ensure complete excision	Once complete removal confirmed, subsequent follow up is based on clinical factors as above

[a]Assumes a full colonoscopy to the cecum in a well-prepared colon by an experienced endoscopist with a withdrawal time of 6–10 min from the cecum. (Adopted from Winawer SJ, Fletcher RH, Miller L, et al. Colorectal cancer screening: clinical guidelines and rationale. Gastroenterology. 1997;112:594–642.)

low enthusiasm for its use as a chemoprevention agent.[10,22] Chemoprevention methods that have been shown repetitively to lead to decreased adenoma development, however, include the intake of aspirin (relative risk between 0.65 and 0.96 for adenoma formation compared to that of controls), calcium (15% decline in adenoma risk), selenium, and cyclooxygenase-2 (cox-2) inhibitors (e.g., celecoxib).[22] Given the variable efficacy of these agents for preventing colon cancer, not all are recommended for institution as standard chemoprevention.[72] Of course, the cox-2 inhibitors have been the subject of controversy due to their association with cardiovascular toxicity that was identified during adenoma prevention trials. These agents were shown conclusively to decrease the development of advanced adenomas in high-risk individuals between 28 and 66% after 3 years of use, but the longevity of these affects was variable once the agents were discontinued due to the concerns about the cardiovascular side effects.[73,74] Further studies are ongoing to assess means to ameliorate the cardiovascular risks while preserving the chemoprevention advantages of these agents.

Special Adenomas

Rectal Adenomas

Rectal adenomas often create a more complex situation in terms of assessment and management than do colonic adenomas. When larger adenomas are encountered in the rectum, they may not be amenable to endoscopic polypectomy and therefore transanal excision or transabdominal radical resection may be necessary to ensure complete extirpation of the polyp as well as accurate pathologic assessment. For lesions in the lower half of the rectum, transanal excision is generally performed and can be facilitated with submucosal injection of saline or epinephrine under the lesion and use of any of the multitude of hemostasis devices that are available. Patient positioning and polyp exposure with appropriate retraction instruments and/or operative anoscopes can greatly facilitate removal of these sometime complex lesions. Other operative options include transsacral (Kraske or York-Mason) or transperineal approaches. For more proximal rectal lesions, transanal endoscopic microsurgery (TEM) may be appropriate. Larger lesions that extend too proximally for transanal excision will usually be best managed by anterior resection. If the lesion extends into the anal canal, anterior resection with anal mucosectomy and hand sewn coloanal anastomosis may be needed in order to maintain intestinal continuity and avoid the need for an abdominoperineal resection for a benign lesion. The technical aspects of TEM and the other noted procedures are discussed in more detail in Chap. 43.

Resection of difficult sessile rectal polyps (lower and middle third of the rectum, primarily) is best performed after full evaluation/staging for underlying malignancy using endorectal ultrasound or other staging procedure (e.g., MRI with endorectal coil). Endorectal ultrasound may offer some guidance for therapy after endoscopic polypectomy of a malignant polyp.[75] In general, however, endorectal ultrasound of these lesions is notoriously inaccurate after polypectomy due to the postprocedure inflammatory response of the local site and local lymph nodes, making accurate determination of the polyp stage difficult prior to neoadjuvant therapy or resection.[76] These staging evaluations are unnecessary if the patient is not even a candidate for radical resection or chemoradiation if an underlying malignancy were to be found.[77]

Malignant Polyps

Malignant polyps are defined as pedunculated or sessile polyps with cancer cells penetrating the lamina propria and muscularis mucosa into the submucosa. These polyps (T_1 lesions by definition) account for 2–12% of polyps in colonoscopic polypectomy series.[78–81] They may appear benign on gross endoscopic appearance and are therefore usually noted to harbor an invasive malignancy only once they are excised and examined histologically. These differ from polyps with high grade dysplasia (also called carcinoma *in situ*) in that dysplastic polyps have their malignant component superficial to the lamina propria and muscularis mucosa and therefore have no chance of metastatic spread. Dysplastic polyps require the same follow up as benign polyps as long as they are completely excised. Malignant polyps also differ from more deeply invasive cancers or larger T_1 lesions in that malignant polyps are excisable endoscopically while the more extensive lesions would require surgical resection for cure. The risk of a malignant polyp increases with patient age, degree of dysplasia noted in the polyp, and polyp size. One study noted the risk of cancer in an adenoma to be 1.3% in polyps <1 cm, 9.5% in polyps between 1 and 2 cm, and 46% in polyps ≥2 cm.[79] The risk of malignancy in another series was 2% for adenomas 0.6–1.5 cm; 19% for polyps 1.6–2.5 cm; 43% for polyps 2.6–3.5 cm; and 76% for polyps >3.5 cm.[78]

The clinical decision to proceed with further treatment after polypectomy for a malignant polyp, such as surgical resection or local excision, depends on the patient's general condition and the depth of invasion of the cancer (which offers a surrogate for the estimated risk of lymph node metastasis).[82] Haggitt's classification system of malignant polyps[83] is based on the level of invasion into the stalk of a pedunculated polyp (or the submucosa underlying a sessile polyp) (Figure 36-5):

Level 0 – noninvasive (high grade dysplasia)
Level 1 – cancer invading through the muscularis mucosa but limited to the head of a pedunculated polyp
Level 2 – cancer invading the neck of a pedunculated polyp
Level 3 – cancer invading the stalk of a pedunculated polyp
Level 4 – cancer invading into the submucosa of the bowel wall below the stalk of a pedunculated polyp. All sessile polyps with invasive cancer are level 4.
FIGURE 36-5. Anatomic landmarks of pedunculated and sessile malignant polyps. (Reprinted from Haggitt RC, Glotzbach RE, Soffer EE, et al. Prognostic factors in colorectal carcinomas arising in adenomas: implications for lesions removed by endoscopic polypectomy. Gastroenterology. 1985;89:328–36. FIGURE 36-6. Depth of submucosal invasion in sessile malignant polyps; Sm_1: invasion into the upper third; Sm_2: invasion into the middle third; Sm_3: invasion into the lower third. (Reprinted with permission from Nivatvongs S. Surgical management of early colorectal cancer. Surg Clin North Am. 2000;8:1052–5).

The stalk of a pedunculated polyp is covered by normal mucosa and has a central core of submucosa. A line drawn at the junction of normal and adenomatous epithelium is the transition between the stalk and the head of the polyp, also called the neck (level 2). The risk of lymph node metastasis is <1% for pedunculated polyps with Haggitt level 1, 2, or 3 invasion.[79,83–85] The risk of lymph node metastasis for Haggitt level 4 lesions, pedunculated or sessile, ranges from 12 to 25%.[79,86–88] In order to better estimate the likelihood of nodal metastasis for a sessile malignant polyp (Haggitt level 4),

Kudo[89] further stratified the depth of submucosal invasion into three levels (Figure 36-6):

SM_1 – invasion into the upper third of the submucosa
SM_2 – invasion into the middle third of the submucosa
SM_3 – invasion into the lower third of the submucosa

Haggitt levels 1, 2, and 3 are all considered equivalent to SM_1 while Haggitt level 4 may be SM_1, SM_2, or SM_3.

SM_3 level of invasion seems to have the greatest impact on likelihood of nodal metastases relative to SM_1 or SM_2.[81,82,86,90]

Other factors reported to be associated with an increased risk of lymph node metastases include lymphovascular invasion (LVI),[79,87,91] poor differentiation,[79,91–93] gender,[94] extensive budding, microacinar structure,[94] and flat or depressed lesions.[93] In a series of 353 T_1 sessile colorectal cancers, the risk factors for lymph node metastasis that were statistically significant on multivariate analysis included SM_3 level of invasion, LVI, and location in the lower third of the rectum.[86] In another study, only SM_3 invasion was an independent risk factor for lymph node metastases.[90] A positive polypectomy margin, regarded as inadequate treatment for a malignant polyp, has not been shown to be associated with increased nodal metastasis in some but not all studies,[95] but it is associated with increased local recurrence, distant metastases, and cancer-related death.[79] A distance of 2 mm beyond the deepest level of invasion is needed to consider the margin of polyp resection clear,[82] although there is debate as to how to define a positive margin.[95,96]

The rate of lymph node metastases from rectal lesions is not different from that of colon lesions. However, T_1 lesions in the distal third of the rectum have been found to have a higher risk of lymph node metastases than more proximal rectal lesions.[79,86] This finding is consistent with the high local recurrence rates, in the range of 5–28%, which have been observed following full thickness local excision of T_1 lesions of the distal rectum.[91,92,97,98] Controversy does exist, however, with some authors suggesting that malignant polyps in this location can actually be effectively treated endoscopically. Current NCCN guidelines for the treatment of rectal cancer recommend at least full thickness transanal excision of T_1 rectal cancers.[96]

In view of the very low risk of lymph node metastases with pedunculated polyps with invasion to Haggitt levels 1–3, these can be safely treated by margin-negative snare polypectomy. Level 4 pedunculated lesions are treated as sessile adenomas. Sessile lesions that are snared in one piece and have a margin of at least 2 mm are considered adequately treated.[82] This excision may be facilitated by endoscopic mucosal resection or other techniques described in above. If a piecemeal polypectomy was performed, margins can be difficult to assess adequately and therefore further endoscopic or surgical treatment is necessary to ensure complete removal of the polyp, staging, and cure. High-risk sessile lesions, such as those with SM_3, a resection margin of <2 mm, LVI, and/or poor differentiation should undergo appropriate oncologic resection.[79] For rectal lesions that are well- to moderately differentiated, <3 cm in size, <30% of the circumference of the bowel wall, mobile, and nonfixed, within 8 cm of the anal verge, without LVI or perineural invasion, and without evidence of nodal metastases on preoperative imaging, full thickness transanal excision with or without consideration of the use of TEM is acceptable based on NCCN guidelines.[96] Otherwise, transabdominal resection is recommended. Transanal excision of these lesions with adjuvant chemoradiation is an alternative approach but not considered the standard of care. See also *Rectal Adenomas* above.

Close endoscopic follow-up is required after polypectomy for a malignant polyp due to the concern for local recurrence of these lesions. A reasonable schedule is to examine the polypectomy site in 2–3 months and then every 6–12 months for the first 2 years with a complete colonoscopy done in the third year, and then at 3–5 year intervals depending on other findings and family history. For further discussion about the management of colorectal malignancies, see Chaps. 41 and 43.

Flat and Depressed Adenomas

Some adenomas display a flat or depressed growth pattern and are therefore not considered "true" polyps since they are not elevated above the mucosal surface.[99] They are defined in some classification systems as being elevated <2.5 mm off the surface of the colon ("flat" or "nonpolypoid") or depressed into the surface <2.5 mm ("depressed").[41,100] These are concerning in that they have a greater tendency to grow laterally or, in the case of the depressed lesions especially, into the wall of the colon rather than into the lumen. This makes their identification and potential for harboring malignancy concerning (between 27 and 36% of depressed cancers invade the submucosa versus <3% of cancers in polypoid lesions).[41] These lesions are recognized macroscopically by color and textural changes and by interruption of the capillary network pattern of the colonic wall.[41,99,101] They are most readily identified by chromoendoscopy with indigo carmine or other dye-spray techniques.[102] The pathogenesis of these lesions is thought to arise through different mechanisms than the traditional adenoma-carcinoma sequence, with a low level of *k-ras* and *APC* mutations in these lesions, a higher level of p53 mutations, and greater prevalence of MSI noted. In addition, these lesions appear to be more frequently associated with *de novo* adenocarcinomas, thus apparently bypassing the adenoma-carcinoma sequence entirely.[41]

The prevalence of flat and depressed adenomas in three Western population studies was approximately 20%, and these lesions contained cancer more often than polypoid adenomas.[103–105] One U.S. series showed <2% of lesions were depressed,[100] and reassessment of the original U.S. National Polyp Study polyp classification showed that 31.4% of the polyps in the original study would have been considered "flat."[41] Large Japanese series have also shown up to 42% of the all identified lesions to be of the nonpolypoid variety with <5% being depressed.[100] In a large UK study of 1,000 patients in which chromoendoscopy was used to search for small flat lesions, 36% of the 321 detected adenomas were flat or depressed.[103] The overall risk of a polypoid lesion containing early cancer was 8% but was 14% for the flat lesions. Flat or depressed lesions that were >1 cm were about twice as likely as polypoid lesions of a similar size to contain high grade dysplasia or cancer. Twenty nine percent of flat lesions >1 cm contained either high grade dysplasia or cancer. The average size of advanced flat and depressed adenomas is smaller than that of their polypoid counterparts.

Because of the risk of cancer, these lesions (except in rare cases with a normal overlying mucosal pattern in a <1 cm nonpolypoid lesions) should be removed, either by endoscopic polypectomy or by operative resection. It has been suggested that using special dyes and magnifying colonoscopy should be incorporated into general endoscopic practice to better identify these lesions.[99]

Serrated Polyps

Serrated polyps are a group of morphologically related lesions of the colon and rectum that differ in terms of their molecular etiology and malignant potential. Initially, these polyps were all categorized as hyperplastic polyps, but further research and closer histologic assessment revealed subsets of serrated polyps distinct from the benign hyperplastic polyps.[55,57,106] Serrated polyps include at least hyperplastic polyps and SSAs. Debate continues over the semantics and pathologic features of other subtypes of these polyps such as "sessile adenomas," "traditional sessile adenomas," and "sessile serrated polyps" (with interobserver variability as high as 40% among "expert" pathologists).[56] Concern about the nomenclature is mainly due to the use of "adenoma" in the names of these lesions and its implications for the malignant potential of these polyps and the need for further surveillance once these lesions are identified and treated. For the purpose of this review, the term "sessile serrated adenoma" will be used to describe those sessile polyps that are dysplastic and are clearly distinct from nondysplastic hyperplastic polyps. More important than the semantics debate is how the research into these lesions has lead to the discovery of the serrated neoplastic pathway, critical to the development of some sporadic and hereditary colorectal cancers with further implications for their treatment.

Hyperplastic Polyps

Hyperplastic polyps are considered metaplastic, nonneoplastic epithelial elevations with well-formed glands and crypts with frequent goblet cells (unlike adenomas with few goblet cells), although mucin-poor and microvesicular variants exist.[41,56] Because of the goblet cells, hyperplastic polyps are frequently coated with a layer of mucous (again, unlike adenomas), and they don't show the papillary infoldings or more prominent vasculature of adenomas, so this can facilitate their gross identification endoscopically. Although hyperplastic and adenomatous polyps have characteristic appearances, biopsy is needed to confirm the diagnosis, especially with smaller lesions. These polyps develop when epithelial cells from the base of the crypts differentiate and mature normally, but the cells accumulate on the mucosal surface leading to crowding of the epithelium and infoldings of the mucosa giving them a saw-toothed appearance histologically without dysplasia (Figure 36-7). This crowding is thought to be due to delayed shedding of the epithelial cells on the surface of the polyp and a failure of programmed cell death.[52,107–109]
FIGURE 36-7. Microscopic view of a hyperplastic polyp (Courtesy of William Chopp, MD).

Endoscopic diagnosis based on visual appearance alone with standard colonoscopy has a sensitivity of 80% and specificity of 71%.[109] Chromoendoscopy can improve the ability to distinguish hyperplastic from adenomatous polyps. Hyperplastic polyps have a characteristic star-like pit pattern when stained with indigo carmine and assessed with magnifying colonoscopy. The sensitivity and specificity of this technique in discriminating between adenomatous and nonadenomatous polyps was found to be 93 and 95%, respectively.[57,111]

Hyperplastic polyps have a prevalence of 10–15% in adults in Western populations and represent 25% of all endoscopically excised polyps. They are usually small (<5 mm), sessile, and often are present in multiples. They are found primarily in the distal colon and rectum, although larger or more proximal lesions are described.[44,56] They are rarely symptomatic regardless of location. Because of their predominantly distal location, hyperplastic polyps are commonly found on flexible sigmoidoscopy. In a study of 1964 diminutive (≤5 mm) polyps on sigmoidoscopy, 41% were adenomas, 37% hyperplastic polyps, and 18% nonneoplastic.[11] Hyperplastic polyps are found more commonly in patients who smoke, consume alcohol, and have low dietary folate intake.[56]

Data conflict as to whether hyperplastic polyps found on a screening examination represent an increased risk of synchronous or metachronous neoplasia. While some authors have suggested that left-sided hyperplastic polyps are predictors of proximal adenomas, the U.S. National Polyp Study found no association between left-sided hyperplastic polyps and synchronous adenomas.[36] A report using data from two large chemoprevention studies demonstrated that hyperplastic polyps were not predictive of an increased risk of developing adenomatous polyps on follow-up colonoscopy.[112] Multiple professional societies state that hyperplastic polyps found on flexible sigmoidoscopy are not an indication for colonoscopy and that small, distal hyperplastic polyps on colonoscopy do not warrant more frequent surveillance.[1,113]

The risk of cancer developing in small, distal hyperplastic polyps is so small that these lesions do not warrant treatment, but lesions >1 cm and those identified in the proximal colon should be excised.[41] While the majority of hyperplastic polyps are thought to be nonneoplastic, these lesions have been implicated in the pathogenesis of some MSI-related and sporadic colorectal cancers. Their malignant degeneration is thought to occur through the serrated neoplasia pathway described below, but this is more likely due to misclassification of a SSA as a hyperplastic polyp.

The rare hereditary syndrome of hyperplastic polyposis facilitated the identification of the serrated neoplasia pathway once it was appreciated that this syndrome was not without cancer risk. This syndrome is characterized by either ≥30 hyperplastic polyps regardless of size or location or by five large (at least one or two being >1 cm) proximal hyperplastic polyps or by any number of hyperplastic polyps with a positive family history of hyperplastic polyposis. The more diffuse variety is thought to have a low malignant potential and be associated with *k-ras* mutations while the type with larger more proximal lesions (more likely SSAs than true hyplerplastic polyps) are thought to have greater malignant potential through the *BRAF*/MSI-related serrated neoplasia pathway.[56,57] The actual genotypic and phenotypic definitions of this syndrome remain under debate. Reports of patients with hyperplastic polyposis syndrome showed an average age of 52 years, >100 polyps in half the cases, an average polyp diameter of 16 mm (range 5–45 mm), and more than half of the patients had a cancer present (half of these in the right colon).[103,108] Management of this syndrome includes endoscopic removal of all polyps >5 mm and consideration of total abdominal colectomy and ileorectal anastomosis (lifelong distal endoscopy still required) for those patients who wish to avoid repeat colonoscopy or if their lesions are not endoscopically treatable due to polyp size, number, or presence of malignancy. Genetic counseling and familial assessment is recommended despite the lack of a clear gene for testing. Surveillance colonoscopy is recommended every 1–2 years with consideration for the use of chromoendoscopy to facilitate identification of the polyps.[57]

Sessile Serrated Adenomas

SSAs are uncommon polyps accounting for approximately 0.2–9% (usually <2%) of colorectal polyps, depending on the definition used.[56,114,115] Initially, these were described as hyperplastic polyps that contained adenomatous features but were later delineated as intermediate polyps. The SSA has exaggerated serrated crypts that are longer and broader than in hyperplastic polyps but still has a similar serrated or sawtooth epithelial appearance.[57] The SSA crypts contain cells with slight cytologic atypia like enlarged hyperchromatic and stratified nuclei (as in adenomas) as well as cells with normally arranged, small, basal nuclei (as in hyperplastic polyps).[103,108] They are also characterized by dilated crypts and crypt branching as well as hypermucinous epithelium
FIGURE 36-8. Microscopic view of a sessile serrated adenoma (Courtesy of M. Kay Washington, MD, PhD).
FIGURE 36-9. Endoscopic appearance of a sessile serrated adenoma.

(Figure 36-8).[56,57] Endoscopically, many SSAs grossly appear like hyperplastic polyps with pale, slightly protruding lesions, and most are in the range of 0.2–7.5 mm in diameter (Figure 36-9). Some SSAs are larger, however, and may resemble villous adenomas grossly. Unlike hyperplastic polyps, SSAs are more often found in the proximal colon and cecum. It is unclear whether SSAs develop in association with hyperplastic polyps or develop *de novo*, but it appears that the former is more likely based on molecular and pathologic studies.[57]

The relationship between SSAs and cancer has evolved since their initial description in the early 1990s and has

elucidated the serrated neoplasia pathway. In one report, 5.8% of colorectal cancers were associated with an adjacent SSA and up to 37% of SSAs harbored dysplasia.[56,57,110,115] One review concluded that the risk of high grade dysplasia was the same in SSAs as in the more common adenomatous phenotypes.[115] In addition, the association of cancer with hyperplastic polyposis syndrome (when the syndrome is characterized by the SSA-predominant type of polyps) seems to make the link between SSAs and cancer development more conclusive. The relative rarity of SSAs being identified at the time of malignant transformation may be due to a rapid transition from dysplasia to malignancy in these lesions. This may be similar to the quick malignant transformation in HNPCC-associated cancers due to germline mismatch repair deficiency. The serrated neoplasia pathway is believed to be characterized by initial loss of *BRAF* with subsequent hypermethylation of promoter regions of a number of genes including the *hMLH1* mismatch repair gene leading to MSI phenotype cancers. When SSAs are found concomitantly with a cancer, their molecular characteristics are often similar, including loss of the *hMLH1* protein, further supporting the serrated neoplasia theory.[55] Individuals with sporadic colorectal cancer with high level MSI (MSI-H) cancers are four times more likely to harbor at least one serrated polyp than individuals with low MSI cancers.[103] Sporadic adenocarcinomas arising through the serrated neoplasia pathway occur in older patients (>70 years), have a female gender bias, and are predominantly located in the right colon, similar to SSAs. Because the rate of malignant degeneration of SSAs and their recurrence rate have not been determined, current recommendations support management and surveillance similar to traditional adenomas.[55,56] Initial detection and treatment of SSAs is also facilitated by the techniques useful in identifying hyperplastic polyps including chromoendoscopy and magnification colonoscopy.[57]

Hamartomas

The term hamartoma was originally coined by Albrecht in 1904 to refer to abnormally arranged but nondysplastic architecture of any of the layers of the normal lining of the colon (or other tissues).[116] These polyps are usually considered nonneoplastic except when associated with rare hereditary disorders that have been linked to an increased risk of colorectal cancer and include the following: familial juvenile polyposis syndrome (JPS), Peutz–Jeghers syndrome (PJS), PTEN hamartoma tumor syndrome (PHTS), multiple endocrine neoplasia syndrome 2B, hereditary mixed polyposis syndrome, Cronkhite–Canada syndrome, basal cell nevus syndrome, and neurofibromatosis 1 (some of which are discussed in Chap. 37). These conditions represent the etiology of <1% of all gastrointestinal malignancies.[117]

Whether part of a syndrome or when occurring as a sporadic hamartomatous polyp, there are two primary hamartoma types described in the colon: juvenile (or retention) polyps and Peutz–Jegher type polyps. The former term was introduced in the late 1950s by Horrilleno after a review of
FIGURE 36-10. Microscopic view of a hamartomatous Peutz–Jegher polyp (Courtesy of Tonia Zuluaga Toro, MD).

pediatric colorectal polyps, but they are named based on their histology and not the age of presentation as they can occur at any age.[118] Juvenile polyps are characterized by three classic histologic features including dilated mucous-filled glands/retention cysts lined by columnar epithelium, an expanded and abundant lamina propria, and infiltration of inflammatory cells, often eosinophils.[118,119] The muscularis is not usually part of the structure of these polyps. They are usually round with a smooth, often shiny appearance and are frequently pedunculated. Juvenile polyps can reach several centimeters in diameter.[119] These are differentiated from the Peutz–Jegher type polyp which are grossly more red and lobulated with their histology characterized by arborizing smooth muscle proliferation from the muscularis mucosa that is then lined by normal colonic epithelium with extensive goblet cells (Figure 36-10). Neither of these polyp types is characterized by abnormal mucosal lining or increase in mitoses to suggest premalignancy.[117]

The majority of isolated colorectal hamartomas present as juvenile polyps before the age of 10 with a peak presentation around the age of 5 years and are diagnosed with endoscopic assessment and biopsy/excision. Sporadic hamartomas represent <1% of polyps identified in adults, are usually larger than 1 cm and pedunculated at the time of diagnosis.[120] The majority of these isolated polyps in adults and children are found in the sigmoid colon and rectum and present with symptoms of rectal bleeding and/or polyp prolapse, but patients may present with anemia, diarrhea, and/or mucoid stools. Colonic intussusception is rarely associated with more proximal polyps. These polyps can autoamputate when they become larger due to their long stalks, and they can therefore be passed in the stool. Treatment of hamartomas is usually endoscopic but may require resection if the polyp is too large to be removed endoscopically or if there is evidence of malignancy within the polyp.

Malignant degeneration of solitary colorectal hamartomas appears to be a very rare phenomenon, so much so that some

authors feel that this is purely "coincidental."[119] The malignant degeneration of these polyps in the hamartomatous polyposis syndromes is not well understood. Theories have been based on histologic findings of hamartoma-related adenomas and cancers as well as genetic studies in hamartomatous polyposis syndrome patients. These theories include a mechanism whereby changes affecting the lamina propria may lead directly to epithelial cancers and/or alterations in cell polarity (due to *STK11* mutations) combined with colonic stem cell expansion leading to cancers (hamartoma to carcinoma sequence),[118,119] a hamartoma to adenoma to carcinoma sequence mechanism,[119,121] or simply "traditional" degeneration of sporadic adenomas in the setting of hamartomatous polyps.[119] More specific theories of malignant degeneration of these polyps suggests that it is related to aberrations in the TGF-β pathway that has been associated with colorectal cancers in Lynch syndrome/HNPCC as well as in some sporadic microsatellite unstable cancers, perhaps due to *SMAD4* mutations (a tumor suppressor gene associated with some hamartomatous polyposis syndromes). Further studies are ongoing to elucidate the likely multifactorial mechanisms associated with the degeneration of these polyps.

Inflammatory Polyps

Inflammatory polyps are islands or elevations of normal or near-normal colonic mucosa and submucosa surrounded by denuded or abnormal colonic lining and therefore are not considered true "polyps" (Figure 36-11). They are usually associated with a chronic inflammatory process of the colon, especially with inflammatory colitis (Crohn's and ulcerative colitis) but can also be due to regeneration of the colonic lining in inflammatory, infectious, or ischemic conditions.[122] Symptoms from the polyps including bleeding and diarrhea can be difficult to differentiate from the symptoms of the underlying condition leading to the development of these polyps.[123] Rarely,
FIGURE 36-11. Microscopic view of an inflammatory polyp (Courtesy of Tania Zuluaga Toro, MD).

obstruction or intussusception can occur if the inflammatory polyps become very large ("giant inflammatory polyposis").[124] Treatment is focused on the underlying disease causing the chronic inflammation or ischemia. Inflammatory polyps are not neoplastic but can make screening for neoplasia in chronic inflammatory conditions of the colon difficult due to their concerning appearance with endoscopic surveillance and their potential to mask an underlying malignancy.[125]

Hereditary Colorectal Cancer

James Church

Colorectal cancer is both a genetic and epigenetic disease. It arises because of an accumulation of genetic and epigenetic abnormalities that perturb gene expression and lead to carcinogenesis within the colorectal mucosa. The classes of genes primarily involved are largely those concerned with regulation of cell growth: tumor suppressor genes and proto-oncogenes, and the average sporadic colorectal cancer has accumulated 90 different mutations.[1] Most mutations occur because of the environment. However, about one third of colorectal cancers have a hereditary component. Hereditary colorectal cancer is important because members of affected families can be identified as high risk and be advised to have early, intensive surveillance or even prophylactic surgery, because of the complex, multidisciplinary care the families need, and because of what it teaches about the biology of sporadic colorectal cancer. In this chapter, the syndromes of hereditary colorectal cancer are reviewed.

Hereditary colorectal cancer can be broadly divided into non-syndromic and syndromic conditions (Figure 37-1). Non-syndromic hereditary colorectal cancer refers to familial clustering that does not fit criteria for the definition of a syndrome. It is associated with a significantly increased risk of colorectal cancer but finding a germ line mutation in a tumor suppressor gene is unlikely. However, because the criteria used to define hereditary colorectal cancer syndromes are not completely sensitive, some of these families may turn out to be "syndromes in disguise." They may also represent inheritance of one or more polymorphisms that confer an altered risk for colorectal cancer, a particularly strong, shared environmental factor, or they may just be unlucky families. Syndromic hereditary colorectal cancer is more important, however, because of the extremely high level of risk associated with it and because it is relatively easier to identify.

Syndromic Hereditary Colorectal Cancer

A syndrome is a condition characterized by a constellation of symptoms, signs, and associations that go together so that the presence of one feature may alert the clinician to the presence of others. Hereditary colorectal cancer syndromes can be broadly separated into those that are associated with multiple polyps (the hereditary polyposis syndromes) and those that are not (hereditary non-polyposis colorectal cancer (HNPCC)). These syndromes and their definitions are listed in Table 37-1. All of them confer an enhanced risk of colorectal and extracolonic cancers on affected patients, and demand a sophisticated knowledge of genetics, medical, and surgical treatment from caregivers.

The Polyposis Syndromes

Multiple colorectal polyps occur in a number of conditions, and include lymphoid follicles, so common and so prominent in young patients, the inflammatory and pseudo-polyps of colitis, intestinal lipomatosis, and neurofibromatosis. Usually, these can all be identified histopathologically, and are not discussed further in this chapter. However, biopsy of a sampling of polyps is always essential in diagnosing polyposis syndromes.

The Adenomatous Polyposes

Familial Adenomatous Polyposis

Familial adenomatous polyposis (FAP) is an autosomal, dominantly inherited condition due to a germ line mutation of *APC*, which occurs with a frequency of about 1:10,000 live births.[2] About 22% of germ line *APC* mutations occur

"de novo," meaning that there is no family history of the syndrome.[3] Inactivating mutations of this tumor suppressor gene result in a generalized disorder of growth regulation with a range of clinical manifestations, principally the formation of multiple gastrointestinal adenomas and carcinomas. FAP is thought to account for between 0.05% and 1% of all colorectal cancers. Patients with a diagnosis of FAP and their family should be referred to a polyposis registry.

Polyposis Registries

The aim of polyposis registries is to provide counseling, support, and clinical services for families with FAP.[4] This

FIGURE 37-1. Colorectal cancer viewed broadly.

includes thorough pedigree analysis and identification of at-risk family members, who are offered genetic testing and clinical surveillance. Those shown to be affected can be offered prophylactic surgery. Some registries also coordinate postoperative surveillance and provide a focal point for education, audit, and research.

Observational studies suggest that the introduction of registries, together with the use of prophylactic surgery, has led to increased life expectancy and a dramatic reduction in the incidence of colorectal cancer in FAP.[5]

Features of FAP

The Large Bowel. The cardinal manifestation of FAP is the development of over 100 colorectal adenomatous polyps, one or more of which inevitably progress to carcinoma if not removed (Figure 37-2). Polyps usually appear in adolescence, with colorectal cancer diagnosed at an average age of about 40 years. The severity of the colorectal polyposis is an important determinant of treatment and is used to define the pattern of FAP. Patients with less than 100 adenomas are classified as having attenuated FAP and this phenotype overlaps significantly that of MYH-associated polyposis (MAP). Patients with 100–1,000 adenomas have classical FAP while those with >1,000 adenomas have profuse FAP. Polyposis severity is partly a reflection of the location of the *APC* mutation[6] and partly due to unidentified modifying factors.

TABLE 37-1. Hereditary colorectal cancer syndromes

Polyposis syndromes	Phenotypic definition	Genotype
Familial adenomatous polyposis	Attenuated: <100 synchronous adenomas Mild: <1,000 synchronous adenomas Severe/Profuse: >1,000 synchronous adenomas	Dominant inheritance of germ line mutation in *APC*
MYH-associated polyposis	Attenuated/mild polyposis	Recessive inheritance: biallelic mutations of *hMUTYH*
Hyperplastic polyposis	>30 hyperplastic polyps of any size or location >10 hyperplastic polyps proximal to sigmoid, 2 >10 mm Any number of hyperplastic polyps with a family history of hyperplastic polyposis	Unknown
Hamartomatous polyposes	Two of the following criteria:	
1. Peutz–Jeghers syndrome	Mucocutaneous pigmentation Gastrointestinal Peutz–Jegher's polyps Family history of Peutz–Jegher's polyposis	Dominant inheritance of germ line mutation in *STK11*
2. Juvenile polyposis coli	>4 Juvenile polyps in the colorectum Any number of juvenile polyps and a family history of juvenile polyposis	Dominant inheritance of germ line mutation in *SMAD4* or *BMPR1*
3. PTEN tumor-hamartoma syndromes		Dominant inheritance of a germ line mutation in *PTEN*
(a) Cowdens syndrome	International Cowden Consortium Criteria	
(b) Bannayan Ruvalcaba Riley syndrome		
(c) Proteus syndrome		
Non-polyposis colorectal cancer		
Lynch syndrome	Dominant family history, microsatellite unstable (high) colorectal cancer, young age of onset	Dominantly inherited germ line mutation of DNA mismatch repair gene: *hMLH1*, *hMSH2*, *hPMS2*, *hMSH6*
Familial Colorectal Cancer Type X	Dominant family history, microsatellite stable tumor	Unknown
FIGURE 37-2. The large bowel in classical familial adenomatous polyposis.

The "hotspot" mutation at *APC* codon 1309 is reliably associated with profuse polyposis.[7]

Genetics

The APC Gene. APC is a large gene on chromosome 5q21 (q = the long arm). It is a key (gatekeeper) gene in colorectal carcinogenesis and is mutated in a majority of sporadic colorectal cancers.[8] Over 820 different germ line *APC* mutations causing FAP have been identified, almost all resulting in truncation of the APC protein.[9] Mutations have been found between codons 168 (exon 4) and 2839 (exon 15), but most are between codons 168 and 1640 (exon 15) in the 5′ half of the coding region, with a particular concentration at two "hotspots," codons 1061 and 1309.

The APC Protein. APC is expressed in all organs, but the mRNA is found at particularly high levels in normal colonic mucosa.[10] In many epithelia, APC is only found when cell replication has ceased and terminal differentiation is established.[11]

The 300 kDa APC protein is found in the cytoplasm and has sites of interaction with a range of other proteins, including β-catenin and the cytoskeleton. It plays a central role in the highly conserved Wnt signaling pathway, which is involved in the normal development of three-dimensional structures and is abnormally activated in some malignancies. APC binds and downregulates cytoplasmic β-catenin, preventing its translocation to the nucleus. Abnormal APC fails to do this so that β-catenin is free to enter the nucleus and form a complex which results in specific transcription of cell cycle stimulating DNA sequences, and hence cell proliferation.[12]

Genotype–Phenotype Correlation in FAP. There is evidence of correlation between the position of the germ line *APC* mutation (genotype) and some aspects of phenotype (Figure 37-3). Mutation at codon 1309 is associated with profuse polyposis,[6,7,13] and between codon 1250 and 1464 with earlier onset of, and death from, colorectal cancer. Mutations
FIGURE 37-3. Schematic representation of the APC gene showing genotype–phenotype correlations.

TABLE 37-2. Extracolonic features of familial adenomatous polyposis[23]

System	Feature	Frequency (%)
Upper gastrointestinal tract	Upper gastrointestinal adenomas	95
	Upper gastrointestinal carcinoma	5
	Fundic gland polyps	40
Connective tissue	Osteomas (especially jaw)	80
	Desmoids	15
Dental	Unerupted and supernumerary teeth	17
Cutaneous	Epidermoid cysts	50
Endocrine	Adrenocortical adenomas	5
	Papillary thyroid carcinoma	1
Hepatobiliary	Biliary tract carcinoma	<1
	Hepatoblastoma	<1
Central nervous system[24]	Congenital Hypertrophy of the Retinal Pigmented Epithelium (CHRPE)	75
	Tumors (especially medulloblastoma)	<1

located 5′ of codon 160 and 3′ of codon 1597 are associated with mild or attenuated colonic polyposis,[14] accounting for about 10% of those affected.

Some extracolonic manifestations have also been associated with mutations at certain sites, although not for upper gastrointestinal polyposis.[6,15] Congenital hypertrophy of the retinal pigmented epithelium (CHRPE) occurs only with mutations between codons 450 (exon 9) and 1444.[16] The association of desmoid disease with germ line *APC* mutations 3′ of codon 1444 can be clinically important,[17] although identical *APC* mutations may be associated with diverse phenotypes, suggesting that other genetic modifiers are involved.[18] The environment probably has some influence.

Clinical Variations of FAP

Extracolonic Manifestations. The extracolonic manifestations of FAP are shown in Table 37-2. Two of these, duodenal cancer and desmoid disease, are major sources of morbidity and mortality (Figure 37-3).[19] Other features may be a useful clue in diagnosis. CHRPE are hyper- or hypo-pigmented spots seen on retinal examination. They have no effect on

vision but act as markers of FAP in the 66% of families that have four or more in both eyes.[20]

Attenuated Familial Adenomatous Polyposis. A group of patients have been described who develop fewer than 100 colorectal adenomas (oligopolyposis) at a greater age (34–44 years) than in "classical" FAP, but who are at high risk of colorectal cancer, may exhibit extracolonic manifestations and carry a germ line *APC* mutation.[21] The colorectal cancers have a later age of onset than with classical or profuse FAP (mean age 56 years). The polyps have a rather different distribution, being more frequently found proximal to the splenic flexure, and their number varies significantly between family members, some of whom may have hundreds of adenomas.

The genotype of this group of patients may be one of the three: germ line *APC* mutation, biallelic *MYH* mutations, and germ line DNA mismatch repair (MMR) gene mutations. *APC* mutations associated with attenuated familial adenomatous polyposis (AFAP) are at either end of the gene: exons 3 and 4, at the 5′ end of the gene, and also at the 3′ end of exon 15. Fundic gland polyps (FGP) and duodenal adenomas are frequent, but CHRPEs are not found in this group. Desmoid disease is rare in those with a 5′ mutation but families with 3′ mutations (beyond about codon 1444) have a high risk of desmoid disease together with attenuated polyposis. The missense *APC* mutation I1307K has been identified in Ashkenazi Jews with multiple adenomas and E1317Q [22] has also been found in association with AFAP. When *APC* is normal, up to 30% of patients with oligopolyposis have biallelic *MYH* mutations.[22]

It is can be difficult to recognize AFAP clinically, leading to the clinical situation of an obstructing transverse colon cancer where right-sided polyposis is only found when the specimen is opened.

Because the polyps in AFAP are predominantly right-sided, screening and work-up must include a full colonoscopy. Genetic testing for germ line *APC* and *MYH* mutations has a relatively low yield, partially because of technical difficulties in detection of abnormalities that may be present and partly because gene expression may be lost for reasons other than a mutation. A careful search (including upper gastrointestinal endoscopy) for extracolonic features of FAP, dye-spray colonoscopy to confirm polyp number, and testing of tumor or polyp tissue for microsatellite instability (MSI) and MMR immunohistochemistry (IHC) (to exclude Lynch syndrome) may be helpful. Genetic testing for a germ line *APC/MYH* mutation should be pursued in patients with a total of ten or more colorectal adenomas, especially if there is a positive family history for colorectal adenomas or cancers. A positive result has implication for family screening, but the patient is managed in the same way regardless of the result. If the polyps are controllable endoscopically, then yearly colonoscopy is reasonable. If the adenoma burden is uncontrollable or dangerous, colectomy with ileorectal anastomosis (IRA) should be performed.

Gardner's Syndrome. Gardner described the association between FAP and epidermoid cysts, osteomas and "fibromas" (later found to be desmoid tumors) in 1953. The term "Gardner's syndrome" was later used to describe colorectal adenomatous polyposis occurring with these extracolonic manifestations. However, Gardner's syndrome is genetically the same as FAP, and systematic examination[23] has revealed that most patients with FAP have at least one extra-intestinal feature. Though it is of historical interest, the term "Gardner's syndrome" is no longer considered a genetic or clinically useful entity and should be regarded as obsolete.

Turcot's Syndrome. This is the association between colorectal adenomatous polyposis and central nervous system tumors. Recent molecular genetic investigation[24] has shown that about two thirds of families have mutations in *APC*, with cerebellar medulloblastoma as the predominant brain tumor. Most of the other third, including Turcot's original family, appear to be variants of HNPCC with glioblastoma as the predominant brain tumor, and multiple (but fewer than 100) colorectal adenomas.

Presentation

Patients with FAP present either with or without symptoms (on screening). There is a significant difference in cancer incidence between these two groups, with over 60% of unscreened, symptomatic patients having colorectal cancer at presentation.[25]

Screening

Clinical FAP screening begins at puberty because the risk of colorectal cancer under the age of 12 years is very small. Genetic testing of at-risk family members in a family with a known mutation usually starts when endoscopic surveillance would start, at ages 12–14. Earlier testing may be requested in a family where a relative has had hepatoblastoma but this is unusual. When a relative is identified as a mutation carrier, full colonoscopy is performed. EGD screening usually begins at age 20 years. Thyroid screening with ultrasound should also start then.

If genetic testing is uninformative or cannot be done in a family with classical FAP, endoscopic screening starts at age 12–14 with flexible sigmoidoscopy. An alternative would be to do retinal examinations for CHRPE or look for other extracolonic examinations with a skull X-ray or panorex examination of the jaw. If a marker of FAP is found, full colonoscopy follows. The polyp burden is documented endoscopically and histologically and a decision made regarding the timing and type of surgery.

Symptoms

About 22% of FAP patients have no family history. While this may be because of adoption, non-paternity, ignorance or alienation from the family, most of the cases are due to a

de novo mutation (occurring at conception).[3] The first thing that the patient knows of the lurking danger in their colon is the rectal bleeding, abdominal pain or diarrhea caused by the neoplasia. Symptomatic patients need expeditious surgery after a diagnostic colonoscopy and EGD. Their parents and siblings are usually unaffected although family screening should be done either genetically or endoscopically. Their children are at the usual 50% risk of inheriting the disease.

Diagnosis

Genetic Testing. Genetic testing should be preceded by counseling, ideally from a Genetic Counselor. Counseling includes the provision of written information about the process and its consequences, after which informed consent is documented. The implications of genetic testing with respect to confidentiality, employment, insurance, and other financial issues vary from country to country, but must be discussed prior to testing. In the USA, the Genetic Information Non-discrimination Act (GINA) that became law in 2008 offers protection against genetic discrimination in Health and Life insurance. Posttest counseling deals with the implications of the genetic test results, and may include psychological help to deal with emotional reactions, such as guilt (in an unaffected person), anxiety (in an affected person), and the effect of the results on family relationships.

DNA from an individual with FAP is sequenced to identify a mutation in *APC*, a process which is successful in about 80% of cases. Failure to detect an *APC* mutation does not exclude a diagnosis of FAP, and may occur for a variety of reasons, including the presence of large deletions or missense mutations. Such results have been misinterpreted as ruling out the diagnosis of FAP,[26] with potentially serious consequences.

If a deleterious mutation is found in an affected family member, at-risk family members can be offered predictive testing with a high degree of accuracy. This is generally done between the ages of 12 and 15 years, when the individual is old enough to take part in genetic counseling. There is no need for testing to be done earlier, as the disease does not usually become clinically manifest and treatment is rarely indicated before the mid-teens. When an individual does not carry the family mutation, that person can be discharged from further surveillance and be reassured that they do not have FAP. This removes the costs and risks of endoscopic surveillance, as well as the anxiety of living with a potential diagnosis of FAP. A positive test result allows surveillance and prophylaxis to be targeted to those who need it, and knowledge of the site of mutation can aid decision making with regard to prophylactic surgery.

If no mutation can be found in an affected patient, then the family must be managed without genetic testing. The negative result does not mean that the family does not have FAP; it means that the genetic cause of the FAP has not been found. Under these circumstances, a negative result in an at-risk relative is unhelpful. In such kindreds, at-risk individuals should be offered regular clinical surveillance with flexible endos-copy. This starts at the age of 12–14 years, when adenomas would be expected to develop. While there have been reports of polyps and even cancers occurring earlier than this, they are very rare. Clearly, anyone at risk of FAP should undergo full colonoscopy if they become symptomatic.

Management of the Large Bowel

Aims of Treatment. While the prevention of cancer remains an important priority in the management of patients with hereditary colorectal cancer, maintaining the quality of life is also important. This is especially the case in young, asymptomatic patients who have been diagnosed by screening. Where options exist for the timing and type of surgery, those with the least impact on social, academic, and vocational activities should be chosen. After all, surgery will not cure FAP.

Prophylactic Surgery. Patients with FAP, if untreated, are almost guaranteed to develop colorectal cancer. Prevention of cancer by endoscopic control of the polyposis is not possible and so colectomy or proctocolectomy is necessary to prevent cancer. Newly diagnosed patients are generally referred to a surgeon soon after diagnosis, and if the diagnosis is certain, then surgery is inevitable. The two questions that the surgeon must answer concern the timing and the type of surgery.

Timing. Patients with severe polyposis (over 1,000 colonic or over 20 rectal polyps), or those who are symptomatic, should have surgery as soon as possible. In asymptomatic patients with mild disease (100–1,000 adenomas, all <1 cm, none with severe dysplasia), surgery can usually be delayed until the patient reaches appropriate physical and intellectual maturity. An important reason for delay is the concern for the development of desmoid disease. Affected women with a family history of desmoid disease, extracolonic manifestations of Gardner's syndrome and a 3′ *APC* mutation are at highest risk.[27] As long as surgery is delayed, annual colonoscopy is recommended to monitor the polyps. Most patients with classical polyposis have surgery between the ages of 16 and 20, which is well before cancer usually develops.

Choice of Operation. The colorectal surgical options for the management of FAP are proctocolectomy with end ileostomy (with or without Koch pouch), colectomy with IRA or proctocolectomy with ileoanal pouch (IPAA). Few patients desire a permanent ileostomy, and so proctocolectomy with ileostomy is rarely done. It remains an option which may be necessary if a low rectal cancer invades the anus, if ileoanal pouch formation is impossible (e.g., because of mesenteric desmoid) or ill advised (e.g., in the presence of poor sphincter function). In most cases, however, the choice of surgery is between the latter two options, and is a matter of considerable ongoing debate, the essence of which is the balance between functional results and morbidity of surgery on the one hand and prevention of cancer on the other. Both procedures can be performed with laparoscopic mobilization of the colon so that a long midline

incision is not essential. Minimally invasive technique offers the advantages of less pain and quicker recovery, advantages that are especially important in the context of familial disease in teenagers.

IRA is more straightforward to perform than IPAA, and requires only one procedure, with a shorter hospital stay and fewer complications.[28] The risks of erectile and ejaculatory dysfunction caused by nerve damage during pelvic dissection are minimized, as is the significant reduction in fecundity observed in women after IPAA.[29] In addition, bowel frequency and soiling are less,[30] and no temporary stoma is necessary. In a teenager facing prophylactic surgery, these factors are important, particularly when most cancer risk is a few decades away and later conversion to a pouch is usually possible.

The critical aspect of cancer control in patients with an IRA is correct selection of which rectum to keep. Polyp counts are a reliable way to identify a low-risk rectum,[31] but patients still need yearly surveillance proctoscopy. Any polyps over 5 mm should be removed and polyps with high-grade dysplasia are relative indications for completion proctectomy. Occasionally, a patient with severe rectal polyposis has an IRA as the index surgery in FAP. This rectum is at high risk of progressive polyposis and cancer.[32]

Compared to an IRA, IPAA has the advantage of removing the entire colon and rectum. Although complication rates and functional results have improved with experience, they are still worse than those associated with IRA. There has been controversy over the need for mucosectomy to remove the anorectal transition zone, which theoretically prevents cuff neoplasia, but causes more complications and perhaps poorer function. Dysplasia in the transition zone occurs after both double-stapled and mucosectomy techniques and the latter is probably only indicated in individuals with severe low rectal polyposis.[33] The indications and contraindications, advantages and disadvantages of each surgical option are summarized in Table 37-3.

In summary, IRA is reasonable and safe in mildly affected patients, particularly if there are fewer than five rectal polyps. Most individuals presenting with severe polyposis or those known to carry a mutation in codon 1309 should be advised to undergo IPAA. But there are other issues. Pouch surgery in young men has an approximately 1% risk of damage to erection, ejaculation, and bladder function; in women, fertility is compromised. Pouch surgery is difficult and a diverting stoma may be impossible in obese patients. In some of these cases, the concept of a "staged pouch" may be applied. Here, an initial IRA is done despite the severity of the polyposis warranting a pouch. The patient is kept under close surveillance with the realization that a proctectomy and pouch will be required some years later. Hopefully by that time circumstances for the surgery will be more propitious. This strategy should not be applied in patients at high risk of desmoid disease.

Postoperative Surveillance. After IRA the retained rectum should be examined using a flexible sigmoidoscope, with a basic interval of 12 months or shorter, depending on the severity of disease. In about two thirds of patients, rectal adenoma regression is seen in the first few years after IRA.[34] Polyps over 5 mm should be removed cleanly with a snare. Repeated polyp fulguration can result in rectal scarring, making future surveillance difficult and unreliable. In patients with chronically scarred rectal mucosa, random biopsy is recommended to detect invisible dysplasia. If severe dysplasia or uncontrolled polyposis develops, completion proctectomy with or without ileoanal pouch formation is indicated.

Surveillance of ileoanal pouches at several centers has shown adenomas in up to 53%[35,36] and even some cancers.[37] IPAA has been available for about 30 years, and has only been performed frequently for FAP in the last 15, so the natural history of pouch adenomatosis will not be clear for some time. However, the cases reported to date confirm that neoplasia occurs in these pouches, and careful follow-up is

TABLE 37-3. Surgical options for familial adenomatous polyposis

Surgical option	Indication	Advantages	Disadvantages
Colectomy and Ileorectal anastomosis (leave 15 cm rectum)	<20 rectal adenomas	Low complication rate No stoma Close to normal bowel function	Risk of rectal cancer
Proctocolectomy and ileal pouch anal anastomosis (stapled)	>20 rectal adenomas Large rectal adenoma Rectal adenoma with severe dysplasia Sparing of low rectum	Minimizes risk of rectal cancer Avoids permanent stoma Bowel function better than with mucosectomy and hand sewn anastomosis	Complex surgery Often needs stoma Bowel function unpredictable but may be quite abnormal Risk of damage to pelvic nerves and decreased the ability of women to conceive Risk of pouch and anal transitional adenomas and cancer
Proctocolectomy and ileal pouch anal anastomosis (hand sewn)	As above but with adenomas to dentate line	Minimizes risk of rectal cancer Avoids permanent stoma	As above but bowel function is worse than with stapled anastomosis
Proctocolectomy with end ileostomy	Low rectal cancer Poor anal sphincters	Simple operation with lower complication rate and minimal chance of reoperation	Permanent stoma

essential. Flexible pouchoscopy after one or two enemas usually gives a good view. Not all pouch polyps are adenomas. Prominent lymphoid follicles are common, especially in children or teenagers. Isolated pouch ulcers are also common, especially over suture lines and at the opening of the afferent limb. These have no clinical significance. Representative polyps are biopsied. Treatment of pouch adenomas depends on their number and size. Polyps over 5 mm should be removed by snare excision while multiple small polyps respond to sulindac (150 mg by mouth twice daily).

Anal transition zone (ATZ) adenomas occur commonly after both stapled and handsewn IPAA, although they are twice as common in the former as the latter. Several case reports of cancer in the ATZ underline the difficulty in following this critical area.[37] In particular, a handsewn anastomosis is often stenotic, the perianal skin excoriated, and patients do not tolerate examination well. Under these circumstances, endoscopy may be possible in the office using xylocaine jelly as lubricant and a pediatric gastro scope. Otherwise, examination under anesthesia is needed. Adenomas in the ATZ can be excised individually (under anesthesia), or the entire ATZ can be stripped. If stripping is chosen because of the extent of the polyposis, the procedure should be performed in two stages to avoid stenosis.

Adenoma Chemoprevention. A range of chemopreventive agents have been studied in FAP, in part because of the problems of managing the retained rectum after IRA, but also because this disease provides a useful experimental model of colorectal carcinogenesis. In placebo controlled trials, both the nonsteroidal anti-inflammatory drugs (NSAIDs) sulindac[38] and the COX-2 inhibitor celecoxib[39] have reduced the number and size of colorectal adenomas. Chemoprevention, however, is not an alternative to prophylactic surgery, as no benefit in terms of cancer reduction has been demonstrated, and there have been reports of rectal carcinoma occurring in patients on sulindac despite reduction in polyp number and size.[40,41] The whole philosophy of artificial manipulation of polyp number, size, and shape, when polyps are the main marker guiding the decision for surgery, is troubling. However, there are circumstances when the use of chemoprevention has a definite place; for example, when completion proctectomy is impossible because of desmoid disease, while awaiting surgery which must otherwise unavoidably be delayed, in patients with a very high family risk of desmoid disease, or in treating pouch polyposis.

Upper Gastrointestinal Polyposis

Fundic gland polyps (FGP), made up of areas of cystic hyperplasia,[42] are found in the stomach of about 80–90% of individuals with FAP. These are benign but a recent prospective survey showed that low-grade dysplasia was present in FGP in 41% of patients.[43] Three percent of patients had high-grade dysplasia in FGP. This is concerning as some patients have profuse FGP, impossible to survey. Current practice is to biopsy representative FGPs during regular surveillance,

but not to try and treat all. Gastric adenomas can be found, usually in the antrum, in 10% of patients in western series. It is likely that these give rise to the very rare gastric cancers in western patients.[44] The incidence of gastric cancers in FAP patients in Japan is seven times that in the West, and for Korea, three times.[45] An excess of gall bladder and bile duct adenomas and carcinoma has also been reported.[46,47]

Prospective studies have demonstrated that over 95% of individuals with FAP have duodenal adenomas,[48] which tend to occur about 15 years later than large bowel polyps.[49] Duodenal cancers are the second most common cause of death in patients with FAP because although they are relatively rare (5%), they are highly lethal. Average age at diagnosis is 50 years.

The highest density of adenomas is on and around the Ampulla of Vater, testimony to the tumorigenic effect of bile. Patients with ampullary adenomas are predisposed to pancreatitis, either spontaneous or after endoscopic biopsy. Fifty percent of normal-appearing ampullas are dysplastic on biopsy.

Adenomas can also be found throughout the small intestine, and early studies of capsule endoscopy show that incidence of jejunal and ileal adenomas is higher in patients with severe duodenal polyposis (Spigelman Stages III and IV).[50] Occasional cases of small bowel adenocarcinoma occur, but routine small bowel screening is not recommended.

Surveillance of the Duodenum. Duodenal adenomas are flat, white mucosal patches, completely different in appearance to colorectal adenomas. There may be clearly defined polyps or more confluent areas, and biopsies of macroscopically normal mucosa may reveal microadenomas. The Spigelman staging system allows an objective assessment of the severity of duodenal polyposis in FAP (Table 37-4).[51] A prospective 10 year follow-up of Spigelman's original cohort has identified a 36% risk of developing invasive carcinoma in those with stage IV disease at the start of the study, and a 2% risk in those with stage II or III disease. Several carcinomas were missed on endoscopy, and all of those who developed cancer died as a result, despite surgery.[52]

Regular endoscopic surveillance of the stomach and duodenum is recommended so that individuals at high risk of developing carcinoma can be identified and offered intervention (although there is currently no evidence that this approach decreases the rate of invasive disease).[53] Examination of the duodenum using both forward and side viewing scopes starts at the age of 25 years. Table 37-5 shows

TABLE 37-4. Scoring of polyp features in Spigelman staging for duodenal adenomas

Points allocated	Number of polyps	Size of polyps (mm)	Histology	Dysplasia
1	1–4	1–4	Tubular	Mild
2	5–20	5–10	Tubulovillous	Moderate
3	>20	>10	Villous	Severe

TABLE 37-5. Derivation of Spigelman stage from scores

Total points	Spigelman stage	Suggested interval to next duodenoscopy (years)
0	0	5
1–4	I	3–5
5–6	II	3
7–8	III	1
9–12	IV	Consider duodenectomy. If not, rescope in 6 months

recommended surveillance intervals according to the severity of duodenal polyposis. Duodenal polyps are sampled for histology and even a normal appearing Ampulla is biopsied.

Management. Management of severe duodenal polyposis is difficult, but once invasive carcinoma has developed the outcome is poor. Duodenectomy and open polypectomy is associated with 100% recurrence a year after surgery.[54] Endoscopic mucosal resection seems a more attractive option, but is made difficult by the frequently plaque-like morphology of the polyps and involvement of the ampulla. Even simple biopsy of the ampulla can result in acute pancreatitis,[55] and repeated diathermy in this region can lead to scarring and stricturing. Argon plasma coagulation is of some use. Photodynamic therapy has been tried, but photosensitization and the need for multiple treatments[56] mean that it is not currently a practical option.

The use of chemoprevention to prevent progression of earlier stage disease has attracted great interest. Calcium, starch, vitamin C, and ranitidine have been tried with no effect. Sulindac can result in regression of small polyps,[57] but has little effect on larger ones. A randomized trial of the COX-2 inhibitor celecoxib showed significant improvement in the Spigelman stage for those with mild to moderate disease.[58]

Duodenectomy, whether by classical Whipple's procedure or using pylorus or pancreas preserving techniques, has been considered a last resort because of its significant morbidity and mortality. However, given the very poor prognosis once neoplasia becomes frankly invasive preemptive duodenectomy should be seriously considered for Spigelman IV disease. Pancreas preserving duodenectomy provides satisfactory control with reasonably low morbidity.[59] When cancer is suspected a Whipple's procedure is the better choice, but carries a high rate of complications.

Desmoid Disease

Desmoids are locally invasive, non-metastasizing clonal proliferations of myofibroblasts that are rare in the general population but can be found in 30% of patients with FAP.[60] Their etiology, pathogenesis, and natural history are not clearly understood. Desmoid disease is the third most common cause of death in FAP patients overall, after colorectal cancer and duodenal cancer.[19] Overall desmoid-related mortality ranges
FIGURE 37-4. Desmoid tumor arising in the small bowel mesentery.

from 10 to 50%[61] and desmoids can also contribute to death from other causes by making surgery for rectal or upper gastrointestinal malignancy difficult or even impossible.[62,63]

Desmoid disease is a spectrum from white, sheet-like plaques to large rapidly growing tumors. When found within the abdomen, desmoid disease can be seen to pucker and distort adjacent tissues, causing obstruction in tubular organs.

Ten to fifteen percent of patients with FAP develop desmoid tumors while another 15% develop the plaques.[60] The peak incidence is around 30 years of age, 2–3 years after surgery. While sporadic desmoids are considerably more common in females than males, this difference is less marked in the setting of FAP.

Clinical Features. Desmoids occurring in association with FAP typically arise within the abdomen (50%), especially in the small bowel mesentery, and in the abdominal wall (45%), although many extra-abdominal sites have been described. Mesenteric desmoids (Figure 37-4) encase or compress mesenteric blood vessels. Rarely, this can result in ischemia and perforation of the bowel, but it always makes resection hazardous.

Trauma (particularly in the form of surgery) and estrogens have both been identified as causes of desmoids, although they can occur spontaneously. There is evidence for some degree of genotype–phenotype correlation in that desmoids have been reported to occur more frequently in patients with 3′ germ line *APC* mutations.[6] Some mutations in this region are associated with severe desmoid disease inherited with high penetrance, but individuals with such mutations do not always develop this manifestation. However, many patients with desmoid have mutations in the 5′ half of the gene so modifier genes may well also play a part. Recent publication

of a "desmoid risk factor" score underlines the importance of female gender, the presence of extracolonic manifestations (especially Gardner's syndrome) and most importantly a family history of desmoids, in alerting surgeons to the likelihood of desmoid disease in their patients.[27] Abdominal surgery in patients at high risk of desmoid disease should be delayed as long as possible, and when performed, should preferably be a laparoscopic ileorectal anastomosis.

Presentation

Asymptomatic desmoid disease can be found incidentally, on physical examination, on CT scan or at laparotomy. Desmoids found in this way are generally small and often plaque-like. Symptomatic desmoids cause pain, bowel or ureteric obstruction, or are apparent as a mass.

Investigation. CT or MRI scans are the mainstays of investigation and follow-up (Figure 37-5), allowing imaging and measurement of the desmoid itself, as well as demonstrating the relationship to other structures, such as the ureter and bowel. Early mesenteric fibrosis appears as ill-defined soft tissue infiltration of the mesenteric fat, with a characteristic, whorled appearance.[64] There is some evidence that MRI, T2 weighted signal intensity correlates with subsequent growth.[65] As only a small proportion of desmoids grow and cause significant clinical problems, the ability to predict such progression might be very useful.

Management. The treatment of desmoids is controversial, often empirical and difficult. The natural history of desmoid disease in FAP is variable, with about 10% resolving spontaneously, 10% growing rapidly and relentlessly and the

Figure 37-5. MRI scan showing intra-abdominal desmoid tumor.

remainder either showing cycles of growth and resolution or remaining stable.[66] A desmoid staging system has been proposed that allows separation of desmoid tumors by prognosis and sets the stage for a more rational approach to treatment.[67,68]

Surgery is widely accepted as the first-line treatment for troublesome extra-abdominal and abdominal wall desmoids. Recurrence is common (20–50%), but complications are few. Within the abdomen the situation is very different, as the majority of desmoids develop in the small bowel mesentery. When the tumors are at the root of the mesentery, encasing the mesenteric vessels, surgery is a last resort and may mean small bowel transplant. Sometimes, intra-abdominal tumors are more distal in the mesentery, or are elsewhere in the abdomen away from the mesentery. Under these circumstances resection is often possible, sacrificing a minimum of small bowel. Preoperative CT scan and abdominal examination are keys in deciding which abdominal tumors are resectable. Even after R0 resections, however, recurrence rates are in the order of 50%.[69] Attempts at resection of desmoids in the mesenteric root may lead to high perioperative mortality rate (usually from hemorrhage)[70] and substantial morbidity, particularly due to extensive loss of small bowel.

Ureteric obstruction is best managed with stents, although even stents may be poorly tolerated due to pain or sepsis. Ureterolysis is rarely effective and may lead to nephrectomy. Renal autotransplant has proven effective, however, when medical treatments do not resolve the ureteric obstruction.[71]

Nonresective surgery may be needed to treat the complications of desmoid disease. Bowel obstruction can be managed by lysis of adhesions although this is tricky as multiple attachments of the small bowel to a retroperitoneal desmoid occur on the mesenteric border, lysis risks perforation, hemorrhage, and devascularization of the bowel. Bypass is safer and as effective. Sometimes, a stoma is necessary if there is no opportunity to bypass to a downstream loop. Enterocutaneous fistulas in the context of desmoid disease are difficult problems and may be unrepairable, committing the patient to lifetime nutritional support or small bowel transplant. However, some fistulas can be repaired, or at least bypassed.

Various medical treatments for desmoid disease have been reported, the most widely used being NSAIDs (particularly sulindac) and antiestrogens (raloxifene, tamoxifen, or toremifene). There have been no prospective controlled trials, and particularly in view of the unpredictable and variable behavior of desmoids, the small retrospective series are difficult to interpret. Cytotoxic chemotherapy has been used in irresectable or aggressive desmoid disease, and objective remissions have been noted with a variety of different agents. There have been a number of encouraging reports of an antisarcoma regimen consisting of doxorubicin and dacarbazine
TABLE 37-6. Staging system for abdominal desmoid tumors

Stage	Definition
I	Size <10 cm, not growing, asymptomatic
II	Size <10 cm, mildly symptomatic, slow growing[a]
III	Size 10–20 cm, moderate symptoms (bowel obstruction, ureteric obstruction), slow growing
IV	Size >20 cm, or rapid growth[b] or severe symptoms (abscess, fistula, hemorrhage)

[a] Slow growth =<50% increase in maximum diameter in 6 months.
[b] Rapid growth =>50% increase in maximum diameter in 6 months.

in the treatment of life-threatening intra-abdominal desmoid disease[72,73] and more recently the better tolerated liposomal doxorubicin has shown benefit. A less toxic combination of vinblastine and methotrexate has also produced some responses.[74]

A treatment regimen can be proposed that uses the staging system outlined in Table 37-6. Stage I tumors may receive either no treatment or sulindac, 150–200 mg twice daily. Stage II tumors are treated with sulindac and an estrogen modifying agent (tamoxifen or raloxifene 120 mg per day). Stages III and IV require chemotherapy. Liposomal doxorubicin is a reasonable agent to use, with methotrexate/vinorelbine as an alternative.[75] If a septic complication precludes chemotherapy, or if the maximum safe dose of adriamycin has been reached, agents such as gleevac, bevacizumab, or erbitux can be tried.

MYH-Associated Polyposis

MAP is an autosomal recessive form of familial adenomatous polyposis, due to mutations in the human MutY homolog (*hMUTYH*) gene. It was originally described in 2003.[76] While many of the individuals identified with biallelic *hMUTYH* mutations have fewer than 100 polyps, some have many hundreds, and thus appear as if they are a genuine clinical case of FAP. Colonic microadenomas and duodenal adenomas, desmoids and fundic gland polyps, sessile serrated polyps, and a variety of extracolonic cancers have also been reported in this group.[77,78] In fact, MAP can mimic many of the other hereditary forms of colorectal cancer, from sporadic cancer to FAP, from Lynch syndrome to hyperplastic polyposis (HPP). This is because the polyp phenotype can vary in number and histology, and the family history can also vary from dominant inheritance to no family history at all.

MAP has major implications for genetic counseling as, for the first time, an autosomal recessive form of FAP has been identified. This diagnosis should be considered in patients where no *APC* mutation has been identified, the mode of inheritance is not clearly autosomal dominant, or polyp numbers are low.

Genetics. Base excision repair corrects the sequelae of oxidative damage to the DNA. Oxidation changes the pattern of guanine coupling from $G=C$ to $G^o=T$. In subsequent cell division, an uncorrected $G^o=T$ becomes $A=T$, creating a

"$G=C$ to $A=T$ transversion." This change, when uncorrected, produces mutations in several genes, including *APC* and *KRAS*. The effect on APC is enough to produce adenomatous polyposis, and serrated polyps harboring similar mutations in *KRAS* have been reported in patients with MAP.[79]

The locations of the pathogenic *hMUTYH* mutations vary according to ethnicity.[80] The common mutations in the USA are Y179C and G396D, and these are screened for in Caucasian patients. If this screen is negative or if the patient is not Caucasian, whole gene sequencing can also be performed. There is some evidence that the Y179C mutation is associated with a more severe phenotype.[81]

Clinical. Patients usually present with oligopolyposis (<100 adenomas), although some cases with hundreds of polyps have been reported. Prior to awareness of these syndromes, patients with MAP were sometimes diagnosed as having attenuated FAP. Although some affected individuals have a very few adenomas, the presence of ten or more synchronous adenomas should trigger a referral for genetic counseling and testing, regardless of family history of colorectal neoplasia. The presence of serrated polyps with multiple adenomas should also stimulate a referral for genetic testing.

Once the genotype of MAP is confirmed, full colonoscopy and EGD are performed. The syndrome has not been known for long enough to have an accurate list of all extracolonic manifestations.

Treatment of the large bowel depends on whether the adenomas can be controlled endoscopically. If this can be done, surgery may be avoided. However, surgery is often necessary, usually colectomy with ileorectal anastomosis. Remaining large intestine is surveyed yearly. If a patient presents with cancer at a young age with either no family history or a weak history, and there is no evidence of Lynch syndrome, testing for MAP should be considered.

Genetic Testing. MAP generally follows an autosomal recessive pattern of inheritance, although monoallelic mutations (carriers) have a mildly increased risk of colorectal cancer. There has been a report of MAP with a dominant pattern of inheritance.[82] However, recessive inheritance means that both parents of a proband are likely to be unaffected carriers, with the risk to siblings being 25%. Genetic testing of a family therefore begins with the affected proband and if mutations are found continues with the spouse. This determines the risks to the children. A negative spouse means that children are carriers and can be counseled accordingly. Carriers should have enhanced colonoscopic surveillance, beginning 10 years before any cancer in the family and continuing at least 5 yearly. If the spouse is a carrier, then the inheritance pattern within that family becomes dominant, with each child at 50% risk of having MAP. In addition, antecedents on both sides of the family must be alerted to the possibility that they are carriers or affected.

In a study screening 9,268 colorectal cancer patients for the two commonly mutated alleles, Lubbe et al. found

biallelic *hMutYH* mutations in 0.3% of cases. This conferred a 28-fold increase in colorectal cancer risk, and was associated with proximal tumors and synchronous adenomas. Monoallelic mutations were not associated with an increase in colorectal cancer risk.[83]

The Hamartomatous Polyposes

Peutz–Jeghers Syndrome

Peutz–Jegher's syndrome (PJS) is a dominantly inherited cancer syndrome defined by the presence of two of the following three characteristics: perioral, buccal, and occasionally genital melanin pigmentation; gastrointestinal hamartomatous (Peutz–Jegher's) polyposis; a family history of PJS. The pigmentation can also be seen on the lips and sometimes on the eyelids, hands, and feet, or be absent altogether. It usually appears in early childhood and tends to fade in the late 20s. The polyps occur predominantly in the small intestine (78%), but are also found in the stomach (38%), colon (42%), and rectum (28%).[84] They are hamartomas with a characteristic branching morphology, containing smooth muscle in the submucosa. Adenomatous change with dysplasia and progression to invasive adenocarcinoma has been observed.[85] PJS has an incidence of 1 in 200,000.

Inheritance

Peutz–Jegher's polyposis is autosomal, dominantly inherited with high penetrance, and is caused by mutation of *LKB1* (also known as *STK11*) on chromosome 19 p13.3. The gene encodes a serine–threonine kinase. Mutation of *LKB1* is only found in about 60–70% of cases, and has been formally excluded in some,[86] suggesting that either other genes are responsible, or *LKB1* may be inactivated by epigenetic mechanisms. While a family history is common, de novo mutations are responsible for a significant number of cases.

Clinical Issues

Polyp-Related Complications. The most common clinical problems in PJS are anemia due to chronic blood loss from large polyps and small bowel obstruction due to intussusception with a polyp at the apex. Repeated emergency bowel resections can lead to increasing operative difficulty and even short-bowel syndrome.

Risk of Malignancy. Follow-up studies have shown that individuals with this syndrome are at increased risk of developing a range of malignancies at a particularly young age.[87] Indeed, by the age of 57 years approximately half of all patients in one series had died of cancer, of which about half were gastrointestinal. The lifetime risk of any cancer in affected patients is over 90%. It is estimated that there is a 50-fold excess of gastrointestinal cancer in Peutz–Jegher's syndrome, resulting in a lifetime risk of approximately 20%

of colorectal cancer and about 5% of gastric cancer, as well as breast, pancreatic (30% lifetime risk), ovarian sex-cord tumors (10% of females), feminizing Sertoli cell testicular tumors in prepubertal boys, pulmonary and cervical malignancies.

Management

Probands usually present at a young age with complications of their small bowel polyposis. This often involves laparotomy for intussusception or bleeding. A symptom-focused approach predisposes to frequent laparotomies as untreated polyps enlarge to cause a new set of symptoms. The technique of laparotomy with intra-operative enteroscopy was introduced to reduce the number of repeat emergency laparotomies and small bowel resections.[88] During laparotomy a colonoscope is passed from below through the colon, and, with the assistance of the surgeon, into the small bowel for as far as it will go. The most proximal site of insertion is marked with a suture or tape. Then, the colonoscope is withdrawn in a darkened operating room and the sites of polyps marked as it is withdrawn. The procedure is repeated with an enteroscope inserted through the stomach and encouraged to pass distally. The mucosa between the limits of endoscopy can usually be examined through an enterotomy. In most patients, the intussusception is obvious and even if it is reduced a serosal dimple can be seen at the site of the polyp. The bowel is palpated and at the site of palpable polyp an enterotomy is made. The polyps are removed and the bowel intussuscepted through the incision up and down as far as possible. All visible lesions are either removed or cauterized. The enterotomies are closed. Polypectomy is best done by ligating the stalk and excising the polyp with cautery distal to the tie. Otherwise, the stalk may bleed copiously. The fourth part of the duodenum and proximal jejunum is typically a difficult part of the bowel to palpate and to operate.

Using this "clean sweep" technique, the entire small bowel is cleared of all macroscopic lesions, minimizing the number of laparotomies in subsequent years.[88] The recent availability of capsule endoscopy and double/single balloon enteroscopy offers the potential for endoscopic diagnosis and treatment of the polyps; however, the vascularity of the polyps makes endoscopic treatment in the mid small bowel worrisome. There is a role for capsule endoscopy, however, in surveillance of asymptomatic patients. Colonic polyps can usually be controlled colonoscopically.[89]

Gastrointestinal Surveillance. Surveillance intervals depend on polyp number, size, histology, and location. A near normal examination can be followed 2 or 3 years later by repeat EGD, capsule endoscopy, and colonoscopy. Hemoglobin should be checked annually. Small bowel polyps causing symptoms or anemia, or measuring over 1.5 cm, should be removed, either endoscopically or at laparotomy with intra-operative enteroscopy.

Extra-intestinal Surveillance. Mammography in premenopausal woman lacks sensitivity, but there is little evidence to support ultrasound or MRI as alternatives. Testicular tumors tend to occur in prepubertal boys, and it would seem sensible to encourage regular examination. Women should undergo standard cervical and breast screening according to nationally agreed protocols.[90] While in some centers regular ultrasound scanning of the pancreas and ovaries are performed, there is no evidence that such measures have any impact on prognosis. It is important that clinicians caring for these patients are aware of the high cancer risk, and maintain a low index of suspicion.

Juvenile Polyposis

Juvenile polyps are hamartomas which lack smooth muscle histologically, having poor anchorage to the bowel wall. They may become detached and are then passed through the anus. Solitary juvenile polyps are the commonest colorectal lesion in children, being found in up to 2%. They have little or no malignant potential.[91] Juvenile polyposis (JPS) is defined as the presence of five or more juvenile polyps in the large bowel, or any number of juvenile polyps in a patient with a family history of JPS. Although the colorectum is always affected, the stomach (and perhaps small intestine) is also affected in about 50%.[91–94] Most affected individuals develop 50–200 polyps, but some have very few.

JPS is rare with a frequency of about 1 per 100,000. It presents with rectal bleeding, anemia, or polyp prolapse, at an average age of about 9 years. The polyps are hamartomas, with a characteristic hyperplastic stroma, abundant lamina propria, cystic glands, and inflammation. They are sometimes reported as inflammatory polyps. Adenomatous dysplasia occurs in up to half, which may then progress to adenocarcinoma.

Other morphologic abnormalities, including macrocephaly, mental retardation, cleft lip or palate, congenital heart disease, genitourinary malformations, and malrotations, are found in 10–20%.[95] Some patients with JPS have a familial pattern of disease, while in others there is no family history. In those with familial disease, the chances of finding a causative mutation are relatively high (>60%).

Genetics

This syndrome is genetically heterogeneous, with three separate genes currently implicated. Mutations in *SMAD4* have been identified in affected individuals. *SMAD4* is a tumor suppressor gene on chromosome 18q21 and is implicated in sporadic colorectal carcinogenesis. It codes for a protein involved in the TGFβ signaling pathway, and germ line mutations have been found in 35–60% of juvenile polyposis patients in the USA, but rather fewer (3–28%) in Europe.[94] Germ line mutations in a second gene, *BMPR1A* on 10q22, have been found in a further 15% of cases.[95] *BMPR1A*

encodes a protein involved in the same signaling pathway. *PTEN* mutations have also been reported in the so-called juvenile polyposis,[96] but it is as yet unclear whether these cases have Cowden's syndrome, or whether they represent is simply a variant of juvenile polyposis.[97]

Patients with JPS due to a *SMAD4* mutation have a high likelihood of also having Hereditary Hemmorhagic Telangiectasia (HHT). This manifests as multiple vascular anomalies that may be in the brain, lungs, mediastinum, and bowels. Patients with a SMAD4 mutation need a vascular assessment to diagnose or exclude this potentially dangerous condition.[94,98]

Cancer Risk and Management

The cumulative risk of colorectal cancer in patients with JPS has been estimated at 30–50%, and that of upper gastrointestinal cancer at 10–20%.[93,99] First degree relatives of affected individuals should be screened by colonoscopy from around the age of 12 years if asymptomatic[100] and, if normal, 5 yearly thereafter. In many cases, the polyps can be controlled by regular endoscopic polypectomy, with both upper gastrointestinal endoscopy and colonoscopy recommended at least every 2 years. In cases where polyps are either too numerous or too large to be managed in this way, or when patients are symptomatic with diarrhea, mucus, bleeding and cramps, colectomy and IRA or restorative proctocolectomy is advised.[101] Cleveland Clinic experience showed a high rate of secondary proctectomy after initial ileorectal anastomosis.[102] Aggressive polyposis is also possible in ileal pouches but can be controlled by sulindac.

It is not clear whether endoscopic surveillance and polypectomy is adequate to prevent malignancy, but there are insufficient data to justify purely prophylactic colectomy. Affected individuals should also undergo upper gastrointestinal surveillance from the age of 25 years.

PTEN Tumor Hamartoma Syndromes

Three very rare dominantly inherited conditions have been described in which hamartomatous colorectal polyps occur together with multiple craniofacial, skeletal, and dermatological phenotypic features. They share a common genetic origin, namely, germ line mutations of *PTEN*. *PTEN* is an important tumor suppressor gene with key roles in the mTOR/AKT pathway.[103]

Cowden's Syndrome

This autosomal dominantly inherited syndrome is characterized by macrocephaly (30%), trichilemmomas (which are considered pathognomonic) and both benign and malignant neoplasms of the thyroid, breast, uterus, and skin. Hamartomas occur in the mouth as well as other parts of the gastrointestinal tract, resulting in a nodular appearance of the

buccal mucosa. The International Cowden's Syndrome Group has described a set of major and minor criteria by which to diagnose the syndrome.[104]

In CS patients, the colon is affected with a variety of polyps, the histology of which includes hamartomas, lipomas, fibromas, neurofibromas, ganglioneuromas, and adenomas. Although CS has not been considered a high risk for colorectal cancer, recent data seems to suggest otherwise.[105] Certainly, it is safe to start colonoscopic screening when patients are in their 30s and to continue it at least every 3 years, or more often if findings indicate. Prophylactic colectomy is indicated when polyposis cannot be controlled endoscopically.

Bannayan–Riley–Ruvalcaba Syndrome

Here, the colorectal hamartomas (50%) are associated with characteristic pigmented penile macules, macrocephaly, mental retardation (50%), lipomatosis and hemangiomas.[106] It seems likely that as Cowden and Bannayan–Riley–Ruvalcaba syndromes are caused by mutation of the same gene, they are slightly different forms of the same disorder,[95] and families have been identified in which both phenotypes are evident.[107] There is no evidence to suggest an increased risk of colorectal cancer in this syndrome.

Serrated Polyposis

Serrated polyps are non-neoplastic lesions of the large bowel that were until recently thought to have no premalignant potential. Over the last 5 years, however, the true significance of these lesions has begun to be appreciated. They are part of a class of lesions termed serrated polyps because the overcrowded hyperplastic glands in the epithelium are thrown into a saw-toothed or serrated pattern. A new nomenclature has arisen wherein serrated polyps with abnormal proliferation are termed sessile serrated polyps (or sessile-serrated adenomas), and are now known to be potential premalignant precursors in a serrated polyp to cancer pathway.[108] This pathway is linked genetically to BRAF mutations and DNA hypermethylation, particularly when it leads to loss of expression of *hMLH1*.[109] While sporadic serrated polyps are common, and mostly of the hyperplastic type, some patients have multiple lesions and are at high risk of developing colorectal cancer. The WHO definition for serrated polyposis is any one of the following: 30 or more serrated polyps of any size and location; more than 10 serrated polyps proximal to the splenic flexure of which 2 are larger than 10 mm; any number or size of serrated polyps with a family history of SPP.[110] There is reason to believe that these criteria are overly restrictive and that high risk families are being missed.

No germ line mutation has been identified as causing serrated polyposis and the pattern of inheritance is still not clear. Many patients with SPP have no family history at all. The presence of multiple synchronous-serrated polyps has,

however, been shown to confer a very high risk of colorectal cancer, approaching 50%.[111]

Treatment

Treatment of patients with SPP is either endoscopic or surgical. Colonoscopy must be careful as serrated polyps can be difficult to recognize and are likely to be easier to miss than adenomas. Yearly, colonoscopy is necessary to prevent cancer. If the polyps are not controllable endoscopically, colectomy, and IRA is indicated. First degree relatives of patients with SPP are candidates for early screening colonoscopy (10 years prior to the earliest age at diagnosis of a neoplastic lesion in the family). If a colon cancer is detected, or if the polyposis is progressive and not able to be controlled, colectomy and IRA is indicated.

Hereditary Non-polyposis Colorectal Cancer

Introduction

HNPCC refers to a dominant pattern of inheritance of colorectal cancer predisposition without an association with unusual numbers of colorectal polyps. This lack of an easily identifiable colonic phenotype makes clinical diagnosis difficult and can affect treatment as surgeons seem reluctant to remove an endoscopically normal colon for prophylaxis. Multiple diagnostic criteria have been proposed for the identification of HNPCC families. The most widely used are the Amsterdam I and II criteria, originally proposed to facilitate research but almost immediately adapted for clinical use (see Table 37-7).[112,113] Subsequent research has shown that Amsterdam I patients can be divided into two broad

TABLE 37-7. Amsterdam criteria

Amsterdam criteria
- At least 3 family members with colorectal cancer, one of whom is first-degree relative of the other 2.
- At least 2 generations with colorectal cancer.
- At least 1 individual <50 years at diagnosis of colorectal cancer.

Amsterdam criteria II
- At least 3 family members with HNPCC-related cancer, one of whom is first-degree relative of the other 2.
- At least 2 generations with HNPCC-related cancer.
- At least 1 individual <50 years at diagnosis of HNPCC-related cancer.

Modified Amsterdam criteria
- 2 first-degree relatives with CRC involving 2 generations.
- At least one case diagnosed before 55 years OR
- 2 first-degree relatives with CRC and a third relative with endometrial cancer or another HNPCC-related cancer.

Modified from Chung DC, Rustgi AK. The hereditary nonpolyposis colorectal cancer syndrome: genetics and clinical implications. Ann Intern Med. 2003;138:560–70.

subgroups: those whose tumors are microsatellite unstable (Lynch syndrome) and those whose tumors are microsatellite stable (Familial Colorectal Cancer Type X).[114] Type X families are likely to be a heterogeneous group of colorectal cancer predisposition states, sharing an apparent dominant inheritance but with different genetic abnormalities. Some may have underlying MAP, some SPP, some Lynch syndrome due to *hMSH6* mutations, and some may have genetic abnormalities yet to be discovered. Type X families have a significantly lower risk of colorectal cancer than that found with Lynch syndrome, and they do not have the same array of extracolonic cancers. Lynch syndrome, or hereditary mismatch repair (MMR) deficiency, is a better defined syndrome and is the main topic of this section.

Lynch Syndrome

Definition

Lynch syndrome is hereditary DNA MMR deficiency associated with the early onset of colorectal and other cancers (mean age for colorectal cancer, 45 years). Multiple generations are affected with a pattern suggesting dominant inheritance. Colorectal cancers tend to be proximal to the splenic flexure, and there is an increased frequency of synchronous and metachronous cancers. There is also a high risk of extracolonic cancers, including endometrial, ovarian, gastric, small bowel, hepatobiliary, and transitional cell carcinomas. The lifetime risk of cancer is up to 80%, with colon cancer being the most commonly diagnosed.[115]

History

Aldred Warthin, a pathologist at the University of Michigan, first described a family with inherited intestinal cancer in 1895. Detailed descriptions of this family, (known as "Family G" because they came from Germany) as well as other families, were published in 1913. Gastric cancer was the predominant cancer but colorectal and uterine cancers also featured.[116] Nearly 50 years later, a medical oncologist named Henry Lynch published the pedigrees of two large midwestern families ("Family N" from Nebraska and "Family M" from Michigan). He commented on the wide spectrum of cancers and the probability of a heritable mutation.[117] By the mid-1980s, two patterns of disease became apparent; Lynch I (colorectal cancer only) and Lynch II (colorectal and other malignancies). Concurrent observations showed that the number of colorectal adenomas in these patients was no greater than that in the general population, and that there was considerable overlap between Lynch I and II syndromes. The syndrome became known as HNPCC. Terminology has now come full circle with Lynch Syndrome now a genetic diagnosis, referring to families with a germ line mutation in a MMR gene.

In order to promote research collaborative studies, an International Collaborative Group on HNPCC met in Amsterdam in 1990.[112] A set of diagnostic guidelines was agreed upon that would allow researchers to gather homogeneous populations to be studied (*Amsterdam I criteria*, see Table 37-7). Once HNPCC was clinically defined, rapid progress was made finding the genetic defects as well as in diagnosis and treatment of the disease. The DNA of colorectal tumors in some Amsterdam positive families was found to have multiple mismatched nucleotides. This unique genetic abnormality was termed replication error phenotype or RER+. Most of the mismatched bases were in areas of the gene called "microsatellites," so the term "microsatellite instability" is now preferred.[118] Extensive research in yeast and *Escherichia coli* had identified a group of genes referred to as MMR genes. Using linkage studies, the first human homolog, *hMSH2*, was identified in 1993 by Fishel[119] and germ line mutations in *hMSH2* were found in families with HNPCC. Other MMR genes were found and associated with HNPCC.

Genetics

DNA Microsatellites

DNA is a very long molecule that is replicated during each cell division. Microsatellites are short, tandem repeating base sequences, usually mononucleotide or dinucleotide base repeats, most often found in the non-coding or intronic portions of DNA. However, microsatellites can occur anywhere within genes, and when they do, mutations within microsatellites can cause changes in gene expression. The length of each microsatellite marker is normally constant within any particular patient, so that when the number of repeats in a microsatellite sequence in a cancer cell is different from the surrounding normal tissue, this is termed "microsatellite instability (MSI)."

DNA Mismatch Repair

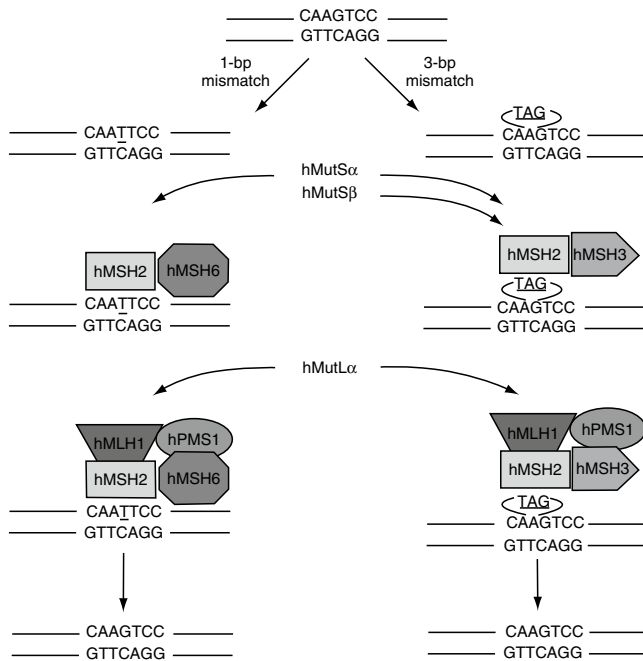
When a cell divides, DNA is replicated. The parent strands separate, and are reconstituted by DNA polymerase into two new double-stranded molecules. DNA mismatches occur when one strand slips on the other as the new DNA molecule is reconstituted. This is especially likely to happen in DNA microsatellites that can be thought of as "slippery" parts of the DNA. Unrepaired mismatches are seen as MSI. The system of DNA MMR in humans involves at least six genes. Their protein products act in pairs to recognize mismatches and excise them, allowing DNA polymerase to restore normal DNA. (Figure 37-6). The genes are *hMLH1*, *hPMS1*, *hPMS2*, *hMSH2*, *hMSH3*, and *hMSH6*. MSH2 acts as a "scout" and identifies the mismatches in the new DNA strand. It then complexes with MSH6 to form the MutSα complex that identifies single nucleotide mismatches. Alternatively, MSH2 can complex with hMSH3 forming MutSβ complex that repairs insertion and deletion loops (IDL) with up to 10 base pairs. Both MSH3 and MSH6 must be


FIGURE 37-6. The DNA mismatch repair system can correct either single base-pair mismatches or larger loops of mismatched DNA. hMSH2 serves as the "scout" that recognizes mismatched DNA. It forms a complex with either hMSH6 or hMSH3, depending on the number of mismatched nucleotides. A second heterodimeric complex (hMLH1/hPMSI) is then recruited to excise the mispaired nucleotides. hMUTSα=hMSH2/hMSH6; hMuTSβ=hMSH2/hMSH3; hMutLα=hMLH1/hPMS1. *bp* base pair. abnormal to have complete loss of hMSH2-dependent mismatch repair.[120]

MLH1 and PMS2 bind to form a second heteroduplex that interacts with the MutS duplex, stimulating excision and resynthesis. When an inactivating mutation silences expression of an MMR gene, the microsatellite mismatches go unrepaired and are propagated into lines of daughter cells as mutations. This so-called mutator phenotype of Lynch syndrome is characterized by an increased genome-wide mutation rate. When tumor suppressor genes contain a microsatellite, they are vulnerable to loss of expression in the mutator phenotype. Examples of such genes are *MSH3*, *MSH6*, *TCF4*, *BLM*,[121] *Caspase-5*,[122] *TGFβRII*, *IGFRII*, *BAX*, *PTEN*, and *APC*,[123] many of which are involved in control of colonocyte growth.

The most commonly mutated genes in Lynch syndrome families are *MLH1* (33% of families) and *MLH2* (31%).[124] Of the mutations identified, 90% occur in *MLH1* and *MSH2*.[125] Recently, a meta-analysis of index families fulfilling the Amsterdam criteria revealed that a mutation in *MLH1* is found in 25.5–29.6% of families, and *MSH2* is found in 14.8–21.6% of the families.

Pathology

Some pathologic features can be seen in tumors associated with the mutator phenotype and MSI. These include mucinous differentiation with signet ring cells, the presence of tumor infiltrating lymphocytes (Figure 37-7A), a Crohn's like reaction (Figure 37-7B), and the absence of dirty necrosis.[126,127] Despite what appears to be unfavorable histology, the incidence of metastatic tumor in lymph nodes is less than that found with sporadic colon cancer.[128]

Flow cytometry has shown that most Lynch syndrome tumors are diploid. This contrasts with the frequent aneuploidy of sporadic colon cancer, where tumorigenesis is related to sporadic mutations and loss of heterozygosity (LOH).[129]

Clinical Features

Patients with Lynch syndrome have an increased lifetime risk of colon cancer and other extracolonic cancers (see Table 37-8). Colon cancer is the most frequently diagnosed cancer (80%) and endometrial cancer is the most frequent extracolonic cancer (50–60%).[130] Colorectal cancers in Lynch syndrome are usually proximal to the splenic flexure (68% vs. 49% of sporadic cancers), more likely to have associated synchronous cancers (7% vs. 1% sporadic colon cancer), and have increased metachronous cancers at 10 years (29% vs. 5% sporadic cancers).[131] Similarly, women with Lynch syndrome-related endometrial cancer have a 75% risk of a second cancer during a 26-year follow-up. The median age of onset of colon cancer is 42 years and for endometrial cancer it is 49 years.[115]

In Lynch syndrome, an adenoma is the precursor lesion for cancer. In a Danish surveillance study, 70% of mutation carriers developed adenoma by age 60 as opposed to 37% in the control group. The adenomas in the mutation carrier group were larger and had a higher proportion of villous components and high-grade dysplasia. Adenomas were located in the proximal colon and 70% of the polyps had an absent MMR protein on immunohistochemistry.[132] One cancer is prevented for every 2.8 polyps removed in HNPCC patients[133] compared to one cancer being prevented for every 41–119 polypectomies in the general population.[134] It is estimated that malignant transformation occurs in 3 years in HNPCC as opposed to 10 years in sporadic colon cancer.

Two other types of polyps – the flat adenoma and serrated adenoma – have been implicated as possible precursors of Lynch syndrome cancers. Flat adenomas are found proximally in up to 50% of Lynch syndrome patients (Figure 37-8A and B).[135] About 20% of flat adenomas show MSI-H and have a mutation in the *TGFβRII* gene.[136] These polyps are difficult to detect during colonoscopy and flat adenomas with advanced histology (high-grade dysplasia or cancer) are significantly smaller (10.7 mm) than comparable polypoid lesions (20 mm).[137]

Genotype/Phenotype Relationships

Few studies evaluate phenotype–genotype correlations in Lynch syndrome. One study of 35 families found the *MSH2* mutation to be associated with a later age of onset of rectal cancer and more extracolonic cancers than in the *MLH1* mutation-positive group.[138] Another study confirmed the association of *MSH2* mutations and extracolonic cancers.[139] Germ line *MSH6* mutations are uncommon, and associated with a particularly high risk of uterine cancer, which is more common than colon cancer in affected women. Colorectal cancer occurs at a later age of onset in these families than in those with the more common *MLH1* and *MSH2* genotypes. In 91 patients with familial colorectal cancer, 6 (7.0%) were found to have *MSH6* mutations, their tumors were microsatellite low (MSI-L), had a median onset of 61 years, and the families did not fulfill Amsterdam I criteria.[140] The International Collaborative Group has collected over 30 potentially

TABLE 37-8. Lifetime risks for cancer associated with the hereditary non-polyposis colorectal cancer syndrome

Type of cancer	Persons with HNPCC	General population
Colorectal	80–82	5–6
Endometrial	50–60	2–3
Gastric	13	1
Ovarian	12	1–2
Small bowel	1–4	0.01

FIGURE 37-9. Detection of microsatellite instability with the use of fluorescent labeling of polymerase chain reaction (PCR) products analyzed in an automatic sequencer. Two markers are analyzed in the same track: the mononucleotide repeat marker BAT26 is shown on the *left*, and the dinucleotide marker D2S123 is shown on the *right*. The upper tracking is from germ line DNA from blood. The lower tracing is from DNA extracted from a histologic section of a tumor containing more than 50% tumor cells. For marker BAT26, germ line DNA shows a *single peak*, indicating that the patient is homozygous for this marker (*arrow*). Tumor DNA shows, in addition to the normal allele (*single arrow*), a new allele (*double arrows*) that has lost approximately five nucleotides. This constitutes microsatellite stability. For marker D2S123, germ line DNA is homozygous, whereas tumor DNA shows two new alleles (*triple arrows*), one with a loss of approximately 10 nucleotides (*left*) and one with a gain of two nucleotides (*right*). Thus, the tumor shows microsatellite instability with both markers. All peaks display "stutter" – that is, small amounts of material with a gain or a loss of one or a few nucleotides. This is a normal phenomenon. (Reprinted with permission from Lynch HT, De la Chapelle A. Hereditary colorectal cancer. N Engl J Med. 2003;348:919–32. Copyright © 2003 Massachusetts Medicine Society. pathogenic *MSH6* mutations. Thirty-five percent of these mutations involve only one amino acid.[141] Colorectal cancers are more frequently left-sided in *MSH6* carriers.[142] The risk of endometrial cancer is increased over *MSH2* or *MLH1* carriers (76% vs. 30%) and that of colon cancer is decreased (32% vs. 80%). The median age of onset is 55 years.[143] Combined MSI testing and immunohistochemistry, as well as the distinctive phenotype are used to select families for *MSH6* mutation analysis (Figures 37-9–37-11).

Muir–Torre Syndrome

The Muir–Torre syndrome is the combination of Lynch syndrome and sebaceous adenomas, sebaceous carcinomas, and

keratoacanthomas. Colorectal cancers are most commonly found (51%) and are often proximal to the splenic flexure (60%). Although only 25% of Muir–Torre patients develop a polyp, 90% of patients who develop polyps develop colon cancer. The second most frequent tumors are genitourinary (24%).[144,145] Germ line mutations in *MLH1* and *MSH2* [[145]] have been identified, and many of the tumors exhibit MSI. The visceral tumors are often low-grade and prolonged survival in the presence of metastatic disease has been reported. The median age of diagnosis is 55 years and only 60% has a positive family history.[144]

Diagnosis

1. Amsterdam Criteria
   The key to the diagnosis of Lynch syndrome is a high index of suspicion and an awareness of some of the subtle phenotypic clues. The easiest clue to detect is a strong family history of colorectal and Lynch syndrome cancers. The first Amsterdam criteria (I) (Table 37-7) were created to identify patients with a high probability of having HNPCC. However, the Amsterdam I criteria were faulted for not including extracolonic cancers, and so Amsterdam II criteria were published to correct this (Table 37-7). A third set of Amsterdam Criteria (Amsterdam-like) have been used, where an advanced adenoma is allowed to qualify one of the three affected individuals, accounting for the phenotype attenuation caused by increasingly widespread screening. However Hampel et al. have shown that when Lynch syndrome was diagnosed by MSI-directed mutational testing, 22% of families did not meet Amsterdam criteria and 10/23 probands were older than 50 years.[146] Therefore, although Amsterdam criteria are still useful, on their own they have a high false negative rate. The "false positive" rate of Amsterdam criteria for MMR gene mutation carriers (Lynch syndrome) represents Familial Colorectal Cancer Type X.

2. Bethesda Criteria
   In 1996, a National Cancer Institute workshop on MSI produced a set of criteria to identify patients who's cancers are likely to be microsatellite unstable. These Bethesda criteria and their revision (Table 37-9).[147,148]

TABLE 37-9. Modified Bethesda guidelines

- Patient with 2 HNPCC-related tumors.
- Patient with CRC with first-degree relative with HNPCC-related cancer; one of the cancers at <50 years or adenoma at <40 years.
- Patient with CRC or endometrial cancer at <50 years.
- Patient with right-sided, undifferentiated CRC at <50 years.
- Patient with signet ring CRC at <50 years.
- Patient with adenoma at <40 years.

Modified from Rodriguez-Bigas MA, Boland CR, Hamilton SR, Henson DE, Jass JR, Khan PM, Lynch H, Perucho M, Smyrk T, Sobin L, Srivastava S. A National Cancer Institute Workshop on hereditary nonpolyposis colorectal cancer syndrome: meeting highlights and Bethesda guidelines. J Natl Cancer Inst. 1997;89:1758–62.

include family history as well as tumor characteristics, such as histology and site. The Bethesda criteria are a useful screen for triaging colorectal cancers for MSI testing but were never intended as diagnostic criteria for Lynch syndrome.

3. Tumor testing with MSI and Immunohistochemistry
   MSI testing is being used as a screening test to detect Lynch syndrome although 15% of sporadic colorectal cancers are unstable due to promoter methylation of *hMLH1*. Thus, in screening colorectal cancers for Lynch syndrome, an MSH-High tumor may be further tested with IHC to detect lack of expression of an MMR protein. If hMSH2 is not expressed, this is good evidence for Lynch syndrome. If hMLH1 is not expressed, the clinical situation (i.e., family history, age and site of the cancer) may give a clue as to the existence of Lynch syndrome. The tumor can also be tested for a *BRAF* mutation which, if present, suggests a sporadic, hypermethylated cancer rather than Lynch. After tumor triage by MSI and IHC testing, patients can be selected for genetic testing for a germ line mutation.

4. Histology
   Pathologists may recognize cancers that have arisen due to the mutator phenotype by the presence of tumor infiltrating lymphocytes, a Crohn's-like reaction, mucinous differentiation, signet ring cells, and the absence of dirty necrosis.[149] A tumor with any of these features is a candidate for MSI or IHC testing. Several institutions now routinely perform either MSI or IHC on every colorectal cancer, which minimizes the importance of a pathologist's suspicion.

5. Predictive models
   At least three predictive scores have been created to predict the presence of MMR deficiency in a patient or tumor. MSPath was constructed by Jenkins et al. using tumor-infiltrating lymphocytes, tumor location (proximal vs. distal), mucinous histology, poor differentiation, Crohn's-like reaction, and diagnosis before age 50 years.[149] It had a sensitivity of 93% and a specificity of 55% for MSI-High. MMRpro was devised by Chen et al. to predict the probability that a patient carries a deleterious mutation of *MLH1*, *MSH2*, or *MSH6*, and the chances of developing colorectal or endometrial cancer in the future.[150] It includes family history, endometrial cancer status, and current age or age at last follow-up (in years) if unaffected. Results of MSI testing or IHC are used if available as is the result of previous germ line testing of *MLH1*, *MSH2*, or *MSH6* (positive or not found). The formula had a concordance index of 0.83 and a ratio of observed to predicted cases of 0.94. It is available online at http://www4.utsouthwestern.edu/breasthealth/cagene/ Barnetson et al.[151] produced a predictive formula to calculate the risk of carrying a germ line MMR gene mutation. It is: $Pr/(1-Pr) = 1.39 \times 0.89$ age at

diagnosis $\times 2.57$ gender (male $= 1$, female $= 0.57$) $\times 4.45$ (site of tumor, proximal $= 1$, distal $= 0$) $\times 9.53$ synchronous or metachronous tumor (yes $= 1$, no $= 0$) $\times 46.26$ family history of colorectal cancer (youngest < 50) $\times 7.04$ family history of colorectal cancer (youngest > 50 years of age) (yes $= 1$, no $= 0$) $\times 59.36$ family history of endometrial cancer < 50 years of age (yes $= 1$, no $= 0$). This model provided a subset of patients in whom preoperative tumor biopsies could be subjected to IHC, and the combination has a positive predictive value of 80% for mutation carriers.

Genetic Testing for a Germ line MMR Gene Mutation

Indications

Patients whose families fulfill Amsterdam I, II and like criteria, patients fulfilling revised Bethesda criteria, patients with MSI-high tumors with wild type *BRAF* or loss of expression of an MMR protein are candidates for genetic testing (Table 37-10).

Procedure

Genetic counseling is routine. Patients and family members must understand the advantages and potential disadvantages of testing. The significance and implications of genetic testing in general, and in Lynch syndrome in particular, are discussed, as they apply to the patient and their family. This includes the remote possibility of genetic discrimination and the protection afforded by the recently enacted GINA. Financial concerns are addressed. After all this, informed consent is obtained.

Sequencing of *MSH2*, *MLH1*, *PMS2* and *hMSH6* is now commercially available. The cost of this testing is usually covered by the patient's health insurance. Once the pathologic mutation in the family has been found, screening of at-risk relatives is considerably cheaper. The mutations themselves include a broad spectrum of truncating, frameshift, and missense mutations. A missense mutation results in the substitution of a single amino acid, and the effect on protein function may be negligible. This type of missense mutation is often reported as a variant of unknown significance. About 31% of *MLH1* mutations are this type

TABLE 37-10. Direct mutation finding ($n = 70$)

Category	Sensitivity (%)	Specificity (%)
Amsterdam [$n = 28$]	61	67
Amsterdam II [$n = 34$]	78	61
Bethesda [$n = 56$]	94	25
Bethesda (1–3) [$n = 44$]	94	49

Adapted and reproduced from Syngal S, Fox EA, Eng C, Kolodner RD, Garber JE. Sensitivity and specificity of clinical criteria for hereditary non-polyposis colorectal cancer associated mutations in MSH2 and MLH1. J Med Genet. 2000;37:641–45.

and further testing by a specialized center is required to determine its clinical significance and usefulness. A data bank of known mutations is kept by the International Society for Gastrointestinal Hereditary Tumors (InSiGHT).[152] Some affected families do not have a point mutation but may have a large gene deletion or an intronic mutation that is not detected by sequencing. Such false negative testing is minimized by other molecular techniques, such as Southern Blotting or Conversion analysis.[153]

Strategy of Genetic Testing

Testing should begin with an affected individual (in whom a Lynch syndrome cancer has been diagnosed). When the proband has a negative or a noninformative test (including variant of unknown significance), genetic testing of at-risk family members is not helpful and all at-risk family members require intensive surveillance. When the proband has a pathologic mutation, at-risk family members can be offered genetic screening. Those that carry the mutation need intensive surveillance and/or prophylactic surgery. At-risk family members who are mutation negative are at average population risk of colorectal cancer.

Surveillance

Colorectal cancers in Lynch syndrome can occur in very young patients and develop within 2 years of a negative colonoscopy.[154,155] Adenomas occur earlier and are more likely to be villous. The adenoma to carcinoma transition occurs early and small cancers can be missed.[156] Screening colonoscopy must therefore be thorough and uncompromising with excellent preparation. Most guidelines suggest beginning colonoscopy at age 21, or 10 years younger than the youngest affected relative's age at diagnosis (whichever is younger). Colonoscopies continue every 2 years until age 40 when they are every year. If an adenoma is found, colonoscopy is every year thereafter.

The value of screening colonoscopy in Lynch syndrome was demonstrated by Järvinen and colleagues who studied a group of 252 individuals belonging to 22 HNPCC families.[155] Of these, 137 participated in screening colonoscopy every 3 years, while the remainder refused such evaluation. Colorectal cancer developed in 8% of the screened family members, compared to 16% of those who refused screening. In those individuals who were known to have a DNA MMR gene mutation (Lynch syndrome), the rate of colorectal cancer in those who underwent screening was 18% compared to 41% in those who did not undergo screening. All cancers that developed in the screened group were either Dukes' A or B lesions, with no attributable deaths, compared to more advanced lesions in the unscreened group and nine deaths due to cancer (8%).

Due to the high risk of endometrial cancer in women, annual pelvic ultrasound to examine the endometrium is

recommended beginning between ages 25 and 35 years as the increased risk for gynecological cancer in these patients begins at age 25.[157,158] Endometrial biopsy is done if the ultrasound is abnormal. There are no data demonstrating the efficacy of this type of screening.[159] Should a Lynch syndrome patient be diagnosed with endometrial cancer, they should undergo surveillance colonoscopy prior to hysterectomy in the event that colonic pathology is present and colonic resection required at the same surgery. Similarly, when a Lynch syndrome patient develops colorectal cancer, prophylactic hysterectomy should be considered at the same time as the bowel resection.

Prophylactic colectomy and hysterectomy is the most effective way to prevent cancer in Lynch syndrome patients. Although prophylactic colectomy is not commonly performed in unaffected mutation carriers, its benefits must be discussed.

Treatment

Surgery

The surgical options for colon cancer in a Lynch syndrome patient are a standard right, left, or sigmoid colectomy, or a colectomy and ileorectal anastomosis. For a rectal cancer, the options are a standard anterior proctosigmoidectomy and colorectal or coloanal anastomosis, or abdominal perineal resection with end colostomy, versus a total proctocolectomy with ileal pouch anal anastomosis or end ileostomy. The aim of the more extensive option in either case is to remove at risk mucosa and prevent metachronous cancer, in the way that is routinely done for classical FAP. Oncologically, IRA is the operation of choice for colon cancer. It minimizes cancer risk, preserves anal sphincter function, and retains the reservoir capacity of the rectum.[160,161] This operation eliminates the need for annual surveillance colonoscopy, since only rigid or fiberoptic examination of the rectum is required. The estimated risk of rectal cancer after colectomy and IRA is 12% at 12 years.[162] However, colectomy and IRA may not be the ideal operation for patients with impaired anal sphincter function due to either obstetrical injury or age, for patients with comorbidities, or for those with decreased mobility. It may also predispose some patients to diarrhea and poor functional results. In these patients, a lesser resection may be preferable. It is essential, however, that both the patient and physician recognize the need for ongoing annual colonoscopy, since the risk for a metachronous colon cancer in HNPCC is 45%.[131]

In cases of rectal cancer not involving the sphincters, either anterior resection, coloanal anastomosis or colectomy and ileal pouch anal anastomosis can be considered. In the event that the last option is chosen, preoperative endorectal ultrasound or MRI staging is desirable. In uT3 or uN1 cancers, preoperative chemoradiation should be given since ileal pouches tolerate radiation poorly.

In women undergoing colectomy, strong consideration should be given to performing a hysterectomy and bilateral salpingo-oophorectomy if their family is complete, due to the increased risk of both endometrial and ovarian carcinoma.

There is controversy as to whether surgical treatment or continued surveillance should be offered to the asymptomatic patient who has a mutation identified by genetic testing, but an as yet "normal" colon. Several studies have examined this question using decision analysis methods; however, factors such as patient compliance must be taken into account.[163,164]

Prognosis

The survival rate in Lynch syndrome patients with colorectal cancer is better than that of patients with sporadic colorectal cancer when matched for stage and age of onset.[165,166] There is also evidence that patients with stage II or III microsatellite unstable colorectal cancers do not benefit from 5-fluorouracil-based adjuvant therapy, and may even do worse with it.[167,168]

Chemoprevention

While data exist to support the efficacy of NSAIDs in reducing the risk of colorectal cancer in the general population, such data are lacking for Lynch syndrome.[169,170] The recent CAPP II trial was a controlled, randomized trial of colorectal polyp and cancer prevention using aspirin and resistant starch in carriers of a germ line MMR gene mutation. Its first report described no impact of this chemoprevention on the development of adenomas or carcinomas,[171] although extended follow-up suggests that there may be a benefit in reduced cancer incidence (J. Burn, personal communication).

Calcium and vitamin D intake have been associated with a decreased risk of sporadic colorectal cancer.[172] A trial of supplemental calcium in HNPCC families did not demonstrate a decrease in epithelial proliferation, although the sample size was small and the study was conducted before genetic testing was available.[173]

Familial Colorectal Cancer Type X

This collection of families, where the history of colorectal cancer is strong enough to comply with Amsterdam Criteria but where tumors are microsatellite stable, is poorly defined. The original report that separated these families from Lynch syndrome found a moderate increase in risk of colorectal cancer but no risk of the usual Lynch spectrum of extracolonic cancers. Genetically, the Type X families may include Lynch syndrome due to *hMSH6* mutations (unlikely as a predominance of uterine cancer would be expected), MAP, SPP, and other as yet unknown genotypes. Until FCC Type X is better defined genetically, intensive colonoscopic surveillance for all related family members is all that can be advised.

Our knowledge about Lynch syndrome continues to grow. This disorder is associated with a germ line mutation in one of several MMR genes. Genetic testing is currently available for mutations in *hMLH1*, *hMHS2*, *hMSH6*, and *hPMS2*.

Suspicion of this disorder in a given patient is raised by a family history of early age onset cancer, an increased number of first-degree relatives with colorectal cancer, or a Lynch syndrome-related cancer. Endometrial cancer is the most common extracolonic cancer. While there is debate regarding the frequency and beginning of screening, most clinicians believe that colonic examinations yearly or every 2 years should be performed beginning in the early 20s, or 10 years younger than the youngest affected relative (whichever is first). Prophylactic colectomy may be offered to known mutation carriers as well as members of at-risk families who develop advanced adenomas. Removal of all of the colon and IRA is suitable for patients with a colon cancer while total proctocolectomy and ileal pouch anal anastomosis should be considered for patients with rectal cancer. Continued surveillance of residual colon, rectum, and pouch is mandatory. With careful surveillance and management, colorectal cancer can be prevented in these patients and the mortality rate decreased. In those who develop colorectal carcinoma, the overall survival rate is more favorable than that of patients with sporadic colorectal cancer.

Registries for Patients with Hereditary Colorectal Cancer and Their Families

Treatment of patients with hereditary colorectal cancer requires a thorough understanding of the role that genetics plays in the origin of the syndromes and their inheritance in the families. Care of affected individuals and their families involves clinical recognition, genetic diagnosis, and clinical management. Ongoing care requires careful follow-up and integration of multiple medical specialties. This sort of sophisticated care is best delivered through a Center or Registry dedicated to hereditary colorectal cancer. Such a Center is ideally positioned to conduct meaningful research on their often illuminating cases and families. This chapter assumes that patients and families have access to doctors with suitable knowledge, experience, and support to deliver the kind of care that is needed.

Registries

Once a diagnosis of HNPCC is suspected, a referral to a registry for inherited colorectal cancer or to a cancer center with a high-risk clinic is important. A registry has a database or list of families and their members who have a high frequency of colorectal cancer. Personnel at the registry may include a coordinator, a genetic counselor and a physician director. The mission of registries is to prevent death from hereditary cancer, and to preserve quality of life for the patients and their families. This is accomplished through expert patient care, careful education of patients and other healthcare providers, and innovative research. Care of families with hereditary colorectal cancer is complex and needs to be multidisciplinary. The registry functions to coordinate care between specialties and between the family doctor and the specialist unit. Registry personnel provide further support for myriad problems, such as family stress, health insurance difficulties, and job discrimination. A local registry can be found by accessing the Collaborative Group of the Americas on Inherited Colorectal Cancer at http://www.cgaicc.com.

Colorectal Cancer: Epidemiology, Etiology, and Molecular Basis

Harvey G. Moore, Nancy N. Baxter, and Jose G. Guillem

Epidemiology

Colorectal cancer (CRC) is a disease with a major worldwide burden. It is the fourth most frequently diagnosed malignancy in men and third most common in women, with almost one million people developing CRC annually.[1] In the world, CRC is the third most common cause of cancer death, responsible for 639,000 deaths annually.[2] In the USA, CRC is the third most common cancer in men and women and the second most common cause of cancer death overall, accounting for 11% of cancers diagnosed.[3] It was estimated that 147,000 cases were diagnosed in the USA in 2009 and that there were 50,000 deaths from the disease.[3]

The worldwide incidence of CRC is increasing; in 1975, the worldwide incidence of CRC was only 500,000.[4] In western countries, some of the increase is due to the aging of the population; however, in countries with a low baseline rate of CRC, the incidence is increasing even after age-adjustment. Prior to 1985, the age-adjusted incidence of CRC in the USA also increased; however, since this time the rates have declined an average of −1.6% per year. In the time period 1998–2005, the rate of decline accelerated; −2.8% per year in men and −2.3% per year in women (Figure 38-1).[3] This reduction has been mainly confined to those of white race and is largely limited to a decrease in the incidence of distal cancers. Although the cause of the decrease in incidence is unknown, and may have been influenced by many factors, it is likely that much may be attributable to screening by sigmoidoscopy and colonoscopy.[5] In contrast, the incidence of proximal cancers has remained relatively stable over the same time period.[5] Currently, the overall probability of an individual developing CRC in the USA over a lifetime is 5.5% in men and 5.1% in women.[6]

From a population perspective, age is the most important risk factor for CRC. CRC is predominantly a disease of older individuals; 90% of cases are diagnosed over the age of 50.[6] The risk of CRC continues to increase with age (Figure 38-2). The incidence per 100,000 people age 80–84 is over seven times the incidence in people age 50–54. However, CRC can occur at any age and the incidence of CRC occurring before age 40 may be increasing.[7]

In the USA, the risk of CRC differs by sex. The age-adjusted incidence of CRC is over 40% higher in men than women. Overall, the incidence of CRC in men is 61 per 100,000 males as compared to 45 per 100,000 females.[6] In addition, the ratio of colon to rectal cancer differs by sex; the ratio of colon to rectal cases for women is 3:1 as compared to 2:1 for males.[6]

Race and ethnicity influence CRC risk. Ashkenazi Jewish individuals appear to be at a slightly increased risk of CRC. At least part of this increased incidence may be due to a higher prevalence of the *I1307K* mutation of the adenomatous polyposis gene (*APC*), a mutation that confers an increased risk of CRC development (18–30% lifetime risk). The *I1307K* mutation is found in 6.1% of unselected Ashkenazi Jewish individuals and 28% of Jewish individuals with CRC[8], while the mutation is rare in other populations. In the USA, the incidence of CRC is higher in African Americans of either sex as compared to white Americans. Asian American/Pacific Islanders, Native Americans, and Hispanic Americans experience a lower incidence of CRC than Caucasians (Table 38-1).[3,6] African Americans have not experienced the substantial reduction in incidence of CRC found to have occurred in whites; prior to 1980 incidence in African Americans was actually lower than in white Americans. In African Americans, the increased rate of cancer is predominantly due to a higher rate of proximal cancers.[9,10]

According to the American Cancer Society, between 1996 and 2004 for all patients diagnosed with CRC, 40% of patients were diagnosed with localized disease, 36% with regional disease and 19% with metastatic disease. Five percent of patients were unstaged. As a proportion of total cases, African Americans were more likely to present with advanced disease; 24% of African Americans have metastatic disease at presentation (Table 38-2).[3] Rates of metastatic disease have fallen overtime, most notably for CRC of the distal colon and rectum in whites.[10]
FIGURE 38-1. Age-adjusted colorectal cancer incidence and death rates in the United States 1975–2006.
FIGURE 38-2. Age-specific SEER incidence rates in the United States 1992–2006.

There is substantial geographic variation in the incidence of CRC, with relatively high rates in North America, Western Europe, and Australia and relatively low rates in Africa and Asia (Figure 38-3).[11] Such observations led to Burkitt's hypothesis; that dietary differences, specifically fiber and fat intake, between populations were responsible for the marked variation in rates of CRC found around the world.[12] Burkitt observed that populations in low-risk areas of the third world had greater stool bulk, a faster colonic transit time, and higher dietary fiber intake than populations in high-risk, westernized regions. Although such ecological studies are confounded by numerous factors (for example, variations in average life expectancy, cancer detection methods, etc.), environmental factors (most prominently dietary factors) are still considered to have a major role in this disease. This is supported by studies of migrants from low prevalence areas to high prevalence areas. Such studies generally demonstrate that the incidence of CRC in the migrants increases rapidly to become similar and in some cases to exceed the incidence of the high-risk area.[13] Interestingly, there is less variation in the incidence of rectal cancer between countries as compared to the incidence of colon cancer.[14]

Mortality from CRC is declining in the USA (Figure 38-1). Age-adjusted CRC death rates peaked in the 1940s at 35 per 100,000. In women, rates steadily declined since this time, and between 2001 and 2005 the CRC death rate in white and African American women was 15.3 and 22.4 per 100,000, respectively. In men, death rates changed little until the 1980s and 1990s, then declined significantly; between 2001 and 2005 the CRC death rate in white and African American men was 22.1 and 31.8 per 100,000, respectively (Table 38-1).[3] Improvements in surgical and medical treatments likely explain some of the change, particularly improvements before 1985. More recently, the reduced mortality rate is likely secondary to the reduced incidence of CRC. However, for those who develop CRC, no improvement in case-fatality has been identified since 1986[15] indicating that the trends in mortality are likely complex. African Americans suffer the highest mortality rate from CRC in the USA (Table 38-1).[3] The reasons for the higher mortality rate are likely multifactorial, including the higher incidence of CRC, and the differences in stage distribution. However, African Americans had worse 5-year survival for all stages of disease, and the difference in 5-year survival rates between white and African Americans has actually increased over time, from an absolute difference of 5% in the 1970s (51% vs. 46%) to an absolute difference of 13% in 1990s (63% vs. 53%).[16] Between 1996 and 2004, 5-year survival for colon cancer in Caucasians and African Americans was 66% and 55%, respectively; for rectal cancer 67% and 59%, respectively.[3] Differences in incidence, stage distribution and survival of CRC between white and African Americans are in part due to differences in socioeconomic status, screening rates and treatment;[17] however, the differences may also be due to genetic and environmental factors that have yet to be elucidated.

TABLE 38-1. Incidence and mortality rates* for CRC by site, race and ethnicity, US 2001–2005

		White	African American	Asian American and Pacific Islander	American Indian/ Alaska Native	Hispanic/Latino
Incidence	Male	58.9	71.2	48.0	46.0	47.3
	Female	43.2	54.5	35.4	41.2	32.8
Mortality	Male	22.1	31.8	14.4	20.5	16.5
	Female	15.3	22.4	10.2	14.2	10.8

FIGURE 38-3. **A** Age-Standardized (to the world population) incidence rates of cancer of the large bowel among females, **B** Age-standardized (to the world population) incidence rates of cancer of the large bowel among males.

Because CRC is a survivable cancer, with a 5-year survival rates adjusted for life expectancy of 64%,[6] the prevalence of people living with a diagnosis of CRC in the population is substantial. In total, over one million Americans alive in 2006 have had a diagnosis of CRC.[18]

Etiology

Dietary Constituents and Supplements

The colon is constantly exposed to the substances we ingest and the by-products of ingestion. Thus, the role of diet in the pathogenesis of CRC has long been speculated. However, the relationship between diet and CRC risk is at best unclear. Studies in this area are difficult to conduct, as exposures tend to be multifactorial and change, with our diet, over time. In addition, because colorectal carcinogenesis is a multistep process, a number or combination of exposures may be necessary, and genetic susceptibility is likely to play a role. In addition, in most cases randomized trials are not feasible, and therefore studies must be observational in nature. When intervention studies are possible, follow-up is relatively short term (compared to the long-term exposure that may be necessary for cancer development), and single dietary components are generally selected for evaluation although the influence of diet may depend on complex interactions between dietary constituents. In addition, to reduce sample size some studies are conducted on patients with a previous history of adenomatous polyps. Some interventions in these patients may not be effective, as such patients may have already acquired numerous genetic alterations in normal appearing colonic mucosa. Some interventions may need to be instituted prior to the development of polyps. Although it can be stated that an individual with no other risk factors for CRC who ingests a diet that is high in fiber, fruits, vegetables, and low in animal fat and red meat is on average at lower risk of CRC than an individual who eats a diet low in fiber, fruits, and vegetables and high in animal fat and red meat, it is difficult to determine with certainty which dietary components or combinations are responsible for the decreased risk.
Dietary Fat

Dietary fat, particularly saturated animal fat, has been implicated in carcinogenesis of the colon and rectum. Early research using animal models demonstrated a carcinogenic effect of dietary fat on colonic mucosa,[19,20] and epidemiologic studies found parallels between CRC rates and dietary fat consumption. Countries with populations eating a high fat diet had higher CRC rates than countries with populations eating a lower fat diet.[21] However, dietary fat consumption is related to a number of other factors that may influence cancer risk, including other dietary factors such as dietary fiber and micronutrient consumption, as well as life-style factors, such as exercise and alcohol consumption. Therefore, ecological comparisons between countries are subject to a substantial risk of confounding.[22]

Over 13 case-control studies have been conducted to evaluate the relationship between dietary fat intake and the risk of CRC. These have been quantitatively summarized by Howe et al.[23] and include 5,287 cases with CRC and 10,470 controls. Although positive associations were identified for total energy intake and CRC in almost all of the studies, there was no energy-independent relationship between dietary fat intake and CRC risk. After controlling for total energy intake, the odds of development of CRC in subjects with the highest dietary fat intake as compared to those with the lowest intake was 0.90 (95% CI, 0.72–1.13). Overall, there was no evidence for any association of total dietary fat intake and development of CRC.

In addition, at least six cohort studies have been conducted to evaluate the relationship between dietary fat and CRC.[24–27] Only one of these studies[25] identified an association between dietary animal fat and development of CRC, with a twofold increase of CRC in the highest consumers of animal fat compared to the lowest consumers. In a randomized, controlled clinical trial, 48,835 women were randomized to either dietary modification (aimed at reducing dietary fat and increasing consumption of fruits, vegetables, and grains) or to the control group (no dietary modification). At a mean follow-up of 8.1 years, there was no difference in the incidence of CRC between those in the dietary modification group and controls (RR = 1.08; 95% CI, 0.91–1.29). Of note, the amount of reduction of dietary fat achieved by patients in the dietary modification group was only 70% of the target reduction described in the original study design, and it is possible that better compliance might have resulted in a positive finding.[28] However, taken together, the preponderance of evidence does not support an increased risk of CRC with increasing consumption of dietary fat.

Red Meat

There are a number of potential carcinogenic mechanisms unrelated to fat content that may result in a causal relationship between red meat ingestion and CRC. Red meat is high in iron, a prooxidant. Dietary iron may increase free radical production in the colon, and these free radicals may cause chronic mucosal damage or promote other carcinogens. In humans, red meat ingestion stimulates the production of N-nitroso compounds in a dose-response fashion.[29] As many N-nitroso compounds are known carcinogens, this is a potential mechanism for an association between red meat and CRC. Formation of heterocyclic amines and polycyclic aromatic hydrocarbons in meat by cooking over an open flame or cooking until well done may be an important factor as these compounds are carcinogenic in animal models.[30] Alternatively, dietary heme, present in red meat, may have a cytotoxic effect on colonic surface epithelium, resulting in rebound inhibition of apoptosis and crypt hyperplasia.[31]

A large number of epidemiologic studies have been conducted to determine the effect of ingestion of red meat on CRC risk. Three meta-analyses have been published,[32–34] one combining the results of 13 cohort studies,[33] the second combining 21 case-control studies and six cohort studies,[34] and the third involving 17 prospective cohort studies and two case-control studies.[32] In the three meta-analyses, the pooled estimate for the increase in the risk of CRC due to red meat consumption was similar; odds of development of CRC in the highest meat consuming groups as compared to the lowest was 1.14–1.28. A daily increase of 100 g of red meat (3.5 oz) was associated with a 12–17% increased risk of CRC (RR = 1.24–1.28). The risk was substantially higher with the ingestion of processed meat in two studies (49–54%),[33,34] but was slightly less for red meat in the most recent analysis.[32] Of note, individuals that consume diets high in red meat generally consume diets low in other dietary factors, such as antioxidants that may themselves be important in colorectal carcinogenesis. It is therefore difficult to rule out the possibility that the apparent effect of red meat on the development of CRC may be confounded or modified by other dietary or lifestyle factors. Genetics may also play a role. In the Fukuoka Colorectal Cancer Study, colon cancer risk was increased in relation to red meat intake only in individuals with a specific polymorphism of Cytochrome P450 2E1 (CYP2E1).[35]

Fruit and Vegetable Intake

The effect of dietary intake of fruit and vegetables on CRC risk has been evaluated extensively. Fruits and vegetables are a source of antioxidants, including carotenoids and ascorbate. Other bioactive constituents in fruits and vegetables that may protect against carcinogenesis include the indoles and isothiocyanates. Previous research, including results from 22 case-control studies and four prospective cohort studies, has provided substantial support for the hypothesis that vegetable intake reduces the risk of CRC, while intake of fruit did not seem to have an effect.[36] Other studies, however, did not demonstrate a convincing link between vegetable or fruit intake and a reduced risk of CRC. In four large prospective cohort studies (the Nurse's Health Study of 121,700 women,

the Health Professionals Follow-up Study of 51,529 men, the Netherlands Cohort Study on Diet and Cancer including 120,852 men and women, and the Cancer Prevention Study II Nutrition Cohort, including 133,163 men and women),[37–39] fruit and vegetable intake was not statistically significantly associated with a reduced risk of CRC.

More recent studies have reported conflicting results. A pooled analysis of 14 cohort studies, including 756,217 men and women followed between 6 and 20 years also did not find a significantly reduced risk of CRC in the highest consumers of total fruits and vegetables, total vegetables, or total fruits. However, when examined by colon site, high total fruit and vegetable intake was inversely correlated with the risk of CRC of the distal colon (RR = 0.74; 95% CI, 0.57–0.95) but not for the proximal colon.[40] Finally, the recently reported European Prospective Investigation into Cancer and Nutrition (EPIC) study, involving a cohort of 452,755 men and women followed an average of 8.8 years, reported a significant inverse relationship between total fruit and vegetable consumption and the risk of colon cancer (RR = 0.76; 95% CI, 0.63–0.91).[41]

The influence of fruit and vegetable consumption on the development of colorectal adenomas has also been investigated. The Polyp Prevention Trial randomized 2,079 people with a history of colorectal adenomas to either intensive dietary counseling with assignment to a diet low in fat and high in fruits, vegetables, and fiber, or to a control group (no dietary change).[42] No difference in adenoma recurrence rate was found in the intervention group as compared to the control group. However, follow-up of 34,467 women participating in the Nurses' Health Study found an inverse relationship for total consumption of fruit, but not vegetables, on the risk of colorectal adenomas. Women who consumed five or more servings of fruit daily had a relative risk of 0.60 (95% CI, 0.44–0.81) for developing adenomas in the distal colon or rectum (<60 cm from the anal verge) compared to women who consumed one or fewer servings.[43] A nested case-control study compared 3,057 men and women with at least one adenoma detected during participation in the Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening trial to 29,413 control subjects. Similar to the Nurses' Health Study, total fruit consumption was associated with a significantly reduced risk of distal adenoma (odds ratio (OR) = 0.75; 95% CI, 0.66–0.86), whereas total vegetable consumption was not. However, high intake of certain vegetable groups, specifically deep-yellow vegetables, onions, and garlic was associated with a lower risk of adenoma development.[44]

Overall, the evidence for an association between fruit and vegetable intake and the risk of CRC is inconsistent. Given this, it is unlikely that a large number of cases of CRC can be attributed directly to a lack of intake of fruits or vegetables, or that major additional interventions to increase consumption would lead to a substantial reduction in the incidence of CRC.

Fiber

Dietary fiber was one of the first dietary components thought to have a protective role in carcinogenesis. An association of a high fiber diet with a decreased risk of CRC was first theorized in 1969 by Burkitt;[12] however, the data regarding the association between fiber and CRC risk are conflicting. A number of mechanisms have been proposed for the protective effects of fiber; fiber may increase intestinal transit and therefore reduce the length of exposure of the colon to carcinogens, or fiber may dilute or absorb various potential carcinogens, particularly bile salts. In addition, products of fiber degradation and fermentation in the colon (such as butyrate) may also play a role.[45] Surprisingly, two large American cohort studies, the Nurses' Health study[46] and the Health Professionals' Follow-up Study[24] found no evidence of benefit of fiber on CRC risk.

However, more recent studies have reopened the debate. In the PLCO Cancer Screening Trial,[47] a nested case control study of over 37,508 people undergoing flexible sigmoidoscopy was performed using food frequency questionnaires. People who reported the highest amounts of fiber in their diets had the lowest risk of colorectal adenomas; 27% risk reduction compared to people who ate the least amount of fiber. The strongest association was found for fiber from grains, cereals, and fruits but not for fiber from legumes and vegetables. When colonic and rectal adenomas were evaluated separately, the effect of fiber was seen only in colonic adenoma. In a second prospective cohort study, comparing the diet of over 500,000 people in 10 European countries, investigators[48,49] found that people who consumed the most fiber had a 25% lower incidence of CRC than those who consumed the least fiber. Again, the protective effect was greater for the colon than for the rectum. These discordant results prompted a meta-analysis in which the data from 13 prospective cohort studies were reanalyzed. Although dietary fiber intake was inversely associated with the risk of CRC in age-adjusted analyses, this association did not hold when adjusted for other dietary risk factors.[50] More recent cohort studies have produced conflicting results.[51,52]

Dietary interventions to increase fiber intake have proven unsuccessful in reducing the risk of colorectal neoplasia. A meta-analysis has evaluated the effect of five intervention trials.[53] These studies randomized a total of 4,349 individuals to some form of fiber supplementation or high fiber dietary intervention. When the data were combined, there was no difference between the intervention and control groups for the number of subjects developing at least one adenoma (RR = 1.04; 95% CI, 0.95–1.13). The authors concluded that there is currently no evidence from randomized studies to suggest that increased dietary fiber intake reduces the incidence or recurrence of adenomatous polyps within a 2–4-year period. However, recently data from the US Polyp Prevention trial revealed that although there was no protective effect of fiber in those assigned

to fiber therapy, in the subgroup of those most adherent to dietary changes (high-fiber, high-fruit and -vegetables, low-fat), defined as "super compliers," there was a 35% reduced incidence of recurrent adenomas (RR = 0.65; 95% CI, 0.47–0.92).[54]

Currently, there is no single accepted definition of fiber. Many different types of fiber exist (soluble/non-soluble; polysaccharides/non-polysaccharides) and these differences may influence CRC risk. Several studies suggest that fiber from whole grains may be protective against CRC.[51,55] In addition, fiber intake itself may not be protective but may be correlated with other healthy lifestyle choices as well as other components of a healthy diet (for example, high vegetable, low fat, and low meat). The lack of effect found in randomized trials as compared to observational studies indicates this may be the case. However, the intervention trials may have been too short in duration to demonstrate an effect.

Calcium and Vitamin D

Substantial epidemiologic and experimental evidence exists to support the beneficial effect of calcium for the prevention of colorectal neoplasia. Calcium has the capacity to bind and precipitate bile acids and may directly influence mucosal cell proliferation. Most, although not all, of the observational studies evaluating the influence of dietary calcium have demonstrated a protective effect of calcium on the risk of CRC. Two randomized, double-blind, placebo-controlled intervention trials of calcium for the prevention of adenoma recurrence that included a total of 1,346 subjects[56,57] have demonstrated that the use of calcium supplementation (1,200 mg daily for a mean duration of 4 years or 2,000 mg daily for a mean duration of 3 years) was associated with a reduction in the recurrence of colorectal adenoma, although only one study[56] achieved statistical significance. In a meta-analysis of the two studies, the relative risk of developing recurrent adenomas was 0.74 for patients randomized to receive calcium as compared to placebo.[58]

The effect of calcium on a non-high-risk cohort is less clear. A meta-analysis of available studies conducted in 1996[59] concluded that the evidence to support the benefit of calcium intake on reduction of colorectal neoplasia was not consistent with a substantial effect. A more recent pooled analysis of ten cohort studies, including 534,536 individuals[60] published in 2004 evaluating the influence of dairy foods and calcium on CRC demonstrated a consistently decreased risk of CRC for those with the highest intake of dietary calcium as compared to those with the lowest intake (RR = 0.86; 95% CI, 0.78–0.95). Several subsequent large cohort studies have reported an inverse relationship between calcium intake and CRC incidence, with relative risks between 0.68 and 0.84 in men and 0.64 and 0.70 in women.[61–64] However, a randomized, placebo-controlled trial of calcium plus vitamin D supplementation involving 36,282 postmenopausal women produced conflicting results. Women randomized to 1,000 mg daily of elemental calcium plus 400 IU vitamin D for an average of 7 years had a relative risk of CRC of 1.08 (95% CI, 0.86–1.34) compared to women who received placebo.[65] This trial has been criticized for having an insufficient follow-up period, too small a dose of daily calcium, and many potential nutritional confounders.[66]

Vitamin D alone may also have a chemopreventive effect via modulation of calcium absorption and gene expression.[67] Observational data provided the first suggestion of a link between vitamin D concentrations and CRC risk.[68] Preclinical investigation revealed several possible mechanisms by which Vitamin D exerts a chemopreventive effect on CRC, including inhibition of β-catenin[69] or other antiproliferative effects.[70,71] A large epidemiological study found a 29% reduction in CRC risk in individuals with the highest Vitamin D intake.[39] In a case control study nested within the Multiethnic Cohort Study, plasma 25 (OH) D levels were measured using a chemiluminescence assay in 229 patients with CRC and 434 matched controls. An inverse trend was observed between Vitamin D level and the risk of CRC (OR, per doubling of 25(OH)D = 0.68; 95% CI, 0.51–0.92).[72] A recent meta-analysis investigated the relationship between circulating 25(OH)D levels and Vitamin D intake on the incidence of colorectal adenomas. Circulating 25(OH)D was inversely correlated with the incidence of adenomas (OR = 0.70; 95% CI, 0.56–0.87) for the high versus low circulating 25(OH)D groups. A similar finding was noted for high versus low Vitamin D intake (OR = 0.89; 95% CI, 0.78–1.02).[73] However, two recent meta-analyses addressing the relationship between Vitamin D and CRC incidence have produced conflicting results.[74,75] In a meta-analysis of eight longitudinal studies addressing the relationship between serum 25(OH)D levels and CRC incidence, in patients with an increase of 25(OH)D by 20 ng/ml the OR for CRC incidence was 0.57 (95% CI, 0.43–0.76).[74] However, a meta-analysis of ten cohort studies involving 2,813 cancer cases reported that Vitamin D intake was associated with only a nonsignificant 6% reduction on CRC risk (RR = 0.94; 95% CI, 0.83–1.06).[75]

Folate

Folate, a B vitamin, is important for normal DNA methylation. Methylation is important in the regulation of cellular gene expression. Folate deficiency may lead to cancer through disruption of DNA synthesis and repair, or loss of control of proto-oncogene activity.[76] In 15 retrospective epidemiologic studies evaluating the association between folate and CRC risk, most demonstrate a statistically significant or trend toward a significant relationship between higher intake of folate and a reduced risk of CRC or adenoma formation. In an unpublished meta-analysis of 11 prior prospective studies, a 20% reduction in the risk of CRC was found in those with the highest folate ingestion as compared to those with the lowest level of ingestion.[77]

However, recently results of two randomized, double-blind, placebo-controlled intervention trials have been published that do not support a protective effect of folate supplementation.[78,79] In the first study, patients with a prior history of colorectal adenomas randomized to 1 mg of folic acid daily had a 44.1% incidence of at least one adenoma during follow-up, versus 42.4% in the placebo group. Patients on folate had a trend toward a higher incidence of advanced adenoma (11.4% vs. 8.6%, RR = 1.32; 95% CI, 0.90–1.32), as well as a higher incidence of ≥3 adenomas (9.9% vs. 4.3%, RR = 2.32; 95% CI, 1.23–4.35).[79] In the second study, 0.5 mg/day of folate was found to have no effect on adenoma recurrence (RR = 1.07; 95% CI, 0.43–0.91). No increase in advanced adenoma for folate users was observed in that study.[78] Taken together, these studies demonstrate that folate supplementation is unlikely to be of benefit as secondary prevention in patients with a history of colorectal adenomas, and may actually be detrimental. One hypothesis to explain these results is that folate plays a "dual-modulator" role. There may be a protective influence of moderate dietary increases initiated before the establishment of neoplastic foci, but a promoter effect on preestablished, clinically occult neoplastic foci. Early prevention is likely due to the protection against DNA damage by maintaining adequate methyl groups for DNA methylation and nucleotide synthesis. A possible mechanism underlying enhanced tumor growth is an increased provision of nucleotide precursors to rapidly replicating neoplastic cells.[80,81]

Consistent with this data, one recent observation suggests folate supplementation may actually increase the risk of CRC. Since 1996 and 1997, the US Food and Drug Administration (FDA) has required folate fortification of all flour and cereal grain products in the USA and Canada, respectively,[82] in an effort to reduce the incidence of neural tube defects. Concurrent with this mandate, a downward trend in CRC incidence seen in the USA and Canada during the early 1990s began to reverse with marked increases seen between 1997 and 1998.[83] While this observation clearly does not establish a causal relationship, it is a provocative finding and underscores the fact that the relationship between folate and CRC deserves further study.

Alcohol

Alcohol ingestion has a possible role in colorectal carcinogenesis. Alcohol may alter folate absorption, increasing CRC through the reduction of folate bioavailability. Acetaldehyde, a product of alcohol metabolism may have a role, and alcohol may also contribute to abnormal DNA methylation directly. A meta-analysis of five follow-up studies and 22 case-control studies published in 1990[84] demonstrated only a weak association between alcohol and CRC, although the effect was stronger when only rectal cancer was considered. Two more recent meta-analyses of 16[85] and 5 cohort studies[86] demonstrate a strong association between alcohol consumption and development of CRC. In the first, high

alcohol intake was significantly associated with an increased risk of colon (RR = 1.50; 95% CI, 1.25–1.79) and rectal cancer (RR = 1.63; 95% CI, 1.35–1.97), corresponding to a 15% increase of colon or rectal cancer for an increase of 100 g of alcohol intake per week.[85] In the second, increasing consumption of alcohol was significantly correlated with an increased risk of CRC in men and women (RR = 2.96; 95% CI, 2.27–3.86 for consumption ≥92 g/day in men).[86] The EPIC trial, a prospective cohort trial involving 478,732 subjects, looked at both baseline and lifetime intake of alcohol as risk factors. Lifetime alcohol intake was significantly correlated with increased CRC risk (RR = 1.08; 95% CI, 1.04–1.12 for 15 g/day increase). Similar results were obtained when only baseline alcohol consumption was considered.[87]

The findings of an association with alcohol intake are consistent, and there are no studies that demonstrate a protective effect of higher alcohol consumption. Thus, the totality of the evidence indicates that a high level of alcohol intake (two or more drinks per day) is associated with an increased risk of CRC.

Of note, higher intake of a Western-style diet (high intake of meat, fat, refined grains, and dessert) versus a prudent diet (high intake of fruits and vegetables, poultry, and fish) has been associated with an increased risk of recurrence and mortality in patients with Stage III colon cancer treated with surgery and adjuvant chemotherapy.[88] In a prospective cohort study involving 1,009 Stage III CRC patients enrolled in a randomized adjuvant chemotherapy trial, food frequency questionnaires were administered during and for 6 months after adjuvant chemotherapy. At a median follow-up of 5.3 years, patients in the highest quintile of Western dietary intake had a significantly worse disease-free (adjusted hazard ratio (AHR) 3.25; 95% CI, 2.04–5.19) and overall survival (AHR 2.32; 95% CI, 1.36–3.96) compared to those in the lowest quintile of Western dietary pattern.

Aspirin and Nonsteroidal Anti-inflammatory Drugs

There is considerable observational evidence that the use of aspirin or other nonsteroidal anti-inflammatory drugs (NSAIDs) has protective effects at all stages of colorectal carcinogenesis (aberrant crypt foci, adenoma, carcinoma, and death from CRC).[67] The mechanism of antineoplastic action of NSAIDs is incompletely understood, but it is believed that both cyclooxygenase (COX)-dependent and COX-independent pathways may be involved.

At least 30 observational studies have been conducted to evaluate the influence of NSAID (primarily aspirin) use on the development of CRC and colorectal adenoma. A consistent reduction in the risk of colorectal neoplasia in NSAID users is identified in these studies of various design.[67] In a pooled analysis of studies evaluating the effect on colorectal adenoma, the summary risk ratio for colorectal adenoma in aspirin users was 0.7 and in NSAID users

was 0.6, indicating a statistically significant reduction of the risk in aspirin and NSAID users.[89] In the pooled analysis of the effect of aspirin and NSAIDs on CRC risk, the results were virtually the same.[90] Overall, the data evaluating the effect of nonaspirin NSAIDs is more limited than that for aspirin.

A number of intervention studies have been conducted, and a Cochrane review of the results of the randomized, controlled intervention trials has been published.[91] The authors of this meta-analysis reviewed one population-based prevention trial (including 22,071 people),[92] three secondary prevention trials in patients with sporadic polyps (including 2,028 patients),[93–95] and four trials in 150 patients with familial adenomatous polyposis.[96–99] The authors conclude based on data from these high quality trials that there is some evidence for the effectiveness of intervention strategies using NSAIDs for the prevention of colorectal adenoma. However, the single primary prevention trial reviewed[92] did not demonstrate a decreased incidence of CRC in the intervention group. Subsequent primary prevention trials also did not demonstrate efficacy,[100,101] leading to a recommendation by the US Preventive Services Task Force against aspirin/NSAID use for primary CRC prevention in average-risk individuals.[102] However, a recent pooled analysis of two large randomized trials from the UK with over 20 years of follow-up revealed a statistically significant reduction in CRC incidence in aspirin users (RR = 0.63; 95% CI, 0.47–0.85, $P = 0.002$, if allocated to aspirin for 5 years or more), but only after a latency period of 10 years or longer.[103]

NSAIDs and aspirin may play an important role in secondary chemoprevention of colorectal adenomas and cancer. Recently, Logan et al.[78] reported a randomized, double-blind trial of aspirin and folate in the prevention of recurrent colorectal adenomas. Patients randomized to aspirin 300 mg/day had a significantly reduced risk of recurrent adenoma compared to the placebo group (RR = 0.79; 95% CI, 0.63–0.99).[7] Baron et al.[104] randomized 2,587 to either the COX-2 inhibitor rofecoxib 25 mg/day versus placebo. Adenoma recurrence was less frequent for rofecoxib subjects than for those randomized to placebo (41% vs. 55%; $P < 0.0001$; RR = 0.76; 95% CI, 0.69–0.83).[104] Other recent studies have evaluated the role of COX-2 inhibitors in the prevention of CRC.[105,106]

Prolonged use of NSAIDs may have additional benefits. Long-term follow-up of the Aspirin/Folate Polyp Prevention Study revealed that patients who used regular NSAIDs in the four years following the study intervention (3 years of 81 mg aspirin/day) had a persistent reduction in the development of adenoma versus patients who were infrequent poststudy NSAID users (RR = 0.62; 95% CI, 0.39–0.98).[107] In addition, regular aspirin use may result in lower cancer-specific mortality in patients with a history of CRC. In a prospective cohort study involving 1,279 patients previously treated for Stage I–III colorectal cancer, regular aspirin users had a significantly reduced risk of CRC-specific mortality versus nonusers (RR = 0.71; 95% CI, 0.53–0.95).[108]

Because chemopreventive agents must be used in the general population to substantially reduce the burden of disease, the risks of chemoprophylaxis with aspirin or NSAIDs may outweigh the benefits. Serious GI complications occur in regular users of aspirin and NSAIDs. Although events are rare, hospitalizations for gastrointestinal complications occur in 7–13 per 1,000 chronic users of NSAIDS per year.[109] In addition, there are potential cardiotoxic effects of COX-2 inhibitors and thus their use in chemoprevention cannot be supported.[110] A number of authors have evaluated the cost-effectiveness of chemoprevention of CRC with NSAIDs[111] or COX-2 inhibitors[112] and found that chemoprophylaxis with these compounds is not cost-effective.

Hormone Replacement Therapy

Observational studies have demonstrated an association between hormone replacement therapy (HRT) in women and a reduction in both incidence and mortality from CRC. Possible mechanisms for the effect of HRT include a reduction in bile acid secretion (a potential promoter or initiator of CRC), as well as estrogen effects on colonic epithelium, both directly and through alterations in insulin-like growth factor with the use of estrogens. A meta-analysis of 18 observational studies of postmenopausal HRT demonstrated a 20% reduction in incidence of CRC in women who had taken HRT as compared to those that had never taken HRT.[113] The Women's Health Initiative was a randomized trial of estrogen plus progestin in 16,608 postmenopausal women. The study was discontinued early, as after a mean of 5.2 years of follow-up, it was determined that the relative risk of breast cancer in the treatment group exceeded the predefined stopping boundary and the overall risk of adverse outcomes exceeded the benefits.[114] At that time, there appeared to be a protective effect of HRT on the incidence of CRC. With further follow-up, a total of 122 cases of CRC developed in this cohort[115] 43 cases in the group receiving HRT and 72 cases in the group receiving placebo, indicating that relatively short-term HRT was associated with a significantly decreased risk of CRC. In a recent case-control study of 2,648 patients with CRC and 2,566 controls self-reported the use of HRT was associated with a 63% relative reduction in the risk of CRC (RR = 0.67; 95% CI, 0.51–0.89). Similar to prior studies,[116] a significant effect was seen only in women who used combined estrogen–progestin combinations, and not in users of estrogen-only preparations.[117] Others, however, have reported a protective effect of HRT regardless of the preparation used.[118] Postmenopausal HRT has also been associated with a decreased incidence of colorectal adenomas[119] and improved colorectal cancer-specific and overall survival (with the initiation of estrogen therapy within 5 years of diagnosis of CRC).[120]

Overall, there appears to be a consistent reduction in the risk of CRC with the use of HRT. However, given the potential adverse effect of HRT, this should not be used as a primary preventive strategy for CRC.[121]

Obesity

Obesity appears to increase the risk of colon cancer in men and premenopausal women. Case-control studies[122,123] and cohort studies[124–126] have demonstrated a strong association between a high body mass index (BMI) and incidence of CRC, with an up to twofold increased risk of CRC found in the obese. A more accurate predictor than BMI may be the waist-hip ratio, a measure of abdominal obesity. A recent meta-analysis of 30 prospective studies revealed an increasing risk of colon cancer with increasing waist-hip ratio (per 0.1 unit) in men (RR = 1.43; 95% CI, 1.19–1.71) and women (RR = 1.20; 95% CI, 1.08–1.33).[127] One of the proposed mechanisms for the association is the relative insulin resistance found in many obese patients. Insulin resistance results in hyperinsulinemia and increased activity of Insulin Growth Factor (IGF) peptides. High IGF-1 levels are associated with cell proliferation[124] and may increase the risk of colonic neoplasia. In the past, most studies have demonstrated a stronger association between obesity and CRC risk in men than in women.[127,128] More recent evidence has demonstrated that in women, the association between obesity and CRC risk may be modified by estrogen. A number of observational studies have demonstrated an increased risk of CRC in obese women; however, the association was limited to premenopausal women.[125,129] In postmenopausal women, the increased estrogen production associated with obesity was thought to mitigate the risk. Of note, not all studies have confirmed this relationship.[124,130,131]

Obesity is also a risk factor for the development of colorectal adenomas, although like the risk of CRC, the effect appears to be stronger in men than in women.[132,133] In a pooled analysis of six prospective trials involving 8,213 participants, obesity was statistically significantly associated with the risk of metachronous adenoma in men (OR = 1.36; 95% CI, 1.17–1.58) but not in women (OR = 1.10; 95% CI, 0.89–1.37).[133] In men, obesity may also be associated with a shortened interval for the development of metachronous adenomas, as well as a higher incidence of advanced adenomas, particularly with a positive family history.[134]

Physical Activity

Over 50 studies have been conducted to evaluate the influence of physical activity on CRC risk. Overall, the literature is relatively consistent with respect to the effect: Greater physical activity (occupational, recreational, or total activity) is associated with a reduced risk of CRC. The effect is relatively small; the estimated increased risk of colon cancer in the sedentary ranges from 1.6 to 2.0. (Of note, this compares to the increased risk of heart disease due to a sedentary lifestyle of 1.3–1.4).[135] The effect of physical activity on colon cancer is consistent in both case-control studies and cohort studies.[136] A meta-analysis of 19 cohort studies and 28 case-control studies revealed a protective

effect against colon cancer in physically active males (RR = 0.78; 95% CI, 0.68–0.91) and females (RR = 0.71, 95% CI, 0.57–0.88).[137] A recent prospective cohort study involving 488,720 participants revealed that men who participated in exercise/sports five or more times a week, compared to rarely or never, had a relative risk of colon cancer of 0.79 (95% CI, 0.68–0.91, P = 0.001), corresponding to a 21% risk reduction. In women, there was a trend toward a protective effect (RR = 0.85, P = 00.376).[135] Sedentary behavior (time spent watching television/videos, ≥9 h/day) was positively correlated with colon cancer (RR = 1.61, 95% CI, 1.14–2.27, P < 0.001) in men.[135] The effect of physical activity on the risk of rectal cancer is somewhat less consistent; some studies demonstrate no effect,[137,138] and in studies that do demonstrate an effect, it is weaker.[135] In the NIH-AARP study, there was a nonsignificant trend toward protection from rectal cancer in men (RR = 0.76, P = 0.07), but no protective effect in women (RR = 0.95, P = 0.23).[135] The amount of physical activity required to have an effect is substantial – risk reduction is estimated to occur with 3.5–4 h of vigorous activity (running) per week but requires 7–35 h of moderate activity (walking at a brisk pace) per week.[135,136]

The biological mechanisms that explain the relationship between physical activity and CRC risk are unclear. Increased physical activity leads to changes in insulin sensitivity and IGF levels, and both insulin and IGF are potentially involved with colorectal carcinogenesis.[139,140] Additional proposed mechanisms include effects of physical activity on prostaglandin synthesis, effects on antitumor immune defenses, and the reduction in percent body fat associated with exercise.[141] The mechanism is almost certainly multifactorial. Nonetheless, for a host of health-related reasons, frequent moderate to vigorous physical activity can be recommended to most patients without hesitation.

Smoking

Consistent with a 35–40 year time lag between exposure and induction of cancer, early studies did not demonstrate an association between cigarette smoking and colorectal neoplasia. More recent studies are more consistently positive. In a review of the literature conducted in 2001,[142] 21 of 22 studies evaluating the relationship between cigarette smoking and colorectal adenoma were positive, smokers demonstrating a two to threefold elevation of adenoma risk as compared with nonsmokers. Twenty-seven epidemiologic studies that demonstrate an association between tobacco and the risk of CRC have been conducted.[142] Of studies in the USA conducted after 1970 in men, and 1990 in women (studies with adequate induction time – 35 to 40 years after smoking became common), most demonstrate an association between heavy smoking and increased CRC risk. The majority of studies demonstrate an effect at relatively high levels of smoking (20 or more cigarettes per day). A recently reported

pooled analysis of the Women's Health Initiative study involving 146,877 women revealed a significant association between cigarette smoking and the risk of CRC overall, but this association was found only for rectal cancer (RR = 1.95; 95% CI, 1.10–3.47) and not colon cancer (RR = 1.03; 95% CI, 0.77–1.38).[143] A meta-analysis of 106 studies revealed a positive dose-response relationship between increasing cigarette consumption and CRC risk. The risk increased by 7.8% for every additional 10 cigarettes per day or by 4.4% for every additional 10 pack-years. The incidence of CRC was 65.5 per 100,000 in smokers and 54.7 per 100,000 in nonsmokers.[144]

Smoking may modify the effect of micronutrients on CRC risk. A recent case-control study revealed a strong protective effect of several dietary carotenoids found in fruits and vegetables, including beta-carotene, on the development of CRC. However, this protective effect was attenuated, or in some cases reversed, in heavy smokers.[145] Similarly, the inverse association found between fruit and vegetable consumption and CRC risk in the EPIC trial for never and former smokers was reversed in current smokers.[41] Another case-control study utilizing a case-unaffected sibling design involving 2,248 siblings did not reveal a positive association between cigarette smoking and CRC overall, but an association between increasing duration of smoking and microsatellite instability-high (MSI-H) tumors was observed (RR = 1.94; 95% CI, 1.09–3.46 for smoking >30 years vs. nonsmokers).[146] There are a number of possible explanations for these findings; cigarette smoke may generate replication errors, overwhelming the DNA mismatch repair (MMR) mechanism, or may affect MMR directly.

Cholecystectomy

Abnormal bile acid metabolism may predispose both to CRC and cholelithiasis. After cholecystectomy, increased quantities of secondary bile acids have been detected in the feces and may have a role in colonic carcinogenesis. Studies in this area are difficult, as dietary and lifestyle factors related to cholelithiasis may confound the relationship between gallbladder disease and CRC risk. A meta-analysis of studies evaluating the effect of cholecystectomy on CRC risk published in 1993[147] demonstrated conflicting results. Analysis of the 33 case-control studies generated a pooled relative risk of CRC after cholecystectomy of 1.34 (95% CI, 1.14–1.57), limited to the proximal colon. However, no significant effect was found when the results of six cohort studies were evaluated.

In a long-term follow-up study of 278,460 patients after cholecystectomy followed for up to 33 years,[148] a significantly increased risk of small bowel malignancies and proximal colonic malignancies was found as compared to the general population. No association was found with more distal bowel cancer. In another study using data from the Nurses' Health Study, a significant positive association between cholecystectomy and the risk of CRC was found

(RR = 1.21; 95% CI, 1.01–1.46 after adjusting for important CRC risk factors, including diet, family history, calcium intake, BMI, and the use of HRT). In this study, the risk of CRC after cholecystectomy was elevated both for proximal bowel and rectal cancers.[149] A more recent retrospective cohort study comparing 55,960 cholecystectomy patients to 574,668 control patients found an increased risk of colon cancer (RR = 1.51) but not rectal cancer (RR = 1.00) following cholecystectomy.[150] Other large studies have found no association between cholecystectomy and CRC.[151,152]

Prior cholecystectomy does not seem to affect the risk of adenoma formation. In the Nurses' Health Study,[149] no elevation in the risk of colorectal adenoma was identified in those patients having had a cholecystectomy. Similarly, in a study involving data from three large randomized adenoma chemoprevention trials, no increased risk for adenomas was observed for patients who had undergone cholecystectomy (RR = 1.02; 95% CI, 0.88–1.18).[153] In summary, prior cholecystectomy does not appear to be a risk factor for adenoma formation. The association with CRC is inconsistent, but seems to be strongest for cancer of the proximal colon.

Inflammatory Bowel Disease

Patients with long-standing inflammatory bowel disease (IBD) are known to be at an elevated risk of CRC, although it is difficult to precisely estimate the risk. The magnitude of the risk has been studied extensively in ulcerative colitis (UC); however, rates vary between studies, particularly those performed in referral centers versus population-based studies. In addition, treatment and surveillance may influence the risk and thus more recent studies may have a lower risk than studies conducted before surveillance was common. A meta-analysis of 116 studies evaluating the risk of CRC in UC patients found the overall prevalence of CRC in UC patients was 3.7% (95% CI, 3.2–4.2%). In 19 of the studies reviewed, the duration of colitis was reported by decade. In the first 10 years, after the onset of colitis the incidence rate of CRC was 2/1,000 per year of disease, for the second decade the incidence rate of CRC was estimated to be 7/1,000 per year of disease, and in the third decade the incidence rate of CRC was 12/1,000 per year of disease. This corresponds to a cumulative probability of CRC of 2% after 10 years of disease, 8% after 20 years, and 18% after 30 years. The risk of CRC varied geographically and was higher in studies conducted in the USA. The meta-analysis did not evaluate the extent of disease (pancolitis vs. left-sided disease vs. proctitis).[154]

These findings are not universal; however, two recent population-based studies from Denmark and the Mayo Clinic failed to demonstrate any increased risk of CRC in ulcerative colitis patients.[155,156] In the Mayo Clinic study, based on 378 ulcerative colitis patients from Olmsted County, Minnesota, six cases of CRC were observed versus 5.38 expected based on SEER data (standardized incidence ratio (SIR) = 1.1; 95%

CI, 0.4–2.4). However, the risk of CRC was increased in the subset of patients with extensive colitis (SIR = 2.4; 95% CI, 0.6–6.0). Similar results were found in a cohort of 1,160 ulcerative colitis patients in Copenhagen, Denmark followed a median of 19 years. The observed number of CRC cases was almost identical to the expected number (13 vs. 12.42, SIR = 1.05; 95% CI, 0.56–1.79).

The extent of disease does appear to have a significant influence on CRC risk in UC. In a Swedish population-based cohort of 3,117 patients with UC,[157] less extensive disease was associated with a lesser risk of CRC. As a ratio of the observed to expected incidence, the increased risk of CRC in this cohort was 1.7 for those with ulcerative proctitis (95% CI, 0.8–3.2); 2.8 for those with left-sided colitis (95% CI, 1.6–4.4); and 14.8 for those with pancolitis (95% CI, 11.4–18.9). Other studies have supported these findings.[158]

Other factors that may modify the risk of CRC in patients with UC include the coexistence of primary sclerosing colangitis (PSC),[159] presence of inflammatory pseudopolyps,[160] and severity of inflammation.[161] For patients with long-standing, extensive UC, colectomy is an effective strategy for the prevention of CRC. Other strategies include endoscopic surveillance for dysplasia and/or the use of chemopreventive agents. Although the efficacy of endoscopic surveillance has not been definitively proven in a randomized trial, a recent Cochrane review found that although there was no direct evidence of prolonged survival, patients with UC in surveillance programs tended to have cancers diagnosed earlier with a correspondingly improved prognosis.[162] Despite a lack of definitive evidence, endoscopic surveillance is commonly performed in patients with pancolitis for more than 10 years duration who wish to avoid colectomy. There is some evidence that chemoprevention of CRC in patients with UC may be possible. 5-ASA products may decrease the rate of dysplasia in patients with UC.[163] Other agents include folate, calcium, and in patients with primary sclerosing cholangitis, Ursodiol.[163]

The relationship between Crohn's disease and the development of CRC has been less consistently demonstrated. In studies using data from referral-based practices, the risk of development of CRC appears to be significantly increased in patients with extensive Crohn's colitis.[158] The magnitude of increased risk appears similar to that of UC.[164] However, in population-based studies, particularly those more recently published, a less dramatic effect is seen. In a Canadian population-based cohort study, the risk of CRC in 2,857 patients with Crohn's disease was compared to a randomly selected group of controls matched 10:1 for age, sex, and geographic location. Patients with Crohn's disease were found to have an elevated risk of colon cancer (incidence rate ratio (IRR) = 2.6; 95% CI, 1.69–4.12) but not rectal cancer (IRR = 1.08; 95% CI, 0.43–2.70). Patients with Crohn's disease also had an elevated risk of cancer of the small intestine (IRR = 17.4; 95% CI, 4.16–72.9), and lymphoma (IRR = 2.40; 95% CI, 1.17–4.97). Some of these results are similar to those from

a population-based study in Denmark of 2,645 patients hospitalized for Crohn's disease[165] and followed for up to 17 years. The rate of CRC in this group was not substantially higher than the expected rate of CRC in the Danish population; the SIR for CRC was 1.1 (95% CI, 0.6–1.9). However, similar to the Canadian study, the risk of small intestinal cancer was increased 18-fold in the Crohn's disease group. In a more recently reported population-based study from Olmsted County, Minnesota, a moderately increased risk of CRC SIR = 1.9; 95% CI, 0.7–4.1) was reported for patients with Crohn's disease. Similar to the other studies, patients with Crohn's disease had a 40-fold increased risk for small intestinal cancer.[155] In summary, it appears that the risk of CRC in patients with Crohn's disease is elevated, but the exact magnitude of increased risk remains unclear and requires further investigation.

Family History

Individuals with a family history of CRC are at an increased risk of themselves developing CRC. In a recent meta-analysis involving 59 studies, the relative risk of developing CRC with one affected first-degree relative was 2.24 (95% CI, 2.06–2.43) and 3.97 if more than two first-degree relatives were affected.[166] This corresponds to a pooled lifetime risk of a 50-year-old of 1.8% with no family history, 3.4% with one affected first-degree relative, and 6.9% with two or more first-degree relatives. The clustering of risk in families may be attributed to an inherited susceptibility, common environmental exposures, or a combination of both. The influence of a more distant family history of CRC on individual risk has not been determined with certainty.

Some of the increased risk attributed to family history is due to inheritance of known susceptibility genes, such as mutations in the *APC* gene, *p53* gene, or in MMR genes, particularly *MSH2*, *MLH1*, and *MSH6*;[167] these are discussed in detail elsewhere in this text. Importantly, the majority of cases of CRC cannot be attributed to known genetic defects even when associated with a family history of CRC as recognized genetic syndromes account for only a small proportion of all cases of CRC. Additional autosomal dominant genetic defects conferring a high risk of CRC almost certainly is found; however, at least some of the increased risk of CRC associated with a family history is likely attributable to other genetic factors, such as recessive susceptibility genes, autosomal dominant genes with low penetrance, or complex interactions between an individual's genetic makeup and environmental factors.

Despite the importance of family history on the risk of CRC, up to 25% of individuals with a first-degree relative with confirmed CRC do not report having such a family history,[168] and even those that do report a history may not be aware of the increased risk associated with this.[169] This has important implications for the assessment of family history as well as patient and family counseling.

Other Risk Factors

Radiation

Cases of rectal carcinoma have been reported in individuals who have undergone radiation for pelvic malignancies, primarily cervical cancer[170] and prostate cancer.[171] Close observation may be required for survivors of childhood pelvic tumors treated with radiation therapy, as secondary colorectal malignancies may develop decades later.[172] Because rectal cancer is relatively common, these cases may represent sporadic rectal cancers developing after long-term survival from other pelvic malignancies. However, the cancers occur in the radiated field, tend to be associated with radiation changes to the adjacent rectal mucosa and are more likely to be of mucinous histology[173] than typical sporadic cancers, thereby strengthening the likelihood of a causal association. Nevertheless, the vast majority of individuals undergoing radiation for pelvic malignancies do not develop rectal cancer.

Ureterosigmoidostomy

Formation of a ureterosigmoidostomy has been associated with an increased risk of carcinoma in the area of the ureter-sigmoid anastomosis. It is difficult to estimate the increase in the risk of colon cancer due to ureterosigmoidostomy – many were fashioned for malignant diseases that may themselves be associated with an increased risk of colon cancer, nevertheless the risk appears to be high. The estimated increase ranges from 100 to 7,000 times the risk in the normal population[174] and up to 24% of patients with a ureterosigmoidostomy develops neoplasia at the anastomosis.[175] The average latency period from the formation of the ureterosigmoidostomy to the development of malignancy is 26 years.[175] Patients who have undergone conversion to another form of urinary diversion remain at the risk of neoplasia if the ureterosigmoid anastomoses were not resected in their entirety. Although the cause of this dramatic increased risk in not known, it appears to require the exposure of colonic mucosa to the mixture of urine and feces[174] with conversion of urinary nitrates into N-nitroso compounds by colonic bacteria.

Fortunately, with a number of options for urinary diversion, this procedure is now rarely performed. Those living with a functional ureterosigmoidostomy should be counseled regarding their heightened risk and undergo regular sigmoidoscopic or colonoscopic surveillance.[174,175]

Acromegaly

Acromegaly, a rare endocrine syndrome resulting from the secretion of excess growth hormone from a pituitary neoplasm has been found to be associated with an increased risk of CRC in a number of studies.[176,177] The magnitude of the risk is unclear, with reports ranging from nonsignificant increases in the risk to a relative risk of 18.3.[177–179] In a population-based cohort study performed in Sweden and Denmark, the standardized incidence ratio of colon cancer in patients with acromegaly as compared to the general population was 2.6 (95% CI, 1.6–2.7).[176] In a more recent meta-analysis, the pooled odds ratio for the development of colon cancer was 4.35 (95% CI, 1.5–12.4)[179] Patients treated with growth hormone have been shown to have an increased incidence of and mortality from CRC.[180] Furthermore, patients with acromegaly have elevated levels of circulating IGF-1, and this may be partly responsible for the increased risk of colorectal neoplasia identified in these patients.[181] Patients with acromegaly also have an increased incidence of adenomatous polyps.[178,182]

Molecular Basis

All cancer has a genetic basis. Carcinogenesis is a multistep process, requiring an accumulation of inherited and acquired genetic alterations. With this succession of genetic alterations, cells acquire a growth advantage over surrounding cells, and in a Darwinian-type process normal cells evolve into cancer cells.[183] In normal cells, growth and replication is a highly regulated process, and disruption of this regulation at multiple levels is required for clinically relevant cancer to develop. Defects in genes that code for important proteins in the regulation of the cell cycle appear to be critical for carcinogenesis. Hanahan and Wienberg[183] have described the following six alterations in regulatory mechanisms that appear constant in most cancers from the several hundred genetic mutations that have been identified in cancer cells Figure 38-4.
FIGURE 38-4. Alterations in regulatory mechanisms important for carcinogenesis.

Self-Sufficiency in Growth Signals

Ordinarily, cells must receive growth signals to actively proliferate, assuring that cellular proliferation occurs only when necessary to maintain homeostasis. To proliferate autonomously, cancer cells must lose this need for exogenous growth signal.

1. Insensitivity to antigrowth signals.
   Normally, there are numerous growth-inhibitory signals that function within a cell to maintain the cell in a quiescent and/or differentiated state. Cells with neoplastic potential must develop mechanisms to evade these antigrowth signals, enabling proliferation and dedifferentiation.

2. Evading Apoptosis
   Development of cancer requires not only a loss of control over cellular proliferation, but also a loss of control over programed cell death (apoptosis). Apoptosis normally occurs in response to the cellular environment and is likely a major mechanism whereby cells that have acquired significant genetic mutations are destroyed. Tumor cells must circumvent apoptosis (either at a regulatory level or at an effector level) to continue to develop and proliferate.

3. Limitless Replicative Potential
   Many cells are able to replicate only a finite number of times, thereby preventing clonal expansion of any given cell. Even after acquiring independence from normal signals for cellular growth and death to develop into clinically significant cancer, cancer cells must gain unlimited capacity for replication. Intrinsic limits to proliferation must be evaded.

4. Sustained Angiogenesis
   Virtually, all cells must reside within 100 µm of a capillary capable of delivering to the cell oxygen and nutrients required for functioning. Angiogenesis in normal tissue is closely regulated, and balancing of inducers and inhibitors of angiogenesis is an essential component of homeostasis. For neoplastic cells to develop into clinically significant cancer, they must develop the ability to circumvent these homeostatic mechanisms and provide an adequate blood supply required for ongoing growth.

5. Development of Ability to Invade and Metastasize
   For cancer cells to develop the ability to invade other tissue and metastasize, a number of changes must occur. Normally, cells in tissue adhere to each other. A loss of this normal cell to cell adhesion must occur in the cancer microenvironment to permit metastasis to occur. In addition, the cancer cells must develop methods of modifying new environments to support continued growth.

Although all six alterations in cell regulation are required for the development of clinically significant cancer, the sequence of events and mechanisms are variable. The sequence of genetic mutations (or alterations) is less important than the accumulation of mutations, although some mutations tend to occur early in the neoplastic process and are termed initiators, where as others tend to occur later and are termed promoters. In addition, certain genetic mutations (somatic or inherited) may be particularly critical and affect cell regulation in a number of important ways. Many such critical genes belong to two broad categories of genes involved in carcinogenesis; oncogenes and tumor suppressor genes. Additionally, caretaker genes that function to prevent the accumulation of somatic mutations are also critical to colorectal carcinogenesis. Abnormalities in caretaker genes greatly increase the risk of cancer development, independent of environmental influence. Of note, although the role of genes in carcinogenesis is described, in reality it is the protein products of the genes that are directly involved in changes in cell regulation.

Mutations in oncogenes result in an abnormal gain or excess of a particular protein function. An oncogene product when expressed in a given cell (or when the product is expressed at the wrong time in the cell cycle, expressed with an enhanced function, or expressed in larger quantities than normally present) contributes to the development of critical alterations in the mechanisms of cell regulation. Mutations causing such expression behave in a dominant fashion, i.e., mutation of only one of the two alleles present is required to produce activation and phenotypic expression and promote carcinogenesis.

The *ras* oncogene is the most frequently mutated oncogene identified in colorectal cancers. The *K-ras* proto-oncogene, located on the short arm of chromosome 12 (12p) is mutated in approximately half of all CRC.[184] The *K-ras* gene product appears to be involved in the transduction of exogenous growth signals. Point mutations in the *K-ras* gene lead to a function gain, conferring a growth advantage to the cells. Patients with mutant K-*ras* may have a poor response to the chemotherapeutic agent erbitiux.[185] Other oncogenes that are frequently identified in sporadic CRC include c-*myc* and *c-erbB2*.[186]

Tumor suppressor genes normally inhibit cellular proliferation or promote apoptosis. When gene expression is lost, there is a loss of this normal inhibitory control of the cell cycle. In general, gene expression is lost only when both alleles of the gene are inactivated (Knudson's 2-hit theory of carcinogenesis,[187] Figure 38-5) either through inherited mutation, somatic mutations or both. There are a number of tumor suppressor genes that have been found to play an important role in CRC carcinogenesis, including the *APC*, *DCC*, *p53*, and *MCC* genes.

The *APC* gene, located on the long arm of chromosome 5 (5q), is considered a gatekeeper gene of colorectal carcinogenesis, as mutations in the *APC* gene appear to be initiators of disease. Mutations in the *APC* gene have been found in 50% of sporadic adenomas and in 75% of sporadic cases of CRC.[184] Familial Adenomatous Polyposis (FAP), discussed in detail elsewhere in this text, results from inheritance of a germ line mutation in the *APC* gene. Mutations involve base-pair mutations, insertions, or deletions that result in the
FIGURE 38-5. Loss of suppressor-gene function.

formation of a stop codon, halting protein synthesis leading to the formation of a truncated or shortened protein product that affects the function of the protein. The location of the germ-line mutation in the *APC* gene varies between families with FAP, and results in the varying phenotypic expression of FAP found between families. Although only a single abnormal allele is inherited in FAP, sporadic mutations are always acquired resulting in the formation of hundreds to thousands of colonic adenomas and ultimately carcinoma. The *APC* protein normally regulates the *Wnt* (wingless signaling pathway), an important pathway in cell regulation and development, through modulation of beta-catenin – a critical protein in the *Wnt* pathway. Normally, the protein product of the *APC* gene binds beta-catenin intracellularly forming a multiprotein complex that inhibits beta-catenin function. The increased functional levels of beta-catenin that result from alterations in *APC* protein product function leads to cell proliferation, and enhances cell-to-cell adhesion, limiting cell migration. Thus, hyperproliferating cells accumulate and result in aberrant crypt foci, the earliest phase of colorectal neoplasia.[188]

The *p53* gene, located on the short arm of chromosome 17 (17p) is an important gatekeeper gene for carcinogenesis – it is the most commonly mutated gene in human cancers.[189] Normally, by slowing the cell cycle, *p53* facilitates DNA repair during replication and when repair is not feasible, *p53* induces apoptosis. Inactivation of *p53* is found in up to 75% of sporadic colorectal tumors,[186] however, the mutation appears to occur late in the tumorigenic sequence. Thus, *p53* gene mutations do not appear to be initiators of carcinogenesis but act as key limiting factors for malignant transformation. This is supported by the finding that patients with Li Fraumeni syndrome (an inherited defect in p53) do not

have an increased risk of CRC.[190] In addition, *p53* expression may be an independent prognostic marker in patients with CRC.[191,192] Most studies demonstrate a lower survival rate in patients with advanced cancers that are *p53* negative as compared to those whose tumors express *p53* gene product, particularly in those who receive chemotherapy.[193]

The "deleted in colorectal cancer" (*DCC*) gene was identified on the long arm of chromosome 18 (18q) in 1989.[194] Mutations in this gene have been found in the majority of CRC. The gene product of *DCC* is a transmembrane protein that is important in cell–cell adhesion, and therefore inactivation of *DCC* may enhance the metastatic potential of CRC through changes in adhesion. Similar to *p53*, patients who have *DCC*-positive tumors may have a better prognosis than those with *DCC*-negative (mutated) tumors.[195]

Located in close proximity to the *DCC* gene, mutations in a group of genes terms *SMADs* (*SMAD2* and *SMAD4*) have been reported in colorectal cancers. The protein products of these genes are components of the transforming growth factor-β (*TGF-β*) signaling pathway, which mediates growth inhibitory signals from cell surface to nucleus.

Because millions of base-pairs must be replicated during mitosis, errors in DNA replication occur and must be corrected by caretaker genes. The MMR system has a critical function in the detection and correction of errors in DNA replication, maintaining DNA integrity. MMR genes function as spell checkers – base-pair mismatches are identified, excised, and the correct sequence is synthesized and replaced.[196] Lack of MMR function results in an accumulation of errors in DNA replication, increasing the probability that a mutation in an important gene in cell regulation occurs and carcinogenesis is thus initiated or promoted. Defects in the MMR system are identified by the detection of microsatellite instability. Microsatellites are small regions of DNA located throughout the genome that do not code for individual genes. They consist of small base sequences that are repeated in a highly polymorphic fashion – the number of repeats may range from dozens to hundreds and the number of repeats varies from allele to allele, and from individual to individual. Microsatellites are particularly susceptible to MMR gene defects, thus in cases of CRC due to MMR gene mutations, microsatellite replication errors accumulate, leading to detectable differences in the pattern of microsatellites in the tumor and in normal tissue – this is termed microsatellite instability (MSI). When testing CRC for MSI, laboratories evaluate a number of microsatellite loci. The National Cancer Institute recommends the testing of five microsatellite sequences[197] to determine the MSI status of a tumor. If two or more of the five sequences demonstrate MSI, the tumor is designated MSI-high (MSI-H). If only one of the five sequences demonstrates changes in tumor microsatellite markers, the tumor is designated MSI-low (MSI-L). If no markers are changed, the tumor is microsatellite stable. Approximately 15% of CRC demonstrate MSI.[197] MSI-H tumors are more likely to be high-grade, right-sided,[198]
FIGURE 38-6. The adenoma to carcinoma sequence of colorectal carcinogenesis.

mucinous, and have tumor infiltrating lymphocytes.[199,200] In addition, MSI tumors may have a better prognosis than microsatellite stable tumors,[201] but may be less responsive to chemotherapy.[202]

A number of MMR genes (*MLH1*, *MSH2*, *MSH3*, *MSH6*, and *PMS1*) have been identified. Germ line mutations in the *MLH1* and *MSH2* genes are responsible for the majority (>90%)[203,204] of cases of the Hereditary Nonpolyposis Colorectal Cancer (HNPCC) (discussed elsewhere in the text), while approximately 5–10% of HNPCC cases are due to mutations in the *MSH6* gene. Germ line mutations in other MMR genes are rare. Similar to tumor suppressor genes, both alleles of an MMR gene must be mutated or inactivated for MMR function to be lost. These tumors are diploid and tend not to demonstrate gross chromosomal abnormalities. MMR defects in these tumors lead to genetic mutations in key cell regulator genes, particularly the *TGF-β* pathway. Sporadic tumors that demonstrate an MSI-H phenotype generally have a loss of *MLH1* function, not due to mutation but due to aberrant methylation of the promoter region of the *MLH1* gene (see below).[205]

MYH is an additional DNA repair gene specifically active for adenine–guanine mismatches.[206] This gene has been found to be responsible for some cases of *APC* mutation-negative FAP. This defect is inherited in an autosomal recessive fashion, i.e., defects must be inherited from both parents to result in phenotypic expression of the disease.[207] Biallelic carriers have a 53-fold increased risk of CRC with a cumulative risk by age 70 of 80%.[208] Monoallelic carriers may also be at increased risk to develop CRC; relative risk estimates for monoallelic carriers have ranged between 1.4 to 3.0.[208–211]

In their landmark article, Vogelstein and Fearon[212] (Figure 38-6) described the pathogenesis of colon cancer as one that follows a predictable sequence of events, from adenoma to carcinoma, with histological changes developing as genetic mutations are acquired over time. Initially, a mutation in a gatekeeper gene such as *APC* occurs resulting in proliferation of the colorectal mucosa and the initial histologically detectable event, the aberrant crypt focus. In aberrant crypt foci, the crypts have larger diameters than normal, stain more darkly with methylene blue,[188] and can be detected in rats as soon as 2 weeks after carcinogen exposure.[213] With additional genetic changes, cells within the aberrant crypt become dysplastic and an adenoma forms. Further genetic alterations are acquired, resulting in an increase in the size of the adenoma. However, the majority of adenomas do not develop into carcinoma. Therefore, additional genetic alterations are required before the severity of dysplasia increases, and eventually, particularly with mutations in tumor promoters, such as *p53*, carcinoma develops. This pathway to carcinogenesis is termed the chromosomal instability pathway. Tumors forming through this pathway demonstrate extensive cytogenetic abnormalities, such as aneuploidy, and visible chromosomal losses and gains.[214] CRC most commonly demonstrates chromosomal instability, indicating this is the most common genetic cause of colorectal carcinogenesis.[215]

Although MSI-H tumors may arise from adenomas, there is increasing evidence that sporadic MSI-H tumors also arise from serrated lesions (hyperplastic polyps, serrated adenomas, and sessile serrated adenomas).[216–220] As only 70% of colorectal carcinomas are believed to arise from classic adenomas, serrated lesions may be the precursor lesion for

a substantial number of cancers.[221] However, the risk associated with serrated lesions, in terms of progression to cancer, is unclear; it has been suggested that serrated polyps progress to cancer faster than do adenomas.[222] This recently described pathway of colorectal carcinogenesis is believed to be initiated by hypermethylation of the promoter region of various genes and is associated with increasing age.[223] Methylation of cytosines in cytosine–guanosine dinucleotide repeats (termed CpG islands) results in the silencing of transcription, without an actual change in the nucleotide sequence of the gene.[224] Tumors exhibiting this phenomenon are referred to as CpG island methylator phenotype (CIMP).[225] Although the *MLH1* gene is often involved (resulting in sporadic, MSI-H CRC), it need not be, and thus approximately 50% of CIMP tumors do not exhibit microsatellite instability. Accumulating evidence indicates that activating somatic mutations in the *BRAF* gene may be responsible for promoter methylation.[216,226] The *MCC* gene may also play a key role in this pathway.[227,228]

Hyperplastic polyposis (HPP) syndrome is characterized by multiple hyperplastic polyps and other serrated lesions and may be familial.[229] There may be an autosomal recessive pattern of inheritance, and the familial HPP-serrated lesions show a similar frequency of CIMP and *BRAF* mutations compared to sporadic serrated polyps.[230] Similarly, the "serrated pathway syndrome" may arise from as of yet unrecognized inherited mutations and shares phenotypic features with HNPCC.[231]

A relatively recent theory of carcinogenesis contends that subpopulations of CRC stem cells are primarily responsible for driving tumor growth.[232] This hypothesis purports that not all cells within a tumor have the same proliferative or tumorigenic capabilities; nonstem cancer cells can neither self-renew nor propagate the tumor. Successful treatment of tumors, therefore, may depend on complete eradication of these "cancer-initiating" stem cells. Colon cancer stem cells may be more resistant to chemotherapy[233] and radiotherapy.[234] A number of mechanisms may be responsible for this survival advantage, among them an ATP-binding cassette drug transporter that results in the extrusion of chemotherapy agents from the cell.[233] A number of markers have been described that may identify CRC stem cells, including CD133,[235,236] Lgr5,[237] Bmil,[238] and CD44.[239] It is likely that colon cancer stem cells arise from normal stem cells that have acquired mutations, (e.g., *APC* gene)[240] and have lost their regulation of self-renewal. The existence of these colon cancer stem cells would have significant implications for the management of CRC, including screening, surgical therapy, delivery of chemotherapy and radiotherapy, and targeted therapy such as gene therapy.[239]

Colorectal Cancer: Screening

Jason F. Hall and Thomas E. Read

Cancer of the colon and rectum is the second leading cause of cancer-related death in the USA. In 2009, it was estimated that 147,000 Americans will be diagnosed with colorectal cancer and 50,000 will die from this disease.[1] Without undergoing screening or preventive action, approximately 1 in every 17 people in this country will develop colorectal cancer at some point in life. There is clear evidence that colorectal adenocarcinoma can be prevented by detecting and removing adenomatous polyps and that detecting early stage cancers reduces mortality from the disease.[2–9] Both polyps and early stage cancers are usually asymptomatic; cancers that have grown large enough to cause symptoms have a much worse prognosis. This contrast highlights the need for screening in asymptomatic persons.

The effectiveness of screening for colorectal cancer has been a subject of controversy. In 1995, the US Preventive Task Force reversed earlier position statements and endorsed screening of asymptomatic average-risk persons, using fecal occult blood testing and sigmoidoscopy.[10,11] In 1996, the federal Agency for Health Care Policy and Research (AHCPR) convened a collaborative group of experts representing the American College of Gastroenterology, American Gastroenterological Association, American Society of Colon and Rectal Surgeons, American Society for Gastrointestinal Endoscopy, and Society of American Gastrointestinal Endoscopic Surgeons to critically evaluate the available evidence on colorectal cancer screening and to develop appropriate clinical practice guidelines.[12] The panel studied 3,500 peer-reviewed publications to assess the performance, effectiveness, acceptability to patients, cost-effectiveness, and outcome of different screening examinations. The AHCPR guidelines[13] were, in essence, endorsed by the American Cancer Society[14] and were used to create the Practice Parameters for the Detection of Colorectal Neoplasms published by the Standards Committee of the American Society of Colon and Rectal Surgeons.[15,16] The AHCPR guidelines provided the framework for colorectal cancer screening guidelines in the USA since they were published. The guidelines have been revised by various groups, including the US Preventive Task Force,[9] based on new data, new technology and evolving expert opinion.

Most people will be of average risk and require screening for colorectal cancer and polyps beginning at age 50. A substantial number of people are at increased risk because of an inherited predisposition to the disease and need screening or treatment as early as puberty. By virtue of their practice, colon and rectal surgeons, gastroenterologists, and medical oncologists have contact with a large number of patients with colorectal carcinoma as well as at-risk family members. These specialists have the opportunity to guide the evaluation of at-risk persons and be advocates for appropriate screening examinations.

Classification of Risk and Screening Recommendations

Making appropriate recommendations for screening of individuals depends on determining a patient's risk of future development of colorectal cancer. The cornerstone of determining a patient's risk for developing colorectal cancer is the family history. Failure to properly investigate a patient's family history of colorectal neoplasia can lead to inappropriate and inadequate treatment of both the patient and at-risk family members.

Average Risk

The majority of patients who develop colorectal cancer have no identifiable risk factors (Table 39-1). Persons considered to be at average risk for colorectal cancer do not fit any of the higher-risk categories. Specifically, average-risk persons have no symptoms associated with colorectal cancer, no personal history of colorectal cancer or adenomatous polyps, no family history of colorectal neoplasia, no inflammatory bowel disease, and no unexplained anemia. In October 2008, the US Preventive Task Force recommended that average-risk persons should undergo one of

TABLE 39-1. Patients with colorectal cancer

75%	Average risk (sporadic)
15–20%	Family history of colorectal cancer
3–8%	Hereditary nonpolyposis colorectal cancer
1%	Familial adenomatous polyposis
1%	Ulcerative colitis

TABLE 39-2. Screening for colorectal cancer and polyps

Risk category	Screening method	Age to begin screening
Average risk	Choose one of the following: 1. High-sensitivity FOBT annually[a] 2. Flexible sigmoidoscopy every 5 years combined with high-sensitivity FOBT every 3 years[a] 3. Colonoscopy every 10 years	50 years
Family history	Choose one of the following: 1. Colonoscopy every 10 years 2. Colonoscopy every 5 years if diagnosis of colorectal cancer was made before age 60 3. Air contrast barium enema every 5 years[b]	40 or 10 years prior to diagnosis of the youngest affected family member, whichever is earliest
Lynch syndrome	Colonoscopy every 1–3 years Genetic counseling Consider genetic testing	21 years
Familial adenomatous polyposis	Flexible sigmoidoscopy or colonoscopy every 1–2 years Genetic counseling Consider genetic testing	Puberty
Inflammatory bowel disease (ulcerative colitis and Crohn's colitis)	Colonoscopy with random biopsies for dysplasia every 1–2 years	7–8 years after the onset of pancolitis; 12–15 years after the onset of left-sided colitis

FOBT fecal occult blood test.

[a]The American Cancer Society recommends the combination of yearly FOBT and flexible sigmoidoscopy is preferable to either examination alone.

[b]Proctoscopy is recommended as an adjunctive examination to allow adequate visualization of the distal rectum. Furthermore, flexible sigmoidoscopy may be necessary to more completely evaluate a tortuous or spastic sigmoid colon.

the following screening regimens, beginning at age 50 and continuing until age 75[9] (Table 39-2):

1. High-sensitivity fecal occult blood testing (FOBT) annually.
2. Flexible sigmoidoscopy every 5 years with high-sensitivity FOBT every 3 years.
3. Colonoscopy every 10 years.

Additionally, the taskforce recommended against routine screening in adults age 76–85, leaving the decision to continuing screening in this age range to the patient and primary care physician. The US Preventive Task Force specifically recommended against screening for colorectal cancer in patients greater than 85 years. Although the panel stated that all of the screening strategies are acceptable, they emphasized that each technique has unique strengths and weaknesses.[9]

The American Cancer Society, the US Multi-Society Task Force on Colorectal Cancer, and the American College of Radiology also recommended screening average-risk persons beginning at age 50. However, these groups did not recommend against routine screening in persons older than 76 years. Screening recommendations included several options[7,17]:

1. High-sensitivity FOBT or fecal immunochemical testing annually
2. Flexible sigmoidoscopy every 5 years
3. Double-contrast barium enema every 5 years
4. CT colonography every 5 years
5. Colonoscopy every 10 years
6. Fecal DNA testing (No interval specified).

In 2000, the American College of Gastroenterology proposed guidelines that outlined a "preferred" strategy for colorectal cancer screening. These were updated in 2008.[18] This approach was proposed based on evidence that patient compliance increased when there is a "preferred" strategy rather than a "menu" of options.[19] Preferred screening recommendations for average-risk persons beginning at age 50 included (screening should begin at age 45 in black patients):

1. Colonoscopy every 10 years
2. Annual fecal immunochemical test (FIT) for blood.

Alternative prevention tests

1. Flexible sigmoidoscopy every 5–10 years
2. CT colonography every 5 years.

Alternative cancer detection tests

1. Annual Hemoccult Sensa
2. Fecal DNA testing every 3 years.

Fecal Screening Tests

There are two types of fecal occult blood tests. The most common is a guaiac-based test for peroxidase activity that is nonspecific and will fail to detect many small cancers and precancerous lesions.[20] Nevertheless, several large randomized controlled trials as well as high-quality systematic reviews have shown that annual or biannual testing for fecal occult blood, with complete diagnostic evaluation of the colon (primarily with colonoscopy) for patients with a positive FOBT, reduces mortality from colorectal cancer.[3,21–24] More sensitive guaiac testing (Hemoccult Sensa, Beckman Coulter) is associated with a slightly higher sensitivity for detecting

colorectal cancer. Testing of three samples is more sensitive than testing of a single sample. An alternative method of FOBT is the fecal immunochemical test. This exam employs antibodies specific to blood components.

A major drawback to using stool testing as a screening technique is poor compliance. Only 38–60% of the patients in prospective trials completed all the planned FOBT tests,[3,21,22] and use of FOBT in the general population is estimated to be lower than that in the research environment.[25] The steps necessary for adequate sample collection, combined with dietary restrictions to avoid agents that can cause false-positive and false-negative results may also hinder compliance with FOBT. Proper performance of FOBT involves the sampling of atraumatically obtained stool from three consecutive bowel movements in a patient who has not ingested red meat, aspirin, nonsteroidal inflammatory medications, turnips, melons, salmon, sardines, horseradish, or vitamin C for the 2 days preceding the test and throughout the test period.[13,26] The restriction of commonly ingested foods and medications, combined with the natural aversion to stool sampling, makes annual FOBT unappealing to many persons.

FOBT should not be confused with random stool guaiac testing, which is the analysis of stool found on digital rectal exam for blood. The lack of adequate diet and medication restriction prior to the test, potential for trauma to the anal canal during digital rectal examination, and the inability to reliably obtain stool from the distal rectum make the test unreliable.[27] To date, random stool guaiac examination has not been demonstrated to have benefit in screening for colorectal cancer.

In some settings, FOBT test slides are rehydrated, which contributes to the high incidence of false-positive tests and is not recommended by the manufacturer. Hemoccult Sensa, which appears to be at least as sensitive as the original hemoccult test, is the guaiac technique currently recommended for use.[28]

In the future, immunochemical techniques or genetic analysis of cellular material in stool may prove to be more effective than current FOBT technology in detecting occult colorectal neoplasms via stool sampling.[29,30] Colonic cells are constantly shed by colonic epithelium, DNA material can isolate from these cells and analyzed. Because there is variation in the genotypes of tumors, the ideal test would screen for a large panel of genetic mutations.[31] In 2004, the Colorectal Cancer Study Group compared Hemoccult II with fecal DNA testing (21 mutations) in 5,486 patients who subsequently underwent a colonoscopy.[32] The sensitivity of the fecal DNA test for advanced neoplasms (cancer, adenomas with villous or dysplastic histology, adenomas ≥ 10 mm) was 18% in comparison to Hemoccult II, which was 11%. The specificities were 94 and 95%, respectively. Another recent large study compared two different fecal DNA tests with Hemoccult II testing in patients who subsequently underwent colonoscopy.[33] The commercially available fecal DNA

test, which examines 21 standard mutations including K-ras, APC, p53, BAT-26, and long DNA, provided no advantage over Hemoccult in the detection of dysplastic neoplasms or cancer. Sensitivity for "screen-relevant neoplasms" was modest: 20% by the DNA test, 11% by Hemoccult, and 21% by Hemoccult Sensa. A second novel fecal DNA test using three tumor-specific markers (K-ras mutations, APC mutator cluster regions, and vimentin methylation) was more sensitive than the commercial DNA test, Hemoccult, or Hemoccult Sensa in the detection of colorectal cancer and large adenomas but less specific. It remains unclear whether there are adequate data to support widespread use of fecal DNA tests as a viable colorectal cancer screening strategy.

Sigmoidoscopy

The effectiveness of sigmoidoscopy as a screening tool depends on its ability to detect cancers and adenomatous polyps in the distal colon. If adenomatous polyps are found at flexible sigmoidoscopy, colonoscopy should be strongly considered because almost one-third of such patients will have neoplastic lesions in the proximal colon.[34] The effectiveness of sigmoidoscopy in reducing mortality from colorectal cancer has never been proven by a randomized controlled trial, although case–control studies have shown a benefit.[2,6,35] There was only a trend toward limited benefit of one-time screening sigmoidoscopy, followed by colonoscopy for patients found to have polyps, in the Telemark study from Norway.[36,37] The Prostate, Lung, Colon, and Ovary Trial supported by the National Cancer Institute is evaluating flexible sigmoidoscopy in a randomized, controlled setting, but mortality data are not available at this time.[13] In this trial, wide variability in polyp detection rate was observed between endoscopists,[38] which raises concern regarding adequacy of the examination in the hands of inexperienced endoscopists. A multicenter prospective trial examining the potential benefit of one-time screening flexible sigmoidoscopy at age 60 is currently underway in the UK and Italy.[39] In this trial, it was noted that women who have undergone hysterectomy had fewer polyps detected at sigmoidoscopy and more pain than other patients, suggesting that these patients have less complete examinations.[40] A large randomized study in Norway could not demonstrate a decreased incidence of colorectal cancer or mortality when comparing one-time flexible sigmoidoscopy to no screening.[41]

Flexible sigmoidoscopy alone will fail to detect neoplasms in the proximal colon unless adenomatous polyps or cancer are found in the distal colon that prompt colonoscopy. For this reason, The American Cancer Society recommends combining flexible sigmoidoscopy every 5 years with annual FOBT, rather than utilizing flexible sigmoidoscopy alone as a screening method.[7,14] Although this combined approach may detect more proximal neoplasms than flexible sigmoidoscopy alone, 15–30% of patients with negative flexible sigmoidoscopy and negative FOBT will have neoplastic lesions

in the proximal colon at colonoscopy, calling the rationale for this approach into question.[42–48] Given all the limitations of flexible sigmoidoscopy, it is unlikely that it will be the screening examination of choice in societies that can afford other screening methods that have greater efficacy and less patient discomfort.

Contrast Enema

The efficacy of barium enema in preventing colorectal cancer mortality has never been evaluated in a controlled trial, but can be inferred from the fact that detecting polyps and early stage cancers by other methods reduce the incidence and mortality from colorectal cancer. Air contrast barium enema will detect 50–80% of polyps < 1 cm, 70–90% of polyps > 1 cm, and 50–80% of Stage I and II adenocarcinomas.[49–52] Single column barium enema is less sensitive and should be combined with flexible sigmoidoscopy, if used as a screening tool.[13] Proctoscopy should be considered as an adjunct exam because the balloon on the enema catheter often prevents adequate imaging of the distal rectum. Another major limitation of barium enema as a screening method is that patients usually require colonoscopy, if lesions are detected.

Colonoscopy

Colonoscopy is the only screening technique that allows the detection and removal of premalignant lesions throughout the colon and rectum and is the final common pathway for any positive screening test. Although its effectiveness depends on the skill and experience of the endoscopist to both reach the cecum and identify small lesions, it remains the gold standard to evaluate the colonic mucosa.[13] The ability of colonoscopy to reduce colorectal cancer mortality has been demonstrated indirectly through studies showing that detecting and removing polyps reduces the incidence of colorectal cancer and that detecting early cancers lowers the mortality from the disease.[2–6] Compliance with screening colonoscopy may be superior to that of other methods because no confirmatory exams are required, and thus, patients are subjected to a single cathartic bowel preparation.

CT Colonography

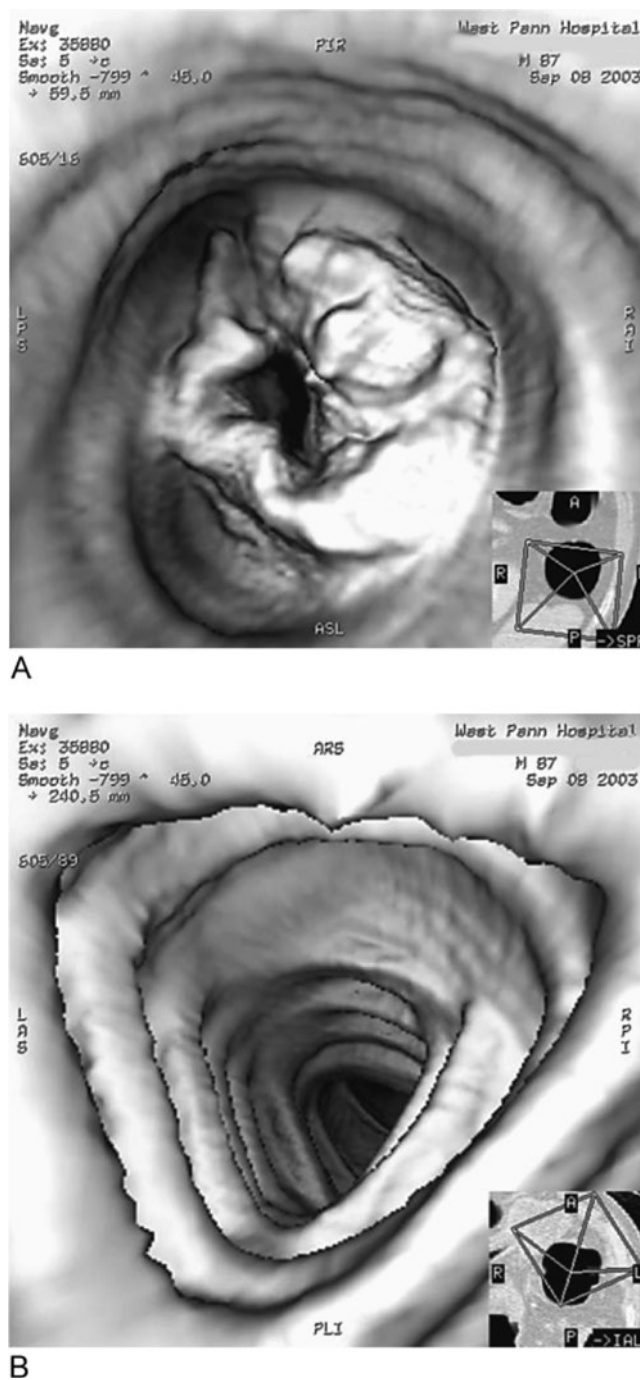
CT colonography (virtual colonoscopy) was developed in an attempt to increase compliance with colorectal cancer screening, based on the impression that people would be more inclined to have a "scan" that a "scope." The technique involves thin-section computed tomography (CT) with three dimensional computer reconstructions to examine the colonic mucosa (Figure 39-1A and B).[53,54] Although the technique has the advantages of being considered "noninvasive" and not requiring sedation, a vigorous oral cathartic laxative preparation is required, because adherent stool cannot be reliably differentiated from neoplasia on CT. In


FIGURE 39-1. **A** CT colonography of an 87-year-old patient with a large tumor of the splenic flexure who could not undergo colonoscopy. The circumferential cancer can be seen occupying the lumen of the colon. **B** CT colonography of an 87-year-old patient with a large tumor of the splenic flexure who could not undergo colonoscopy. This image is of the transverse colon proximal to the cancer.

addition, a rectal catheter and air insufflation is utilized to distend the colon. CT colonography cannot be assumed to be more appealing to all patients who are reluctant to undergo colonoscopy, because many patients are deterred more by

the laxative preparation beforehand than by the endoscopic procedure itself and find rectal air insufflation in the absence of sedation uncomfortable.[55] Initial trials demonstrated that CT colonography was not as sensitive as colonoscopy in the detection of small polyps.[56] Recent improvements in technology and experience with interpretation have resulted in improved performance of the test. The sensitivity for the detection of polyps 10 mm or larger can be up to 90% with a specificity of 86% in the hands of interested radiologists.[57] Polyps that are 6 mm or larger have detection rate of up to 78% with a specificity of 88%.[7,57–60] CT colonography is both less sensitive and less specific in the detection of polyps less than 6 mm in size.

Controversy exists regarding the size of polyp detected at CT colonography that should prompt optical colonoscopy. If the polyp size cutoff is small, then the number of patients that are referred for colonoscopy will be large and the cost of the program high. If the polyp size cutoff is larger, then the number of patients that are referred for colonoscopy will be smaller and the cost of the program will be lower, although there is an increased risk of leaving neoplastic polyps in situ. If 6 mm is chosen as a cutoff size, it is estimated that 15–25% of patient undergoing screening CT colonography would be referred for colonoscopy.[59,61,62] Even at this small polyp cutoff size, there is controversy regarding the practice of leaving polyps in situ because the natural history of small polyps (<6 mm) is unknown.[59,63] Regardless of its accuracy, CT colonography suffers (as does contrast enema) from the disadvantage that biopsies cannot be obtained and positive findings require endoscopic confirmation. Other disadvantages include radiation exposure and the cost of managing extracolonic findings. It is estimated that 27–69% of patients who have CT colonography will have at least one potentially pathologic finding in an organ outside of the colon.[7–9]

For all these reasons, CT colonography is not utilized at most centers as the preferred initial screening test. CT colonography is an excellent choice, however, for the evaluation of a patient who has just had an incomplete colonoscopy. The colon is already prepared and it is distended by air. Ultimately, if stool labeling technology improves to the point where cathartic bowel preparation and transanal gas insufflation of the colon are no longer necessary, then CT colonography could gain traction as the preferred initial screening test for colorectal cancer.

Cost and Reimbursement

The Office of Technology Assessment of the US Congress found that FOBT, flexible sigmoidoscopy, air contrast barium enema, and colonoscopy are equally cost-effective as screening strategies, with an estimated cost of less than $20,000 per year of life saved (assuming screening begins at age 50 and is discontinued at age 85).[13,64,65] Although cost–benefit analyses such as these are exceedingly complex, this estimate is

well within the acceptable range of cost-effectiveness by US health standards and compares favorably to screening mammography for women over age 50. As of January 1, 1998, the Centers for Medicare and Medicaid Services (CMS) has reimbursed screening examinations for colorectal cancer in average-risk persons over the age of 50.[66] In 2001, CMS authorized reimbursement for screening colonoscopy for average-risk persons. As of January 2010, the CMS guidelines for reimbursement for colorectal cancer screening are as follows (excerpted from their website, http://www.cms.hhs.gov/ColorectalCancerScreening).

- Fecal occult blood test (FOBT) – once every year.
- Flexible sigmoidoscopy – once every 4 years.
- Colonoscopy – once every 2 years, if the patient is at high risk for colon cancer; and once every 10 years (but not within 47 months of a screening sigmoidoscopy), if the patient is not at high risk for colon cancer.
- Double-contrast barium enema – physician can decide to use instead of a sigmoidoscopy or colonoscopy.

At present, the choice of screening strategy for average-risk persons is made with influence from primary care physicians, patients, and third-party payors. Several of the recommended strategies depend on compliance with yearly FOBT, which has been extremely difficult to achieve even in the setting of controlled trials. Only air contrast barium enema and colonoscopy provide total colonic evaluation, and contrast enema suffers from the necessity of performing colonoscopy if a lesion is detected. The American College of Gastroenterology suggested that screening colonoscopy every 10 years beginning at age 50 is the preferred method of screening average-risk persons for colorectal cancer.[18]

Personal History of Adenomatous Polyps or Adenocarcinoma

A personal history of adenomatous polyps or colorectal adenocarcinoma places a person at higher than average risk for the development of metachronous neoplasms. Patients who undergo curative resection of colorectal adenocarcinoma should undergo regular surveillance colonoscopy to detect new metachronous primary neoplasms. The recommendation of the Standards Task Committee of the American Society of Colon and Rectal Surgeons is for initial postresection colonoscopy at 1 year, followed by colonoscopy every 3–5 years thereafter, depending on the pathology found at the preceding colonoscopic examination. The US Multi-Society Task Force on Colorectal Cancer and the American Cancer Society outlined guidelines for colonoscopy after polypectomy and colorectal cancer resection in 2008.[67] This panel recommended that patients with hyperplastic polyps should be considered average risk and therefore screened every 10 years. Patients with an adenomatous polyp greater than 1 cm should have a repeat colonoscopy in 3 years. Patients who

have adenomas with villous features or high-grade dysplasia are also recommended to have a surveillance colonoscopy in 3 years. Patients with fewer than three small adenomas may be surveyed every 5–10 years. After resection of colorectal cancers, the panel recommended that patients undergo a colonoscopy at 1 year.

Clearly, these recommendations can be altered given the specific details of the clinical situation. A rational surveillance strategy should take into account the patient's age, comorbid conditions, life expectancy, completeness of prior examinations, pattern of neoplastic growth, family history, and histologic features of previously resected neoplasms. For example, a patient in good health who is found to have adenomas that are multiple, large, sessile, dysplastic, or removed in a piecemeal fashion on initial screening colonoscopy should be considered for colonoscopy at an earlier interval, such as 6–12 months. However, a 90-year-old patient with severe comorbidities and limited life expectancy may not benefit from surveillance examinations, because removal of premalignant lesions will probably not alter lifespan or quality of life.

Family History of Colorectal Cancer or Adenomatous Polyps

A family history of colorectal cancer or adenomatous polyps increases the risk of developing colorectal cancer. In general, closer familial relationships to affected relatives, younger age of onset, and larger numbers of affected relatives increase the risk.[13,68,69] A careful family history should always be obtained to exclude one of the better-defined inherited colorectal cancer syndromes, such as Lynch syndrome or familial adenomatous polyposis (FAP).

As a greater understanding of the molecular genetics of colorectal cancer is gained, many patients with familial colorectal cancer may eventually be categorized as having distinct inherited syndromes. For example, a germline mutation of the adenomatous polyposis coli gene (I1307K variant) was identified in persons of Ashkenazi Jewish descent that predisposes to the development of colorectal adenomas and carcinoma.[12,70–75] The mutation causes hypermutability of the adenomatous polyposis coli gene and is thought to contribute to carcinogenesis independent of mismatch repair deficiency.[72] In the future, genetic testing for this mutation in at-risk persons may have clinical utility.

Screening Recommendations

The AHCPR panel recommended that patients with first-degree relatives with colorectal cancer or adenomatous polyps begin screening for colorectal neoplasia at age 40, or 10 years prior to the age at diagnosis of the affected relative, whichever is earliest.[13] Those patients whose first-degree relatives developed colorectal cancer prior to age 50 may

be at higher risk, and complete colonic evaluation with colonoscopy should be strongly considered.[13] Patients with a second-degree relative with colorectal cancer, or relative with adenomatous polyps diagnosed over age 60, may be screened as an average-risk person.[13]

More recently, the American College of Gastroenterology recommended that patients with a single first-degree relative (<60 years) with colorectal cancer or an adenoma > 1 cm or an adenoma with villous features or high-grade dysplasia begin screening at age 40 or 10 years before the diagnosis in the youngest affected relative. Surveillance should be repeated every 5 years. If the initial diagnosis of colorectal cancer was made after age 60, then surveillance can be carried out every 10 years. This recommendation emphasizes that an increased level of screening is not recommended for a history of adenomas without adverse features in a first-degree relative.[18]

Lynch Syndrome

Lynch syndrome (formerly hereditary nonpolyposis colorectal cancer syndrome) is an inherited disorder that predisposes patients to the development of colorectal cancer, with up to 75% of patients developing colorectal cancer by age 65.[76–79] Lynch syndrome is inherited in an autosomal dominant fashion and is thought to be the result of germline mutations in mismatch repair genes (genes that code for proteins responsible for correcting errors during DNA replication). Patients with Lynch syndrome typically develop cancer between age 40 and 50 and most tumors occur proximal to the splenic flexure. "Nonpolyposis" in the term "hereditary nonpolyposis colorectal cancer" refers to the distinction between Lynch syndrome and FAP (in which patients have hundreds of polyps), but is somewhat misleading as patients with Lynch syndrome will develop adenomatous polyps. The major distinction is that progression from adenoma to carcinoma appears to be accelerated in Lynch syndrome patients as compared to patients with sporadic cancers and FAP, and there is a tendency to develop multiple colorectal cancers in Lynch syndrome.[76,80–82] Patients with Lynch syndrome have germline mutations and are also at high risk for the development of other cancers including endometrial, ovarian, gastric, transitional cell, small bowel, and hepatobiliary neoplasms.

The ability to conclusively identify gene carriers is not yet fully developed, thus the penetrance of colorectal cancer in gene carriers can only be estimated (about 90%). In addition, some patients in Lynch syndrome families who do not have identifiable germline mismatch repair gene mutations will develop colorectal cancer.[83] For these reasons, the diagnosis of Lynch syndrome in a family remains clinical. The Amsterdam I criteria (colorectal cancer in three or more family members, two generations affected, one affected person a first-degree relative of another, and one

cancer diagnosed prior to age 50) are the most stringent criteria and have the highest concordance with known mismatch repair gene mutations.[83] These criteria were originally developed for research purposes, to standardize the definition of Lynch syndrome. However, they fail to identify patients who may be affected with Lynch syndrome but do not fit the strict criteria because of unknown or abbreviated family histories, as well as patients with a personal or family history of extracolonic malignancies associated with Lynch syndrome. The Bethesda criteria were developed to acknowledge the shortcomings of the Amsterdam I criteria as clinical guidelines and to expand the clinical suspicion of Lynch syndrome to a broader range of patients.[79,84] Other groups have also published revised criteria for Lynch syndrome because of the above reasons. It is thus of paramount importance that persons being interviewed to determine their risk for colorectal cancer be questioned regarding a family history of the most common Lynch syndrome-related cancers.

Microsatellite instability has been reported in 85–90% of Lynch syndrome colorectal cancers.[77] Detection of this phenotype has been proposed as a screening method to trigger germline mutational analysis in kindreds with uncertain family histories.[79] However, microsatellite instability is also found in approximately 15% of sporadic cancers and has not been universally found to be predictive of familial cancer.[83,85] Patients who satisfy the Bethesda criteria should have immunohistochemistry staining for mismatch repair proteins or microsatellite testing of their, or an afflicted family member's, neoplasm. Germline mutational analysis can then be performed. If a proband tests positive, the appropriate family members can be offered screening. Clinically, the absence of microsatellite instability or mismatch repair gene mutation does not negate a family history that suggests an autosomal dominant predisposition to developing colorectal cancer. At-risk family members still require aggressive screening.

Screening Recommendations

The American College of Gastroenterology recommends that persons who are members of a family that fits clinical criteria for Lynch syndrome undergo colonoscopy at age 20–25 and repeat colonoscopy every 2 years until age 40. The panel recommends that patients should have annual colonoscopies after age 40.[18] The short-time interval between colonoscopies results from the accelerated adenoma to carcinoma progression thought to occur in Lynch syndrome. Patients and at-risk family members should be referred for genetic counseling. A number of authors have recommended that patients with Lynch syndrome may have increased polyp detection rates, if they are screened with chromoendoscopy or narrow band imaging.[86–89] It is not known whether these techniques may allow longer screening intervals in the future.

Familial Adenomatous Polyposis

Familial adenomatous polyposis (FAP) is caused by a germline defect in the adenomatous polyposis coli gene, which is inherited in autosomal dominant fashion.[90] Patients with FAP develop hundreds of adenomatous polyps as early as puberty and will ultimately develop colorectal cancer usually by age 40.[91,92] Patients with FAP are also prone to develop a variety of extracolonic tumors, notably duodenal adenomas and carcinomas, and desmoid tumors.[91] FAP mutations do occur spontaneously, accounting for patients who are diagnosed with the disease without a family history of FAP.[93] Attenuated FAP is a rare variant of the disease, with polyps and cancers developing later in life.[94]

In the past, a commonly used genetic test for FAP was an assay for a truncated protein product of the mutated adenomatous polyposis coli gene. Because only about 80% of families with FAP will have a mutation that produces a truncated protein, the predictive value of testing at-risk family members is greatest if the proband (affected relative) has a positive test.[95] At present, germline mutational analysis is the preferred method of confirmation of the disease. If patients suspected of having FAP are not found to have an APC mutation, then MYH polyposis should be considered.

Screening Recommendations

Patients with a family history of FAP should undergo flexible sigmoidoscopy or colonoscopy at puberty.[13,96] Lower endoscopy should be repeated every 1–2 years. Patients with FAP are also at risk for the development of gastric, periampullary, and duodenal adenomas. Patients with FAP should undergo upper endoscopic surveillance every 1–3 years.[18,97] Genetic testing should be considered, especially in large pedigrees where genotyping might be more cost-effective than repeated endoscopy.[96] If the proband has a positive genetic assay, at-risk relatives who test negative may be screened as average-risk persons.[96]

Because of the socioeconomic, medicolegal, and emotional issues surrounding genetic testing, it cannot be emphasized enough that genetic testing for FAP should be done after genetic counseling and informed consent.[95] Trained genetic counselors can guide patients through the testing process and help interpret results. Lest physicians think that they do not need assistance in this regard, they should look at the work of Giardiello et al. who found that 32% of physicians ordering genetic tests for FAP misinterpreted the results of the test and that less than 20% of patients tested had received pretest genetic counseling or written informed consent.[95] These numbers are sobering when one considers that FAP has 100% mortality if left untreated. Patients should also undergo screening upper endoscopy for duodenal adenomas.[98]

Inflammatory Bowel Disease

Patients with ulcerative colitis have an increased risk of developing colorectal cancer, probably because of the chronic effects of inflammation on the mucosa, leading to malignant degeneration. However, because of the altered appearance of the mucosa, carcinomas are sometimes difficult to identify endoscopically. Frequent colonoscopy with random biopsy is recommended, in an attempt to identify early stage carcinomas or premalignant change (dysplasia) that would predict the presence of occult carcinoma or predict the subsequent development of carcinoma. Proctocolectomy could then be performed for cure or prophylaxis. The risk of colorectal cancer in patients with Crohn's disease is now considered to be similar to that of patients with ulcerative colitis and therefore they should be screened in similar fashion.[97,99]

Screening Recommendations

It is now common practice for patients with inflammatory bowel disease to undergo screening colonoscopy with multiple random biopsies looking for dysplasia every 1–2 years, beginning 7–8 years after disease onset in patients with pancolitis, and 12–15 years after disease onset in patients with left-sided colitis.[13,100,101] Mucosal biopsies are taken every 10 cm from normal appearing mucosa. Abnormal appearing lesions should also be biopsied.[97] Random biopsies should be avoided in areas of acute colitis. Despite the consensus recommendation to perform surveillance colonoscopy with random biopsy, definitive evidence that surveillance reduces mortality, or is better than timing a colectomy according to extent and duration of disease, is lacking.[13,100,101]

Future Directions

It is troubling that so much energy and expense is devoted to the cure of advanced or recurrent colorectal cancer in the USA, while so little is devoted to screening for polyps and early stage cancers. It is estimated that only 50% of adults over the age of 50 in this country underwent FOBT or endoscopy for colorectal cancer screening in 2005.[102] Although this represents a substantial increase from screening rates of the past, it is still woefully inadequate given that colorectal cancer is the second leading cause of cancer-related death and is largely preventable by adequate screening. In a report issued in 2002, the US General Accounting Office found that colorectal cancer screening is the least utilized preventive health benefit available to Medicare beneficiaries (General Accounting Office, Medicare – Beneficiary Use of Clinical Preventive Services, Report No. GAO-22-422; April 2002). As is the case in the general population, only 25% of Medicare beneficiaries are screened each year with FOBT, compared with much higher rates for other regular cancer screening tests such as mammography (75%) or Pap smear testing (66%). More recent data suggest that among Medicare beneficiaries aged 65–80, colonoscopy rates have increased while FOBT rates decreased.[103] Both health care professionals and the public need to become more aware of the potential benefits of colorectal cancer screening.

As the genetics of inherited colorectal cancer syndromes become better understood, it will be possible to conclusively identify high-risk populations. It is of paramount importance that screening efforts be directed toward these populations. Genetic counselors are invaluable resources, both to counsel family members and to help direct genetic testing.

Colon Cancer Evaluation and Staging

Eric G. Weiss

Introduction

Colorectal cancer is the third most common cancer affecting persons in the USA. In 2008, there were an estimated 148,810 new cases of colon and rectal cancer with colon cancer making up the majority of new cases at 107,143 and the remaining 28% arising in the rectum.[1] Overall, approximately 33.6% of newly diagnosed patients with colorectal cancer in the USA will die of their disease.

Clinical Presentation

His beneficial that colon cancers are diagnosed when patients are asymptomatic, who undergo surveillance, or who are investigated for problems such as anemia. This underscores the importance of colorectal cancer screening in the asymptomatic patient based on age, and also any other associated risk factors that would increase the risk and require earlier screening. Currently the most common screening test is standard colonoscopy, but combinations of DRE, FOBT, FFS, and BE are still acceptable. In symptomatic patients, the most common presenting symptoms are abdominal pain, change in bowel habits, rectal bleeding, and occult blood in the stool.[2] These symptoms are more frequently associated with a tumor that is more advanced than in asymptomatic patients.

Abdominal pain is the most common presenting symptom of colon cancer. The pain can vary in type, location, and intensity. In the early phases or stages of colon cancer without evidence of obstructive symptoms, the pain can be vague, dull, and poorly localized. The pain is often in the lower abdomen, but may also occur periumbilically or elsewhere. With progression of the disease and a larger mass or a mass causing obstruction, symptoms of intestinal obstruction will eventually occur. This type of pain is characterized by crampy, colicky pain, often associated with meals, and occurring after meals. The location of the pain is often periumbilical or midabdominal, but can be located at the site of obstruction.

A change in bowel habits is the second most common symptom of colon cancer. The changes seen can be very subtle or very significant. In early lesions the change may be minor, with only a change in stool frequency. There can be changes in size, shape, and/or consistency of bowel movements. Characteristic changes include narrowing of the stool, irregular shape, and typically looser or diarrheal stool. The symptoms will depend on the location of the tumor. Right-sided tumors occur where the bowel lumen is larger and the stool is liquid. Symptoms occur later, but on the left side where the stool is more solid and the lumen narrower symptoms occur at an earlier stage.

Rectal bleeding may be present in as many as 25% of patients with colon cancer.[3,4] The bleeding may be of varying intensity and color. Bright red rectal bleeding is more consistent with a more distal location of a cancer. The mistake of attributing rectal bleeding to hemorrhoids even in a young population can lead to serious and at times fatal delays in the diagnosis of a colon cancer. Almost all patients regardless of age who present with rectal bleeding should undergo colonoscopic evaluation or a minimum flexible sigmoidoscopy depending on patient age and characteristics of the bleeding. In a series of 570 patients, 50 years of age or younger with rectal bleeding who underwent endoscopic evaluation, there was a 17.5% incidence of colorectal neoplasm.[5]

Patients undergoing stool guaiac tests for occult blood in the stool for routine screening with a positive result have a 5.1% chance of having an invasive cancer and a 24% chance of having a benign polyp.[6] Newer tests of either blood or DNA in the stool may be more sensitive than standard guaiac and lead to increased yields. The fecal immunohistochemical test (FIT) uses a monoclonal antibody to human hemoglobin and is more specific to colorectal cancer or advanced adenomas.[7]

As mentioned previously some of the symptoms that occur may be early or late based on the distribution of cancer

within the colon. There has been an overall more proximal shift of colon cancers with more tumors being in the proximal colon. The Lahey Clinic reported a 10-year representative anatomical site distribution in which the cancer was located in the right colon in 18%, the transverse colon in 9%, the descending colon in 5%, the sigmoid colon in 25%, and the rectum in 43%.[8]

Staging and Prognostic Factors

Evolution of Staging Systems

The original staging system for colorectal cancer was reported by Cuthbert Dukes' in 1930 and then revised by him in 1932.[9] This classification had three stages, A, B, and C. Stage A had the cancer limited to the bowel wall, Stage B had cancer that spread by direct extension to extrarectal tissues, and Stage C had cancer with regional lymph node metastasis. Dukes' further revised the classification in 1944 to subdivide the Stage C group into those with positive regional lymph nodes below a ligature (C1) and at a ligature (C2). In addition, a more advanced stage, Stage D was added for distant metastases.

Others have subsequently modified the Dukes' staging system in an attempt to further stratify, prognosticate, and treat patients with a more useful system. Kirklin first modified this system by subdividing Dukes' B into B1 and B2 based on invasion of the submucosa and muscularis propria versus full thickness invasion.[10] The most common modification is known as the Astler–Coller Modification.[11] In this modification, the Dukes' B and Dukes' C tumors are subdivided into two groups, depending on depth of tumor invasion Stage B, tumors penetrate partially into the muscularis propria, Stage B2 penetrate full thickness; both lack lymph node metastases. Stage C, and C2 parallel B1 and B2 but have lymph node metastases. Although both the Dukes' and Modified Dukes' staging systems are still utilized, the TMN staging system is the preferred method of colorectal cancer staging.

Current Staging Systems

The TNM classification is the system developed by the American Joint Committee on Cancer (AJCC) and the International Union Against Cancer (UICC). It utilizes three descriptors based on each letter in the name, T for tumor depth, N for nodal involvement, and M for metastases. Based on a combination of T, N, and M for any given tumor, an overall stage from Stage I to IV can be determined. The most recent AJCC/UICC definitions were published in 2010.[12]

The T stage can be divided into seven possible categories based on the depth of invasion. Tis, carcinoma in situ represents a nonmalignant tumor; T1 has invasion into the submucosa; T2 has invasion into the muscularis propria; T3 has invasion

into the subserosa or nonperitonealized pericolonic or rectal tissue (through the bowel wall); and T4 has invasion of other organs or structures. The T3 category can be further subdivided by the depth of penetration into the muscularis propria. The N stage can be divided into three categories. N0, with no lymph node involvement; N1, with one to three lymph nodes involved; and N2 with four or more lymph nodes involved. The M stage is only divided into two categories, either no metastases (M0) or distant metastases (M1).

Typically, the combination of T, N, and M will lead to one of the four stages based on the combination of findings. Stage 0 is Tis, N0, and M0. Stage 1 is T1 or T2, N0, M0. Stage 2 is T3 or T4, N0, M0. Stage 3 is Any T, N1 or N2, and M0. Stage 4 is Any T, Any N and M1. In the most recent AJCC/UICC definitions, Stage II and III are further subdivided, Stage IIA (T3, N0, and M0) and Stage IIB (T4, N0, and M0); and three Stage III categories, Stage IIIA (T1 or T2, N1, and M0), Stage IIIB (T3 or T4, N1, and M0), and Stage IIIC (Any T, N2, and M0).

In the seventh Edition of the AJCC Staging Manual, Stage II and Stage III colon cancers were reclassified based on the Hindgut Taskforce recommendations.[13] Based on SEER population based data compared to NCDB data the reclassification occurred. T4bN0 was reclassified from IIB to IIC, T1-2N2a from IIIC to IIIB, T1-2N2b from IIIC to IIIB as well as T3N2a. T4bN1a and T4bN1b both were reclassified from IIIB to IIIC.

The importance of staging is for treatment planning and prognosis.

Clinical Prognostic Factors

Age

As with many cancers, colon cancer incidence increases with increasing age. Most series report a mean age in the sixth decade for nonhereditary colon cancer. Patients with familial adenomatous polyposis (FAP) will present with colon cancer in their mid to late 30s if colectomy is not performed prior to this age. Patients with HNPCC can present at any age, but tend to have colon cancer between the ages of 40 and 60, significantly younger than individuals with nonhereditary colon cancers.

It has been reported that younger patients present with worse tumors of more advanced stage and grade. However, recent studies refute this claim. O'Connell et al. recently reported (using SEER data) a comparison of two groups of patients with colon cancer.[14] The SEER database is a prospectively entered database of the National Cancer Institute in the USA and stands for Surveillance, Epidemiology, and End Results. They compared outcome in patients 20–40 years of age to those 40–60 years of age. Although there was an increased incidence of higher stage tumors, stage for stage they had an equivalent or improved 5-year survival.

Symptoms

Obstruction and perforation are poor prognostic signs often associated with advanced disease. In addition, because patients are operated on in an urgent fashion, their operative morbidity and mortality is increased. Chen et al. reported outcome in patients with obstructing and/or perforated colon cancer.[15] Perforated cancers had a 9% operative mortality compared to obstructed cancers of 5%. Overall 5-year survival was 33% in each group, much lower than the expected rate based on similar stages in noncomplicated cases.

Blood Transfusion

Blood transfusions can cause immunosuppression in the postoperative period, which may allow for an inability to combat tumor cells shed at the time of surgery and theoretically lead to a worse prognosis. Sibbering et al. reported on 266 patients with colon cancer some of who received blood transfusions and others who did not.[16] There was no difference in survival when comparing the two groups. However, Chung et al. reviewed 20 papers, representing 5,236 patients supporting the hypothesis that perioperative blood transfusions are associated with an increased recurrence and death from colon carcinoma.[17]

Adjacent Organ Involvement

Local extension of colon carcinoma can involve any structure or organ adjacent to the primary tumor. It occurs in 5–12% of colorectal cancers. All tumors with local extension would be considered T4. For right colon cancers the most commonly involved structures are the liver, duodenum, pancreas, and abdominal wall. Kama et al. reported a 75% disease-free survival of 14–41 months following en bloc pancreaticoduodenectomy and right colectomy.[18] Similarly Izbicki et al. reported on 83 patients with colorectal cancer undergoing extended en bloc resections.[19] Comparing extended to nonextended resections, mean survival of both groups was around 45 months conferring the benefit of extended resections when necessary to achieve R0 resections. These data were supported by Kroneman et al. where 4-year survival was 33 % following en bloc resection compared to those receiving noncurable resections, of 6 months.[20]

Histologic/Biochemical/Genetic Factors

Histologic Grade

Broders described classifying adenocarinomas by the degree of differentiation. He described four grades based on how much of the tumor had differentiated cells within it. Today, three grades are used and include Grade 1 with well-differentiated features, Grade 2 moderately differentiated, and Grade 3

poorly differentiated. The vast majority of colon cancers are moderately differentiated (Grade 2) with preservation of gland forming architecture. However, the amount of preservation of this architecture is variable and when absent leads to sheets of invasive cells classified as poorly differentiated. The degree of differentiation corresponds to prognosis. Poorly differentiated tumors have a worse prognosis stage for stage compared to better differentiated tumors.[21]

Tumor Budding

Tumor budding is now recognized and reported by pathologists and represents an undifferentiated portion of tumors at the leading invasive edge. There is a transition from the glandular structures to single cells or clusters of cells at the invasive margin. Also known as dedifferentiation and first described by Morodomi et al. in 1989[22], it is recognized by less than five cells of single infiltrating cancer cells at the invasive edge. Tumor budding is associated with a high risk of recurrence.[23] In addition, it has been associated as an independent risk factor for local spread, lymph node and distant metastases, and worse survival.[24]

Mucin Production and MSI

The most common pathway for the development of colorectal cancer is via the mechanism of chromosomal instability pathway (microsatellite stable or MSS). This pathway is responsible for an estimated 75–85% of all colorectal cancers. The remaining 15–20% of colorectal cancers occur via a different pathway associated with a high frequency of MSI.

Microsatellite Instability known as MSI is associated with HNPCC. MSI is an alteration in mismatch repair genes, which are important to repairing errors in replication. When altered, they can lead to colorectal cancer. Since there is loss of one of the two alleles in HNPCC, these patients tend to present earlier in life, with multiple colonic and extracolonic cancers. Many HNPCC cancers are mucin producing, which when present have a better prognosis compared to non-mucin producing tumors in these patients.

Signet-Cell Histology

Signet-ring or signet-cell tumors have a worse prognosis in many intestinal cancers. Signet-cell tumors tend to be of a more advanced stage when discovered. In a comparison between signet-ring and nonsignet ring colon cancers, it was noted that patients with signet-ring cancers were younger, had more advanced stages, and an increased incidence of liver metastases.[25] In addition, the rate of curative resection was lower at 35% compared to 79%. This rate was similar to poorly differentiated tumors at 46% at 5 years. In another study, the risk of peritoneal seeding was higher in signet-cell tumors leading to a high incidence of palliative resections and a mean survival of 16 months.[26]

Venous Invasion

Blood vessel invasion has been linked with poor prognosis both independently as well as with its association with lymph node metastasis. Blood vessel invasion can occur intramurally within the wall of the colon itself or in the surrounding tissue. Although arterial invasion occurs, most series define and describe vascular invasion based on venous invasion. Venous invasion in colon cancer occurs in 42% of patients and increases with increasing grade and stage.[27] Patients with blood vessel invasion had a 74% survival compared to those without it at 85%. In those patients with both intramural and extramural vascular invasion the prognosis was even worse at 32%.

Perineural Invasion

The growth of tumor along perineural spaces is known as perineural invasion and like venous invasion it increases with increasing grade and stage of the tumor. It occurs in 14–32% of colorectal cancers and can extend to as far away as 10 cm from the primary tumor. Numerous studies have confirmed poorer prognosis when perineural invasion is noted.[28,29]

Lymph Node Involvement

Lymph node metastasis has been long understood to be one of if not the most important prognostic factor in colon cancer outcome. All currently utilized staging systems as described above for colon cancer employ and rely on the presence or absence of lymph node metastases. It is therefore important to adequately remove the lymph node bearing tissue associated with the underlying colon cancer. It has been reported by Scott and Grace that if 13 lymph nodes are not recovered, adequate staging cannot be performed.[30] The main determinant for an adequate lymph node harvest is surgical, but a variety of means to enhance the yield have been developed and include fat clearance with xylene, other chemicals, and PCR techniques.[31–33] Using these techniques more lymph nodes or lymph nodes not found by standard techniques can be discovered, thus improving the accuracy of staging and allowing for better prognosis and application of adjuvant treatment. The ability to find occult metastases in otherwise H&E negative lymph nodes may improve survival by upstaging patients to a Stage 3, which would then lead to a recommendation for adjuvant chemotherapy. Cytokeratin immunohistochemistry can convert 25–30% of otherwise H&E negative lymph nodes in patients with colorectal cancer.[34]

Carcinoembryonic Antigen

Carcinoembryonic antigen (CEA), a glycoprotein absent in normal colonic mucosa, but present in 97% of patients with colon cancer was discovered in 1965.[35] CEA elevation correlates with either disease that has metastasized to the liver or with very large tumors. Patients with disease confined to the colonic mucosa or submucosa will have elevated CEA in 30–40% of cases. It is therefore not useful for screening, but can be used to follow patients with colon cancer. In patients with elevated CEA preoperatively and localized disease that is expectable, the CEA should fall following surgery. If the CEA level does not fall then occult metastases may be present and may be an indication for adjuvant therapy. The absolute level of CEA is also important. A CEA of greater than 15 mg/ml predicts an increased risk of metastases in an otherwise apparently curable colon cancer.[36] A normal preoperative CEA may become elevated with metastatic disease. Controversy exists as to the utility of following CEA postoperatively as it may not allow any advantage to salvage or treatment when compared to symptomatic recurrences[37] despite the fact that routine periodic CEA measurement is endorsed by the American Society of Colon and Rectal Surgeons in their practice parameters.[38]

Sentinel Node

The idea of a sentinel lymph node being present and if identified be able to predict lymph node metastases has become standard of care in breast cancer and melanoma. Its application to colon cancer is in its infancy and may be less important in colon cancer than the others. The idea that the lymphatic drainage can be mapped, and the first node identified, has significance in oncologic surgery. In colon cancer, resecting the associated lymphovascular pedicle with the primary cancer is considered paramount to performing an adequate operation; this adds little to no morbidity unlike excising level 3 nodes in breast cancer patients. In an attempt to validate the sentinel lymph node theory in colon cancer, Paramo et al. reported on their experience with 45 patients who underwent intraoperative sentinel lymph node mapping using isosulfan blue dye.[39] Sentinel lymph nodes were identified 82% of the time and predicted regional metastases in 98% of cases, with only a single case of a false-negative sentinel lymph node. Others have agreed that its utility may be marginal in colon cancer.[40]

DNA Ploidy

Normal cells are made up of diploid cells. Tumors can maintain normal diploid cells or can be aneuploid. Numerous studies show that nondiploid tumors have a worse prognosis and correlate with more advanced Dukes' stage.[41]

Spreading Patterns

Colon cancer can spread via a variety of pathways. Spread can be local or distant based on these pathways.

Intramural Spread

Intramural spread is tumor spreading along the bowel wall either proximally or distally in one of the bowel wall layers. Like rectal cancers, colon cancer rarely spreads this way. In a study of 42 colorectal cancers of which 64% were colonic, the maximum extent of intramural spread was 2 cm.[42] This supports the practice of excising 5 cm or more of colon on either side of a tumor to decrease the risk of anastomotic recurrence.[43]

Transmural Spread

As they become more advanced, colon cancers invade the colonic wall. Almost all colon cancers start as a mucosal lesion and then penetrate a variable degree into deeper layers of the colonic wall. This colonic wall invasion is the basis of many of the currently used staging systems including the Dukes' and TNM. Transmural spread is the mechanism that produces T4 tumors. T4 tumors penetrate full thickness into the colonic wall and then by direct extension or adherence, invade into other structures in proximity to the primary tumor. When present, en bloc resection is mandatory for an R0 resection. Preoperative evaluation can sometimes predict adjacent organ involvement, but often it is an intraoperative finding.

Margins

The acceptable bowel wall margins are dictated by three issues: First, thickness of penetration of the bowel wall margin and the risk based on the distance of local tumor spread intramurally. As described above, colon cancer rarely invades proximally or distally along the bowel wall for more than 2 cm. Convention has led to the recommendation that proximal and distal margins be a minimum of 5 cm. It has been stated that the "ideal extent of a bowel resection is defined by removing the blood supply and the lymphatics at the level of the origin of the primary feeding arterial vessel.[43]" These other two factors may modify the length of the proximal and/or distal margins as further resections may be required due to these issues.

Radial Margins

The circumferential margins are important to both colon and rectal cancer, but most series and studies have been confined to rectal cancers. It has been shown that positive circumferential margins in rectal cancer are associated with local recurrence rates as high as 85%.[44] In colon cancer the radial margins are less important with the exception of T4 tumors where en bloc resection is required. Typically for colon cancer the only radial margin which may be involved in a tumor less then T4 are those tumors with serosal involvement.

In 279 patients with colon cancer, serosal involvement was not associated with a poorer outcome, and outcome was related only to tumor stage.[45]

Transperitoneal/Implantation

Tumors with serosal involvement can shed viable tumor cells which can spread throughout the peritoneal cavity and implant on a variety of structures. Most commonly tumors will implant on the ovaries, omentum, serosal or peritoneal surfaces. When widespread, this is known as carcinomatosis. When localized to the ovaries, which occurs in 3–5% of patients, bilateral oophorectomy should be performed. In a recent series, 86% of patients with ovarian metastases had transmural extension of the primary colon cancers.[46]

Lymphatic

Lymphatic invasion is the most common mechanism leading to metastatic disease. Lymphatics exist within the colonic wall and lymphatic invasion correlates with the depth of penetration of colon cancers. T1 tumors have a risk of lymph node involvement up to 9%, T2 up to 25% and T3 up to 45%. Most currently used staging systems assign increased stage to increasing T stage and lymph node involvement and prognosis correlates with the overall stage. The lymphatic drainage goes along the venous drainage of the colon, ultimately coursing through the portal vein and into the liver. Metastatic liver disease is felt to occur typically due to lymphatic spread.

Hematogenous

Hematogenous spread of colon cancer is less common than lymphatic spread. Hematogenous spread will bypass the liver and allow tumor cells to go peripherally into the systemic circulation. This is thought to be the mechanism for the development of pulmonary metastases.

Metastatic Evaluation

Once diagnosed with colon carcinoma, a search for metastatic disease is often performed. This assessment includes a variety of imaging studies, laboratory tests, and endoscopic procedures.

Detection and Management of Synchronous Lesions

Synchronous polyps and cancers occur in patients with colon cancer. Most colon cancers are diagnosed by colonoscopy and the remainder of the colon is evaluated at the same time by colonoscopy. However, if an obstructing lesion is noted that will not allow a colonoscope to pass, evaluation of the more proximal colon may be jeopardized. Alternatives to evaluating the remainder of the colon in these instances

include contrast enemas, CT colonoscopy, or intraoperative colonoscopy at the time of resection. In a series of 158 patients with incomplete colonoscopies, barium enema was used to examine the remainder of the colon. Six lesions greater than 1 cm were identified with five of six being proximal cancers or advanced adenomas.[47] CT colonoscopy was used in 34 patients suspected of colon cancer with incomplete colonoscopies. CT colonoscopy identified all primary and three synchronous tumors proximal to the primary tumor.[48]

More recently, the combination of PET/CT colonography was used to evaluate the colon proximal to obstructive colon cancer in 13 patients previously diagnosed with colorectal cancer by standard colonoscopy. PET/CT colonography was performed to evaluate both the proximal colon as well as to identify metastatic disease. PET/CT Colonography identified the 13 primary tumors, two synchronous tumors proximal to the obstructions, and metastatic lung and liver disease in two and four patients respectively.[49]

When a colon cancer is diagnosed by colonoscopy, synchronous cancers occur in 6% or less of patients. When present, it should raise the suspicion of HNPCC which is associated with synchronous colon cancer. When synchronous colon cancer is diagnosed, the treatment should include a subtotal colectomy.

Distant Metastatic Disease

Distant metastatic disease associated with colon cancer is almost always either liver or lung metastases. Although bone, brain, and other organ involvement can occur, it is rare and therefore the search for these metastases in an asymptomatic patient is unwarranted. The search for liver and lung metastases can be accomplished by a variety of imaging studies including; ultrasound, CT scan, MRI, CXR, and PET scans. Each test has different abilities, availabilities, and costs.

Liver Metastases

An easily available test for the evaluation of the liver for metastases is surface ultrasound. Surface ultrasound is available in almost all institutions, however, its accuracy compared to newer modalities is lower in studies comparing it to CT and liver scans.[50,51]

CT scan is the most commonly employed method to preoperatively and postoperatively determine the presence or absence of liver metastases associated with colon cancer. There are numerous advantages to cross sectional imaging such as CT over US and include the ability to find abdominal wall or contiguous organ invasion as well as liver metastases. Standard CT scan is 64% sensitive in identifying liver lesions greater than 1 cm. MRI of the liver has been poorly studied and is not typically utilized in the evaluation of liver metastases.

Lung Metastases

Lung metastases occur in 3.5% of patients with colon cancer[52]; there are limited data on the utility of plain chest radiographs or CT scans in the initial evaluation of the lungs for metastatic disease. CT scan clearly has advantages over plain radiographs and can identify and characterize lung pathology better than plain X-rays. Given that most patients will undergo CT imaging of the abdomen prior to surgical intervention, the addition of imaging of the chest via CT seems reasonable. One must be careful about the amount of intravenous contrast when simultaneously scanning multiple regions such as chest, abdomen, and pelvis.

PET Scans

PET scans were initially approved only for patients with suspected metastatic disease and not for the use in primary staging of colon cancer. More recently with increased experience as well as the combination of PET & CT scans as well as further combinations with CT colonography, their roles in determining if any metastatic disease exists at the time of initial diagnosis are increasing.

Most commonly, PET scans involve the IV administration of a glucose analog, ^{18}F-flourodeoxyglucose (FDG). This glucose analog is preferentially taken up and trapped by tumor cells making those areas with trapped FDG show up brightly on PET scanning. Due to the lack of spatial resolution, the specific anatomic locations of the lesion(s) are difficult. Therefore combinations of PET with CT allow for precise spatial correlation and location with abnormally identified areas on PET. There are few publications supporting PET or PET/CT for initial staging of colon cancer, but there are initial rectal cancer for staging.

A recent meta-analysis was reported in 2005 using 61 published studies comparing CT, MR, and PET for the diagnosis of liver metastases in colorectal cancer.[53] Comparisons of nonhelical and helical CT, 1.5 T MR and FDG-PET showed sensitivities of 60.2, 64.7, 75.8, and 94.6%. FDG-PET had a significantly higher sensitivity compared to the other studies.

Response to Potential Chemotherapy

Recent publications and clinical trials have shown that patients with metastatic colorectal cancer benefit from treatment with monoclonal antibodies to EGFR. Monoclonal antibodies to EGFR include cetuximab, panitumumab, and the more commonly used bevacizumab. Patients with KRAS mutations at codon 12 or 13 do not appear to benefit from this therapy. It is therefore important to determine if patients have KRAS mutations so that expensive therapy and ineffective therapy is not given. Patients without KRAS mutations are known as wild type KRAS whereas those with mutations are considered abnormal. Multiple methods exist to determine KRAS mutations including PCR and Direct Sequencing. A recent Provisional Clinical Opinion by the American Society of Clinical Oncology about testing for KRAS gene mutations was published in 2009.[52]

Other markers that may predict the response to anti EGFR therapy include mutations of BRAF, PIK3CA, or loss of PTEN expression.[54]

Thymidylate synthase (TS), an enzyme required for DNA synthesis and targeted by competitive inhibition by 5FU based chemotherapy can now be measured. It is measured by either IHC or RT-PCR, but it is unclear as to which is the more reliable method. Elevated levels of TS in tumor cells are associated with resistance to 5FU based chemotherapy.[55]

Surgical Management of Colon Cancer

Matthew Mutch and Christina Cellini

Introduction

All colorectal cancer develops from a single transformed cell which ultimately grows large enough to present as a macroscopic lesion involving the lumen of the bowel. The staging of colorectal cancer is most dependent upon the depth of penetration of the bowel wall and the involvement of regional lymph nodes. An increasingly wide variety of putative molecular markers for aggressiveness and metastatic potential have been analyzed; however, the two most important prognostic indicators remain the degree of bowel wall invasion and status of the lymph nodes. This fact has lead to the continued importance of adequate locoregional oncological principles when performing curative resections of colon cancer. The purpose of this chapter is to primarily address issues directly related to the safe and oncologically sound methods of performing a curative resection of a colonic carcinoma. Important and related issues, such as clinicopathologic staging systems, the role of adjuvant or neoadjuvant treatments, and molecular markers are addressed in detail in other sections of this text.

Preoperative Preparation

Effective preparation of the patient requiring a colonic resection for colon cancer requires knowledge of the patient's physiologic status, tumor location, and clinical stage.

A variety of scoring systems are available for grading operative risk of surgical patients. The most widely applied scoring system is the American Society of Anesthesia (ASA) score;[1–4] however, this tool only provides information regarding the risk of an anesthesia complication given a certain physiologic status.[1,2] An alternative tool is the POSSUM and the modified p-POSSUM which include the additional risks related to underlying nutritional status and the performance of a colectomy.[3–5] Recent studies have found that POSSUM and P-POSSUM overpredict mortality in colorectal cancer patients undergoing elective surgery and underpredict mortality in the elderly patients and those undergoing emergency cases.[6] This has led to the development of a colorectal specific POSSUM (CR-POSSUM) score.[7] CR-POSSUM differs from the previous scoring systems in terms of number and type of physiologic and operative measures. Multicenter and single center analyses have shown that CR-POSSUM is an accurate predictor of mortality in colorectal cancer surgery in the UK and the USA.[8–11] These tools, while of limited specificity for the individual patient, do provide an estimation of the relative risks for both the patient and the entire surgical team. Additional discussions are presented in Chap. 8.

Localization of the tumor and its histopathology are important in selecting an operative plan and the optimal resection margins. The presence of a lesion at watershed areas of vascular supply may require a more extensive resection of the colon. In addition, information consistent with the Hereditary Non-Polyposis Colon Cancer Syndrome [(HNPCC) – right-sided lesion, Crohn's like inflammatory response, young patient, family history] would support resection of the entire abdominal colon rather than a segment. This diagnosis may also be supported by special stains of the biopsy specimen which demonstrate microsatellite instability, the hallmark of the disease.

Colonoscopy is widely used today and represents the optimal means of detecting a cancer, identifying its location, providing histopathologic material, and tattooing for intraoperative localization when required. Precise localization of the lesion with ink tattooing is paramount in the era of laparoscopy since manual palpation is not possible. The lesion should be inked in three separate areas around the circumference of the colon wall distal to the lesion. A second option is to place endoscopic mucosal clips distal to the lesion and obtain an abdominal radiograph in the recovery area. The clips can be seen on the X-ray and anatomically localize the lesion. Contrast enema is another means of localizing the lesion anatomically. Computer tomography (CT) allows the localization of larger lesions, identification of local organ invasion, and provides important staging information regarding the presence of extracolonic disease, particularly liver involvement.

The preoperative detection of distant metastasis can influence the initial management of a colorectal cancer patient. Computed tomography is the most widely used imaging modality to screen for liver metastasis because of its availability and relative low cost compared to positron emission tomography (PET). However, combined PET/CT imaging appears to provide the most accurate detection of liver metastasis (PET alone 93%, CT alone 92%, and PET/CT combined 97%).[12] It is unknown at this time if this increased accuracy has any impact on the management of those patients. The PET scan has a role in detecting recurrent disease or extrahepatic disease when evaluating a patient for surgical resection of the local recurrence or liver metastasis.

Bowel preparation has historically been considered an essential component of the preoperative preparation of the patient. Mechanical cleansing combined with oral antibiotics reduces the concentration of aerobic and anaerobic bacteria within the colon and decreases the incidence of wound infection from 35 to 9%.[13–15] However, more recent prospective randomized studies have questioned the additional benefit of luminal preparation, compared to the use of appropriate intravenous antibiotics administered in a timely manner. A meta-analysis by Bucher et al.[16] reviewed 565 patients with a mechanical bowel preparation versus 579 without a preparation. Interestingly, all but one study demonstrated a higher anastomotic leak rate in the mechanical prep group with an odds ratio of 1.8.[17,18] Other surgical site infectious complications were also more frequent in the mechanical preparation group. More recently, Slim et al.[19] reported an updated review and meta-analysis of randomized controlled trials of patients. They found no difference between the groups for anastomotic leak rate or the incidence of pelvic or abdominal abscess. There was a slightly higher risk of deep abdominal abscess with no bowel preparation; however, given that the number needed to have a complication was greater than 300 patients, they concluded that this risk did not seem to be clinically relevant. The study did not confirm the harmful effect of mechanical bowel preparation suggested in the previous studies.[16,20,21] While there is not enough data to make recommendations for the use of bowel preparation in rectal surgery with low anastomosis, the authors conclude that the routine use of mechanical bowel preparation should be abandoned.

Surgical Technique

Surgery remains the mainstay for the treatment of colon cancer. The 2000 National Cancer Institute issued guidelines for the surgical management of colon cancer.[22] They stated that the principles of an oncologic resection were a wide mesenteric resection achieved by ligating the feeding artery at its origin with adequate distal and proximal margins. They recommend that a minimum of 12 lymph nodes should be examined. There are several studies that support a survival benefit for patients who have 12 or more lymph nodes examined after surgical resection. This benefit most likely occurs

for two reasons. First, the greater number of lymph nodes examined increases the accuracy of the final pathologic staging, a phenomenon known as stage migration.[23] Second, there is clearly an oncologic benefit to a radical mesenteric resection, where all involved lymph nodes are resected.[24]

Right Colectomy

The patient is placed supine on the operating table. If laparotomy rather than a minimally invasive technique is chosen, a vertical midline incision is made sufficiently long to allow complete visualization of the operative field. A self-retaining retractor should be placed so as to allow the entire surgical team free hands to conduct the surgical procedure. After the incision is fashioned, a thorough examination of the abdominal and pelvic contents should be performed. Particular attention should be paid to potential metastatic sites, especially the liver. The increasing access and familiarity with intraoperative ultrasound has demonstrated the superiority of liver assessment with this modality compared to clinical exam or CT.[25] In the female patient, the ovaries should be examined not only for metastatic deposits, but also for primary neoplasms. The resectability of the tumor should be assessed with minimal manipulation of the lesion. It is important to determine if disease is adherent to adjacent viscera which should then be included as an en bloc resection. It is rare that a right-sided tumor is unresectable, however, extensive involvement of the vena cava, superior mesenteric artery, or the pancreas may dictate a palliative resection or bypass procedure.

The key to an oncologically safe and effective resection of a colon cancer requires clear lateral margins, resection of the locoregional lymph node bearing mesentery for both cure and staging, and performance of an accurate and well-vascularized anastomosis.

A right-sided hemicolectomy begins by gaining access to the retroperitoneum. This maneuver can be accomplished via four different approaches. First, there is the traditional lateral to medial mobilization begun by incising the lateral peritoneal attachments of the colon. Second, a posterior approach (Figure 41-1) enters the retroperitoneum by reflecting the small bowel to the right upper quadrant and incising the peritoneum under the small bowel mesentery from the fourth portion of the duodenum to the cecum. Third, the superior approach enters the retroperitoneum by opening the lesser sac and incising the peritoneum at the hepatic flexure. Finally, with the medial to lateral approach, the ileocolic pedicle is grasped and elevated. The peritoneum on the caudal side of the pedicle is incised and the retroperitoneum is entered. Regardless of how the retroperitoneum is accessed, the principles of the resection are the same. The right colon mesentery is elevated off the retroperitoneum and the duodenum is identified. The lateral attachments are incised and the hepatic flexure is fully mobilized. For cancer operations, it is best to resect the omentum with the specimen, so when entering the lesser sac, the lesser omentum or gastrocolic attachments are divided. The ileocolic (Figure 41-2)

FIGURE 41-1. The drawing demonstrates the incision made at the root of the right colon mesentery just caudal to the third portion of the duodenum to the right of the superior mesenteric artery.
FIGURE 41-2 The vessel(s) is elevated off the retroperitoneum and a proximal ligation is performed at the origin of the superior mesenteric artery. The surgeon's finger is used to demonstrate the vascular origin for accurate placement of the ligation.
FIGURE 41-3. The drawing demonstrates the appropriate levels for vascular ligation and colonic transition for a right hemicolectomy. Notably, the transverse colon is divided just to the right of the main trunk of the MCA, although the right branch of the MCA may be taken, if required. The middle colic vessels are demonstrated and may be ligated during the performance of an extended right hemi-colectomy. This leaves the descending colon in place supported by the left colic artery.

and right or hepatic branch of the middle colic vessels are ligated at their origins. The terminal ileum should be divided 10–15 cm proximal to the ileocecal valve to allow for good vascular supply (see Figure 41-3 for extent of resection). The transverse colon is divided just to the right of the main trunk of the middle colic artery. The ileocolic anastomosis can be fashioned according to the desire of the operating surgeon. The authors prefer to divide the ileum and colon with linear staplers and perform a functional end-to-end anastomosis by anastomosing the antimesenteric surfaces of the bowel segments with a linear stapler and closing the remaining colostomy with a linear stapler or sutures.

Extended Right Colectomy

An extended right colectomy should usually be performed for any lesion involving the transverse colon. This procedure once again should achieve complete resection, lymph node clearance, and most importantly two optimally vascularized bowel segments for anastomosis.

The operation proceeds in similar fashion as the right colectomy described above. However, rather than proceeding through the transverse colon mesentery to ligate and

divide the right branch of the middle colic artery, dissection continues in the retroperitoneal plane to identify the main middle colic arterial trunk anterior to the pancreas. This vessel is ligated and divided. The right colon is then mobilized medially as before, and the lesser omentum is divided along the entire transverse colon. The splenic flexure is released and the bowel with its mesentery is divided just proximal to the left colic artery which is preserved for right-sided lesions. The left colic may be sacrificed for left transverse colon lesions, where a more distal colonic anastomosis is desired. The ileocolic anastomosis is then constructed based upon surgeon preference.

Left Colectomy

The left colon can be mobilized in either a lateral to medial or medial to lateral approach. For the lateral to medial approach, the small bowel is packed to the right upper quadrant. The lateral peritoneum from the sigmoid colon to the splenic flexure is incised. The left colon mesentery is elevated off the retroperitoneum, so the left ureter is exposed and the colon and its mesentery are brought to the midline. This allows the inferior mesenteric artery to be ligated at its origin at the aorta and the inferior mesenteric vein to be ligated near the ligament of Treitz and the inferior border of the pancreas. For the medial to lateral approach, the small bowel mesentery is mobilized to the right upper quadrant to expose the origin of the inferior mesenteric artery located just caudal to the third portion of the duodenum. The superior rectal artery is grasped at the level of the sacral promontory, the peritoneum is incised, and the retroperitoneum is entered. The left ureter is reflected into the retroperitoneum and the IMA is traced up to its origin. A window is then created on the cephalad side of the artery, medial to the IMV, and the artery is then ligated. The inferior mesenteric vein is ligated at the base of the pancreas. The mesentery is elevated off the retroperitoneum toward the abdominal wall and the lateral attachments are then incised (Figure 41-4). For either approach, the splenic flexure is mobilized by separating the omentum from the transverse colon. This completely opens the lesser sac and allows the posterior attachments to the inferior border of the pancreas to be divided. The bowel is transected with at least a 5 cm proximal margin and the distal site of resection on the top of the rectum.

The authors' preference is to perform an end-to-end circular stapled anastomosis, after dividing the rectosigmoid junction with a linear stapler or purse-string suture. A leak test with air insufflation of a submerged anastomotic segment should be performed in all cases.

Resection of proximal left colon lesions may require division of the middle colic artery to allow the right transverse colon to reach the rectal stump for an anastomosis. However, an extended right colectomy and ileosigmoid
FIGURE 41-4. The small bowel mesentery is mobilized to the right upper quadrant to expose the origin of the IMA located just caudal to the third portion of the duodenum (see figure). An incision running along the base of the left colic and sigmoid mesentery from the sacral promontory to the ligament of Treitz, exposes the aorta, bifurcation of the common iliac arteries, and IMA vein. The IMA is ligated and divided proximal to the take-off of the left colic artery. The left branch of the middle colic vessels requires ligation and division for a formal left colectomy.

or ileorectal anastomosis may be preferable if there is any concern related to the blood supply. Another alternative is to perform a retroileal right colon to rectum anastomosis if maintenance of the right colon is desired (Figure 41-5). Once again the type of anastomosis is left to the discretion of the surgeon.

Total Abdominal Colectomy with Ileorectal Anastomosis

This procedure should be applied to circumstances, where the patient has been diagnosed with HNPCC, attenuated Familial Adenomatous Polyposis, metachronous cancers in separate colon segments, and frequently in acute malignant distal colon obstructions with unknown status of the proximal bowel. The access to vascular supply and mesenteric dissection has been described above. The terminal ileum should be sufficiently mobilized to allow easy reach to the rectum. The authors prefer a circular stapled end-to-end anastomotic technique.
FIGURE 41-5. An alternative method of reconstruction that preserves the right colon is a retroileal right colon to rectum anastomosis. This is performed by swinging the fully mobilized colon in a counter-clockwise direction down into the pelvis to place the cut edge of the right colon mesentery across the pelvic brim.

Special Circumstances

Laparoscopic Colon Resection for Cancer

The application of laparoscopic techniques has been used in colorectal surgery for more than 15 years. However, it is only since the publication of the multicenter prospective randomized COST trial results in 2004 that it has been widely applied to the management of colorectal cancer.[26] The first publication from the COST trial focused on the quality of life.[27] It demonstrated many of the short-term benefits of laparoscopy, such as faster return of bowel function, shorter length of stay, and less narcotic use, but there was minimal short-term quality of life benefit with laparoscopy. In 2004, the 3-year oncologic results were published.[26] The study was designed as a noninferiority study and was not designed to demonstrate that laparoscopy was better. The overall survival

was equivalent between the laparoscopic and open groups. Additionally, there was no difference in survival or recurrence for any stage of cancer. Port site recurrences were not an issue in this study, which has put this controversial issue to rest. These results have held up through the 5-year follow-up period.[28] Furthermore, it was demonstrated that conversion did not have a negative impact on the oncologic outcome of these patients.

The findings of the COST trial have been confirmed by at least two additional international, multicenter, prospective randomized trials on laparoscopy versus open colectomy for cancer. In 2007 and 2009, the 3-year follow-up results from the UK CLASICC and the European COLOR trials were published.[29,30] Both studies reported equivalent survival and recurrence rates stage for stage for laparoscopic and open colectomy for colon cancer. The CLASICC trial included the quality of life measures and once again found no difference between laparoscopic and open colectomy. Both trials demonstrated that a significant learning curve is associated with laparoscopic colectomy. The CLASICC trial saw the conversion rate fall from 38% in year 1 to 16% in year 6 of the study.[31] Similarly, the COLOR trial found that case volume impacted many of the parameters of the study. High volume centers (>20 cases/year) had shorter operative times, fewer conversions, and fewer complications than medium volume (10–20 cases/year) and low volume (<10 cases/year) centers.[30] Therefore, with adequate experience, laparoscopic colectomy for right- or left-sided colon cancers is safe and provides similar outcomes to open colectomy. There currently is no data regarding laparoscopic resection of transverse colon cancers.

Acute Obstruction

Acute colonic obstruction produces dilated bowel with a large amount of fecal loading proximal to the blockage. The associated bacterial overgrowth coupled with possible impairment of blood flow in the proximal bowel has been the primary factors that have classically dictated resection and proximal diversion. Lee et al.[32–36] compared left- and right-sided resections managed by primary anastomosis and found similar leak rates (left-6.9% vs. right-5.2%) or mortality rates (left-8.9% vs. right-7.3%). On-table colonic lavage has been advocated as an alternative means of dealing with the obstructed colon. A number of cohort studies have demonstrated the safety and efficacy of this approach for avoiding a colostomy without increasing leak rates (<5%) or sepsis.[34–36] Another approach to protect at-risk anastomoses has been omental wrapping. A large prospective randomized trial by Merad et al.[37] did not demonstrate any significant difference in anastomotic leak rates or the sequelae of those leaks. The success of managing these patients without a need for colostomy depends upon the amount of colonic and small bowel distention and the physiologic state of the patient.

More recently, endoscopically placed self expanding metal stents have been used to manage patients with malignant large bowel obstruction. Emergency surgery is associated with operative mortalities as high as 23% and a reduced quality of life.[38–40] Colonic stenting can serve as a bridge to elective surgery converting an emergency procedure into an elective one in patients with operable cancers.[41] Recent large reviews have reported technical and clinical success rates of over 90% for stenting.[42,43] Complications of the procedure include stent migration, blockage, and perforation although migration and blockage is not as big a concern if elective surgery is to follow shortly after the resolution of obstruction and optimization of medical comorbidities. Nonrandomized trials have shown that stenting used as a bridge to surgery helps reduce postanastomotic leak rates, reduces wound infection rate, decreases in-hospital length of stay and has comparable survival rates to emergency resections.[44–46] Other advantages include opportunity for preoperative visualization of the entire colon prior to surgery as well as avoidance of stoma creation as the majority of patients do not achieve stoma closure after a Hartmann's procedure.[47] Stenting has been used largely for left-sided lesions; however, some studies have shown success with stenting lesions proximal to the splenic flexure with better postoperative outcomes when compared to emergency surgeries.[48] Stenting is therefore feasible over the entire colon except the lower rectum because of pain and tenesmus. The presence of a stent does not seem to compromise a laparoscopic approach.[39,41,49,50] The wider application of this treatment option warrants further studies.

Prophylactic Oophorectomy

The debate continues regarding the relative risks and benefits of a prophylactic bilateral oophorectomy in women with colon cancer. The potential benefits are the removal of an ovary seeded by colon cancer cells which manifests as a delayed metastatic site and the reduction in the risk of primary ovarian cancer in this age group. The data are limited for both issues. The risk of micrometastatic implants in the ovary increases with tumor stage and approaches 10%.[51,52] A comparison of cohorts of women with and without prophylactic oophorectomy could not demonstrate a survival advantage, but a 3.2 vs. 0% risk of primary ovarian cancer in survivors with ovaries not resected was noted.[53]

Colon Cancer and Abdominal Aortic Aneurysm

This is a frequently employed line of questioning in board examinations; however, the best answer is not available based upon incontrovertible evidence. In fact, a survey of general surgery program directors revealed that the vascular surgeons preferred to repair the aneurysm first, whereas the nonvascular surgeons preferred colectomy.[54] The primary risk is that performing either operation first may cause complications that significantly delay the second procedure.

The risk of performing a colectomy synchronously with the placement of graft material is a graft infection; however, this risk does not appear excessive based upon the small data sets available.[55–57] Probably, the best guidance suggests that any aneurysm >6 cm should be repaired first or synchronously with the removal of a colon cancer to avoid the risk of rupture.[58] The advent of endovascular repairs, when feasible, has greatly impacted the management of synchronous colon neoplasms and abdominal aortic aneurysms. The aneurysm and cancer can be addressed in either a staged fashion (endovascular repair followed by colectomy within the next couple of days) or synchronously under a single anesthetic, and this is being increasingly supported by the literature.[59,60]

Management of Colon Cancer and Liver Metastases

The potential benefit of simultaneous colectomy and hepatectomy is the avoidance of two laparotomies and possible reduction in operative risk. Conversely, delayed management of colonic hepatic metastases offers the ability to accurately stage patients and avoid the risk of hepatectomy in a group of patients who prove to have more widely metastatic disease in several months. The risks of simultaneous colectomy and hepatectomy do not appear to be excessive in select patients operated by expert groups[61–63] and long-term survival rates seem to be similar.[64] However, the risks may be less with smaller nonanatomic liver resections coupled with right colectomy. In the situation where liver metastases are unresectable, recent studies suggest that upfront chemotherapy without prophylactic resection of the primary tumor is appropriate.[65] In addition, up to 16% of previously unresectable patients can be downstaged and eventually undergo curative resection with as high as 40% 5-year survival.[66,67]

The role of resection of the primary tumor in patients with unresectable liver metastases is debatable. About 70% of patients diagnosed with Stage IV colorectal cancer in the USA during the last two decades underwent primary tumor resection as their initial treatment.[68] Studies have shown that resection of with primary lesions is safe, provides good local control, and allows the patient to proceed to adjuvant therapy in a timely fashion.[69–71] In addition, some retrospective data suggest that noncurative resection of asymptomatic colorectal primary tumors may prolong survival when compared to nonresected patients.[72–74] Median survival in these studies ranged from 11 to 16 months in resected groups versus 2–9 months in the unresected groups. Other studies, however, have not reported a survival benefit.[75,76] Local complications caused by primary tumors left in situ may prompt surgeons to opt for preemptive resection. In a recent study, Poultsides et al.[65] retrospectively studied 233 patients with synchronous stage IV colorectal cancer who received up front chemotherapy. They found that only 7% of these patients required surgical palliation for their intact primary tumor. Previous studies have noted a 9–29% need for operative

intervention due to tumor-related complications.[72,77–79] In the era of improved chemotherapeutic agents and multimodality treatment, patients with metastatic rectal cancer are achieving significant improvements in outcomes and can now be approached with curative intent. When metastatic disease is not resectable, upfront chemotherapy without resection of the primary lesion may be a reasonable approach although as patients live longer with disease, the need for palliative surgical intervention may increase.

Sentinel Node Assessment

Sentinel node assessment was first described as a means of improving staging and treatment for melanoma patients and is currently considered the standard of care for breast cancer patients.[80,81] Saha[82] described the application of sentinel node identification for colorectal cancer patients with the proposed benefit of a high rate of node identification and pathologic upstaging. The technique involves either in vivo injection of 0.5–1 cc of isosulfan blue dye subserosally at the periphery of the tumor (node visualization within 30–60 s), or ex vivo injection of 1–2 cc in a similar fashion after the bowel has been resected.[83] Subsequent evaluation of the technique, including some modifications, has demonstrated a false negative rate approaching 60%, and limitations have been noted in rectal cancers.[84–86]

There are several concerns which restrict routine implementation of sentinel node assessment in colorectal cancer. First, there is no consensus of opinion regarding the prognostic significance of micrometastatic lymph nodes in colorectal cancer, particularly those identified by immunohistochemistry or PCR.[87–90] Second, the relatively high false negative rates and/or lack of node visualization mentioned previously, limit the confidence in restricting microsectioning and the use of special stains to the group with stained nodes. Finally, there is limited data that the technique is sufficiently accurate to alter the extent of surgical resection in a reasonable number of patients. Before sentinel node assessment can be routinely recommended, two hurdles must be overcome: (1) provision of incontrovertible evidence that micrometastatic disease identified by any technique correlates with survival; and (2) that the survival rates can be favorably impacted by an adjuvant chemotherapy regimen.

Outcome of Colectomy for Colon Cancer

In general, the operative outcome and long-term survival following colon cancer resections parallels the American Joint Committee on Cancer staging system (I: well above 90%; II: 65–90%; III: 45–75%) which may be modulated by adjuvant chemotherapy.[91–93] The risk of locoregional recurrence following colectomy is a rare occurrence and should be below 5%.[94,95] However, the impact of the surgeon's experience and the expertise of the institution have recently been found to have a profound effect on outcome. High volume surgeons, particularly those at high volume institutions have demonstrated significantly lower perioperative complications and improved survival after colectomy for colon cancer.[96–98]

In addition to experience, the overall surgical approach to the management of margins and extent of resection has a significant effect on outcome after colon cancer resection. Although not clearly defined, it is generally agreed that 5 cm proximal and distal bowel margins are sufficient to allow resection of mural tumor spread. Grinnell originally evaluated the patterns of mural spread of tumor in the colon via lymphatics and found no instance of spread greater than 4 cm in the most advanced cases.[99] More recent data would suggest that mural tumor migration is rarely greater than 2 cm either proximal or distal to the palpable tumor edge.[100] Similarly, there is no need to resect any specific amount of terminal ileum, other than defined by vascular supply as mural spread to the ileum is a very rare event. Vascular ligation is generally performed at the origin of the primary feeder vessel to a colonic segment. For resection of the right colon and transverse colon, the debate is relatively moot due to the constraints of the arterial origin of the right colic and middle colic arteries. Ligation for left-sided resections has been debated, primarily in sigmoid or anterior resections as ligation of the inferior mesenteric artery may be performed at the aorta, or just distal to the left colic artery takeoff. A report from St. Marks assessed this issue in 1,370 patients and found that survival was equivalent for all stages for the ligation options except for the most advanced node positive cases who fared worse with ligation at the aorta.[101] This counter-intuitive finding was more likely related to the higher stage of patients identified by the wider lymphatic resection. A comparison of left hemicolectomy and segmental colectomy (ligation of the IMA vs. more distal) by the French Association for Surgical Research could not discern either a different survival rate or pattern based upon the ligation or resection performed.[102] Jagoditsch et al.[92] demonstrated the benefits of careful surgical technique which resulted in a complete resection of all tumor (R0). Their data demonstrated an operative mortality of 1.3% and a 5-year survival rate of 71.8% for curative operations in Stage I–III disease.

Summary

Surgery for colonic cancer has been increasingly better defined and the data clearly support the benefits of wide mesenteric resection, clear radial margins, and resection of adherent adjacent organs. The mesenteric resection is obtained by ligating the feeding vessel at its origin. This maximizes the chances that 12 or more lymph nodes are examined to allow for accurate staging. Attentions to surgical detail, coupled with improved perioperative care strategies, are essential to minimize operative morbidity and mortality.

The Preoperative Staging of Rectal Cancer

Susan L. Gearhart and Jonathan E. Efron

Introduction

The classification of a newly diagnosed cancer of the rectum into a staging system with both therapeutic and prognostic applications has been the goal of pathologists and clinicians for the greater part of the last century. Most staging systems rely on the examination of the pathological specimen as well as information gained during surgery. Thus, they are useful only in the postoperative setting and have little use for the purpose of preoperative therapy. Cuthberg Dukes declared in 1932 "If it would be possible to decide the category of the case before operating, this would be very useful information."[1] As the therapeutic options available for the treatment of rectal cancer increase, the ability to accurately stage a rectal tumor preoperatively takes on greater importance. Accurate and reproducible preoperative staging provides uniformity among numerous investigative centers; specifically, those involved in adjuvant preoperative therapy trials.

The effective evaluation of a newly diagnosed rectal cancer should result in a determination of the need for neoadjuvant therapy, the potential for sphincter preservation, and the expected quality of life following treatment. Furthermore, the ability to stage the tumor preoperatively permits the physician to convey more accurate information to the patient and the family with regards to therapeutic options and expected overall prognosis. However, the ability of the treating physician to make these determinants is based on the methods of assessment currently available. The accuracy of these methods is variable and is discussed in this chapter. The currently used system proposed by American Joint Committee on Cancer (AJCC) Staging of Squamous Cell Carcinoma (SCC) for staging colorectal cancer is listed in Table 20-1.

The tumor-related factors of prognostic significance which may be evaluated prior to the treatment of rectal cancer include the depth of penetration of the tumor through the rectal wall, the presence or absence of metastases to the regional and pelvic lymph nodes, and the presence of distant metastases.

Clinicians have a variety of diagnostic tools at their disposal that can aid in delineating these aforementioned factors. The most commonly used modalities for the preoperative staging of rectal tumors available today are digital rectal examination, computed tomography (CT), endorectal ultrasonography (ERUS), magnetic resonance imaging (MRI), and positron emission tomography combined with computerized tomography (PET/CT).

Local and Regional Staging

Digital Rectal Examination

Careful digital exam of rectal tumor may yield valuable information regarding the location and degree of fixation of the tumor to the sphincter muscles. Table 42-1 lists some of the important parameters that should be recorded during the DRE of a tumor. A clinical staging system based on tumor mobility was first established by York-Mason in 1976[2] and subsequently modified in 1982.[3] In this clinical staging system, tumor mobility is correlated with the level of tumor penetration in the different layers of the rectal wall. Nicholls et al.[3] evaluated this clinical staging system and discovered that senior examiners had an 80% accuracy in distinguishing superficial tumors from deep tumors and was more accurate with more advanced lesions, but only a 50% accuracy in detecting lymph node metastasis. Therefore, the accuracy of DRE in staging rectal cancer was considered not dependable and directly proportional to the experience of the examiner. The use of DRE alone in the staging of rectal cancer is considered inadequate.

Endorectal Ultrasound

Endorectal ultrasound (EUS) is an outpatient procedure requiring only enema preparation and often no sedation or

anesthesia. Endoscopic assessment can occur with a rigid or flexible ultrasound probe. The frequency of the ultrasound transducer determines its focal range and ultrasonographic resolution. Complete circular imaging of the rectal wall can be obtained with the 360-degree rotating endorectal probe. Most investigators use a two-dimensional (2D) 7.0 or a 10 mHz transducer which provides a five layer anatomic model of the rectal wall with three hyperechoic circles and two hypoechoic concentric circles (Figure 42-1A and B).[4] A multiplanar three-dimensional (3D) ERUS with coronal, sagittal, and transverse images has more recently been employed to increase the accuracy of the 2D ERUS.

The accuracy of ERUS in the initial evaluation of rectal cancer is user dependent and variable. Mor et al.[5] surveyed 100 members of the American Society of Colon and Rectal Surgery (ASCRS) who were experienced in EUS. The survey asked members to review and stage 26 ultrasound images. The overall accuracy was 39–60% with 15% of tumors overstaged and 23% understaged. The Minnesota series is one of the largest series published in 2002 by Garcia-Aguilar et al.[6] These investigators reported their experience with 1,184 patients with rectal carcinoma or villous adenoma that underwent ERUS. Histopathologic correlation was available for the 545 patients who had no prior radiotherapy. The accuracy of ERUS in assessing the level of penetration was only 69%, with 18% overstaged and 13% understaged. The

accuracy was notably higher for benign lesions and for full thickness lesions. Lower accuracy rates occurred for T1 and T2 lesions. For nodal involvement, the accuracy in the 238 patients who had radical surgery was poor, 64% with 25% overstaged and 11% understaged. However, a recent meta-analysis suggests that the sensitivity and specificity for nodal staging in rectal cancer is 75%.[7]

Early studies by Hunerbein et al.[8] using 3D ultrasound in the initial staging of rectal cancer demonstrated no significant benefit between conventional ERUS or 3D ERUS. However, the investigators did suggested that the multiplanar effect of 3D imaging may be useful in planning surgery. More recently, Kim et al.[9] demonstrated in 86 patients that the accuracy of 3D ERUS was 10% improved over conventional ERUS. This study also demonstrated that conical protrusions along the deep tumor border seen best on 3D images correlated closely with tumor infiltration, advanced T-stage, and lymph node metastasis.

There are several limitations to the use of ERUS. There is a significant learning curve associated with the interpretation of the endorectal ultrasound image. Orrom and Wong et al.[10] at the University of Minnesota demonstrated an accuracy of 75% at determining bowel wall invasion; however, during the last 6 months of the study, the authors showed improvement with a 95% accuracy. Rafalesen et al.[11] reported that the reader experience had a significant effect of the assessment of penetration of the bowel wall by tumor. When comparing more experienced with less experienced radiologist, the accuracy for bowel wall penetration was 90% vs. 66%, respectively.

Overstaging tumor is common in many reported series because of the inability of ultrasound to differentiate perirectal inflammation from tumor infiltration in the perirectal fat. Furthermore, the differentiation between inflammatory or neoplastic nodes is difficult with ERUS. Morphologic criteria suggestive of metastatic involvement within the

FIGURE 42-1. **A** EUS demonstrating the five layers of the rectum. **B** Standard EUS of rectal tumor.

lymph node are listed in Table 42-2. Methods to differentiate include further characterization of the node with ERUS or ERUS-guided biopsy. Hildebrandt et al.[12] determined that hypoechoic lymph nodes represented tumor metastases, whereas hyperechoic lymph nodes represented inflammatory changes. They reported an overall accuracy rate of 78%. Errors in ERUS lymph node staging were attributed to micrometastases, mixed lymph nodes, and changing echo patterns within inflammatory nodes. The impact of ERUS-guided fine-needle aspiration of perirectal nodes has been investigated by Harewood et al.[13] ERUS-guided biopsy was utilized in the preoperative staging of 80 consecutive patients with rectal cancer.[13] In this series, FNA did not significantly improve nodal staging over ERUS alone. Based on these results and the potential risk of spreading cancer cells into the mesorectum, ultrasound-guided biopsy of enlarged perirectal nodes is not routinely used in clinical practice.

ERUS is difficult to perform in near obstructing lesions and those higher up in the rectum. Early studies by Sentovich et al.[14] and Senesse et al.[15] reported significantly better result in determining the depth of invasion of a rectal tumor that was within 6 cm of the anal verge as compared to those >6 cm from the anal verge. One suggested method to improve placement of the ultrasound probe to accurately evaluate higher tumors is by insertion of the probe with the assistance of a proctoscope.[5] Using this method, Santoro et al. was able to demonstrate staging with pathological correlation to an accuracy of 78.9% for tumors of the upper rectum.[16]

Magnetic Resonance Imaging

Accuracy rates for MRI in the preoperative staging of rectal cancer have varied according to technique. Initial experience with using body-coil MRI was poor. However, with the introduction of dedicated phase array coils, high-resolution imaging of the anorectum is possible without an intraluminal coil. The main concept in the use of MRI to stage rectal cancer is to obtain high-resolution images within small field-of-view thin sections with fast/turbo spin echo (FSE/TSE) T-2 weighted axial and coronal views of the rectum (Figure 42-2A and B).[17] This method provides inherent contrast between the hypointense extramural component of the tumor and the bright signal of the mesorectal fat. Acquiring images that are directly parallel or perpendicular to the tumor and distending the rectum with gel increase the accuracy of MRI on determining the depth of bowel wall invasion.

FIGURE 42-2. **A** and **B** The main concept in the use of MRI to stage rectal cancer is to obtain high-resolution images within small field-of-view thin sections with fast/turbo spin echo (FSE/TSE) T-2 weighted axial and coronal views of the rectum.

Since its original description in 1986, multiple studies have evaluated the accuracy of MRI in staging rectal cancer. Kim et al.[18] in the largest published trial to date examining the accuracy of MRI staging of rectal cancer, compared the histopathological staging with the preoperative staging in 217 patients. The accuracy for the depth of invasion was 81% and for regional lymph node metastasis was 63%. Similar to staging of bowel wall infiltration on EUS, MRI T staging has been defined by Brown et al.[19] (Table 42-3).

MRI identification of metastatic lymph node involvement has not been standardized. According to Brown et al.[20] criteria that are most predictable for determining lymph node metastasis are signal heterogeneity and an irregular border. Size criteria are not adequate. It is important to remember that in patients with rectal cancer, approximately 15% of lymph nodes smaller than 5 mm are positive for metastasis. With the use of ultrasmall superparamagnetic iron oxide (UPSIO)-enhanced MRI, recent advances have been made in the evaluation of lymph nodes. The iron oxide nanoparticle is given intravenously and is transported to the lymphatic system where it is picked by macrophages. The nanoparticle causes a decrease in signal intensity, and therefore, inflammatory lymph nodes exhibit less signal intensity. Initial results using this technique demonstrate up to a 93% sensitivity and 96% specificity for perirectal lymph node metastasis.[21] However, larger prospective trials are needed to validate initial findings.

In recent years, tumor involvement of the circumferential resection margin (CRM) has been identified as an important predictor of locoregional recurrence in rectal cancer patients undergoing a radical proctectomy with total mesorectal excision (TME).[22–25] Postoperative radiation is not effective in reducing the risk of local recurrence in patients with a positive CRM,[26] and a curative operation in these patients requires either tumor downstaging by preoperative chemoradiation, an extended resection, or both. Consequently, the preoperative assessment of the relationship of the tumor with the fascia propria of the rectum, the CRM in patients treated with TME, has become upmost importance in deciding the type of neoadjuvant therapy and planning the surgical resection. The fascia propria of the rectum is well visualized by phased-array coil MRI, and several studies have

suggested that MRI can predict with high degree of accuracy the distance of the tumor to the fascia propria of the rectum (Figure 42-3).[27,28] Furthermore, due to its multiplanar capabilities, MRI is the most accurate imaging technique in assessing the relationship of the tumor with the levator plate and the sphincter complex. This information may be useful in selecting patients with low rectal cancer for a sphincter saving procedure.

In 2004, Bipat et al.[29] reported their findings on a metaanalysis looking at the assessment of local staging for rectal cancer by ERUS, MRI, and CT. Their findings demonstrated that ERUS proved to be the most accurate modality overall. However, the sensitivity and specificity of each method varied greatly dependent on the depth of tumor invasion or the presence of lymph node metastasis (Table 42-4). The authors concluded from their findings suggest that MRI may result in overstaging of early lesions. Furthermore, this analysis did not show any difference in the known MR technique that was used in imaging (body coil alone, body coil and additional coil, unenhanced, enhance with gadolinium, low vs. high magnetic field). Newer studies using phase-array MR techniques have only shown a marginal benefit with the detection of lymph node metastasis (Table 42-5).[30] Figure 42-3 demonstrates a small pelvic lymph node detected on phase-array MR.

TABLE 42-3. MRI T staging as proposed by Brown et al[19]

MRI T stage

T1: Low signal in the submucosal layer or replacement of the submucosal layer by abnormal signal not extending into circular muscle layer.

T2: Intermediate signal intensity within muscularis propria. Outer muscle coat replaced by tumor of intermediate signal intensity that does not extend beyond the outer rectal muscle into perirectal fat.

T3: Broad-based bulge or nodular projection (not fine speculation) of intermediate signal intensity projecting beyond outer muscle coat.

T4: Extension of abnormal signal into adjacent organ, extension of tumor signal through the peritoneal reflection.

MRI magnetic resonance imaging.

Distant Metastases

Computed Tomography

The detection of distant metastasis is of prime importance for the accurate staging of rectal cancer. The most common sites of distant metastasis include the liver and lung. The common imaging modalities used today to detect liver metastasis preoperatively is computerized tomography; however, MRI and PET/CT are being used more frequently. Even after preoperative imaging, up to one-third of colorectal cancer patients are found at the time of surgery to have unsuspected additional liver lesions or extrahepatic metastases. A recent meta-analysis reported by Bipat et al.[31] evaluated the use of CT, MRI, or PET for the diagnosis of colorectal liver metastasis. The investigators found that 18-fluorodeoxyglucose positron emission tomography (FDG-PET) was the more accurate method to detect liver metastasis on a per-patient basis. When evaluating different lesions, MR imaging at 1.5T and FDG-PET were comparable and significantly more accurate than CT. Sensitivity estimates for all imaging modalities studied for lesions less than 1 cm, where much less than for lesions ≥1 cm (11.6–29.3% vs. 65.7–90.2%).

CT is universally available which makes it appealing as a method for local regional staging. However, CT has not proven to be very accurate in determining the depth of penetration of the tumor through rectal wall or assessing involved perirectal lymph nodes metastasis. The reported accuracy rate of CT in determining tumor penetration through the rectal wall is 52–100% and in determining lymph node involvement is 35–70%.[32–39] Newer technology, such as the multidetector-row computed tomography (MDRCT), may significantly improve the ability of CT scans to accurately determine the depth of invasion and lymph node metastasis in rectal cancer. MDRCT utilizes four detectors which result in a much higher resolution and better multiplanar reformation of the images. Matsuoka et al.[40] compared 21 patients who had MDRCT to 21 patients that had MRI evaluations of the pelvis for rectal cancer. They reported an accuracy rate of 95% on the depth of invasion for MDRCT vs. 100% for MRI, whereas lymph node accuracy was 70% vs. 61% for MDRCT and MRI, respectively.

18-Fluorodeoxyglucose Positron Emission Tomography

At the present time, FDG-PET is primarily used for the diagnosis of local and distant recurrence after curative surgery for colorectal cancer. It is also being used with increased frequency to detect distant metastasis of the time of the primary diagnosis of rectal cancer. FDG-PET has been shown to have higher sensitivity and specificity in detecting recurrent rectal cancer than both CT and MRI.[41,42] While sensitivity and specificity for diagnosing tumor recurrence are higher for
FIGURE 42-4. PET scan.

FDG-PET, its specificity for the tumor location is not very accurate, and therefore other studies, such as MRI and/or CT scans are required to define the precise location of the tumor to important anatomical landmarks. To enhance the image, current scanners that fuse CT or MR images with the FDG-PET images are available. When comparing FDG-PET scan and PET/CT images in a series of 45 patients with colorectal cancer, the overall staging accuracy increased from 78 to 89% with PET/CT.[43]

The impact of FDG-PET and FDG-PET/CT in the preoperative staging and management of rectal cancer patients has been studied by Heriot et al.[44] in a series of 46 patients who were assessed with FDG-PET scans at the time of their initial diagnosis. The surgical management was changed in 17% of the patients because of positive FDG-PET scan findings that upstaged the disease. Furthermore, Gearhart et al. demonstrated in 37 patients that FDG-PET/CT was able to demonstrate additional significant findings in 38% of patients with a known primary rectal cancer resulting in an alteration in the treatment planning for 27% of patients.[45] These changes in management included canceling surgery and changing the field of administered radiation.

Radiographic Assessment of Response to Neoadjuvant Therapy

Preoperative radiation of rectal cancer causes various degrees of tumor regression resulting in scarring and fibrosis that impairs accurate imaging. Napoleon et al.[46] demonstrated that EUS was not accurate at determining bowel wall invasion following radiation. The depth of wall invasion was correctly determined in 86% of patients without radiotherapy, but in only 47% in those patients in whom previous radiotherapy had been administered. The use of EUS in restaging rectal cancer following radiation is limited.

The limitation of MRI imaging in rectal cancer has been its inherent inability to differentiate fibrosis from residual tumor following treatment. For this reason, conventional MRI has not been shown to be useful in determining response to therapy.

However, functional MR imaging, has been demonstrated to be useful in the evaluation of the response of rectal cancer to neoadjuvant therapy. Functional MR techniques provide in vivo physiologic and metabolic information about a tumor over time. The components of functional MR include spectroscopy, diffusion, and contrast enhancement. Spectroscopy provides assessment of the concentration of several metabolites and is useful as a noninvasive technique as a means of studying the biochemistry of a lesion relative to normal tissue. Diffusion-weighted MR measures the apparent diffusion coefficient (ADC) which detects thermally induced motion of water molecules and cellular integrity. Viable tumors have intact cell membranes limiting the mobility of water molecules that is reflected as a low ADC value. If there is cellular necrosis, there is enhanced cell membrane permeability which allows for increased motion of water molecules and results in a rise in the ADV value. Kim et al.[47] demonstrated that the diagnostic accuracy of diffusion-weighted MR was significantly improved over conventional MR at predicting a complete response to neoadjuvant therapy. Finally, Dynamic Contrast-enhanced MRI (DCE-MRI) measures the degree of extracellular contrast enhancement which reflects vascular integrity. A decrease in contrast enhancement of a lesion is expected after locoregional therapy and may predict the extent of tumor necrosis. Further studies to validate these findings are necessary.

The use of serial FDG-PET/CT in predicting response to neoadjuvant therapy has been evaluated by several investigators.[48–57] Melton et al.[48] demonstrated that serial FDG-PET/CT is more effective at discerning the presence of minimal or microscopic disease and less effective at identifying lymph node metastasis when correlated with histological findings at the time of surgery (Figure 42-4). The reported specificity for predicting a near complete or complete pathological response to therapy with serial FDG-PET/CT is 60–95% (Table 42-6).[49–51] The timing of serial FDG-PET appears to be important in that FDG-PET/CT after 2 weeks of treatment can predict pathological response with similar specificity to FDG-PET/CT performed at the end of treatment.[52] This earlier time period may be advantageous for determining if the neoadjuvant regimen should be modified in patients that appear not to be responding.

Currently, the use of a newer modality, 3′-deoxy-3′ (^{18}F) fluorothymidine (FLT) in PET scanning has been utilized in the assessment of malignant tumors because of its potential to noninvasively monitor cellular proliferation. The appeal of monitoring thymidine activity is the importance of thymidine in DNA synthesis and cell proliferation. Cell uptake studies have demonstrated that FLT accumulates in cancer cells and tumors in proportion to their rate of cellular proliferation. Furthermore, several studies have indicated that early changes in FLT uptake, measured soon after treatment begins, may be able to predict a tumors response to chemoradiation.[53–55] The use of this modality in monitoring response to therapy in colorectal cancer has not been formally evaluated.

TABLE 42-6. Specificity of FDG-PET to predict near complete or complete pathologic response following chemoradiation for primary rectal cancer

The role of dual-time combined 18-fluoridedoexyglucose positron emission tomography and computed tomography in the staging and restaging workup of locally advanced rectal cancer, treated with preoperative chemoradiation therapy and radical surgery. Int J Radiation Oncology Biol Phys. 2009;74:1461–69.[51]
VRS visual response score, *RI* response index, *TRG* tumor regression grade.

Finally, perfusion CT has emerged as a noninvasive method to assess the microvascular status of tumor tissue. Regression of tumor microvasculature is considered an important surrogate marker for response to treatment. Sequential imaging using CT perfusion techniques is thought to provide a better method for the determination of response of the tumor to chemoradiation.[56] However, perfusion techniques in DCE-MRI have demonstrated superiority in gauging response with MRI.[57]

Conclusion

The accurate preoperative tumor staging is essential to select the best therapy for the rectal cancer patient. Presently, the depth of invasion and evidence of perirectal lymph nodes involvement is best assessed with high-resolution MRI. Whole-body CT scanning or abdominal MRI is also important to detect extrarectal tumor. The role of serial imaging modalities to determine clinical response is currently under investigation.

Local Excision of Rectal Cancer

Peter A. Cataldo

The earliest surgery for rectal cancer involved local excision. Due to limitations in anesthesia, surgical instruments, operative techniques, and blood transfusions, transabdominal, radical resections were thought to be too risky. Local excision, however safe, was associated with high local recurrence rates and poor overall survival, perhaps due to patient selection and inability to remove peritumoral lymph nodes containing regional metastases. For these reasons, Sir Earnest Miles expanded the indications for abdominal–perineal resection[1] (APR), originally described by Faget for perianal sepsis[2] for the treatment of rectal cancer. He believed that excision of regional lymph nodes would improve overall cure rates. Miles theories were correct, but not without consequences, as seven of his original nine patients died from complications of surgery.[1] Complication concerns following APR continue today with mortality rates ranging from 0 to 6.3%[3,4] and complication rates as high as 61%.[5] In addition, APR is associated with a high rate of sexual dysfunction (67%) and stoma related problems (66%).[6] Finally, despite these complications and long-term functional consequences, some early rectal cancers recur despite radical surgery. The 5-year survival for Stage I rectal cancer following radical surgery is 73% as reported by the National Cancer Data Base.[7]

For these reasons, many surgeons have sought alternative treatment options for early rectal cancer. These include chemoradiotherapy alone, and local excision with or without adjuvant treatment. Appropriate treatment always begins with appropriate patient selection, and in the case of cancer therapy, proper patient selection is dependent upon accurate (preoperative) tumor staging. This is the major challenge for local excision of rectal cancer.

In the case of rectal cancer, staging can be divided into local and distant (or systemic) staging. Staging of distant disease is straightforward and well-established. Computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET) scanning have very high accuracy rates when detecting distant disease and are discussed in Chap. 40. Local staging represents a much more difficult and important challenge in rectal cancer. Tumor staging must include the depth of penetration of the rectal wall (T-Stage) and evaluation of adjacent lymph nodes (N-Stage). The impact of this information helps identify which patients are candidates for local excision (T1), prompt surgery (T2), or who require neoadjuvant chemoradiotherapy (T3). The presence or absence of lymphadenopathy has great impact as patients with metastatic regional lymph nodes (N+) are not candidates for any type of curative local excision.

Unfortunately, the accuracy of local staging with both pelvic MRI (with or without endorectal coil) and endorectal ultrasound is variable at best. Accuracy rates range from 71 to 90% for T-Stage assessment by ultrasound[8] and 54 to 81% for MRI, respectively.[9,10] Similarly, the accuracy for lymph nodes staging remains poor 61–80% for EUS[8] and 41–55% for MRI.[11] Perhaps more importantly, the accuracy of these techniques is not improving and is unlikely to improve in the near future. Andreola et al. evaluated lymph node metastases in 101 patients with distal rectal cancer. Forty-five percent of all metastatic lymph nodes were smaller than 5 mm. Fourteen percent of Stage III patients (only) had lymph nodes <5 mm, and 43% of these patients eventually developed metastatic disease.[12] Small metastatic lymph nodes are common and clinically significant, and it is unlikely that our current staging techniques identify these lymph nodes. MRI with tumor injection of ultra-small magnetic particles has shown some promise, but is not clinically available at this time.

Treatment Algorithm

With the aforementioned caveats, rectal cancer should be staged as accurately as possible, both locally and systemically, and patients considered for local excision if appropriate. Any stage patient may be a candidate for *palliative* local excision provided the lesion is accessible and safe excision (and rectal closure) is technically possible. However, the criteria for "*curative*" transanal excision (TAE) are much stricter. Opinions and practice patterns vary widely as do published oncologic results. A reasonable patient selection guide and

treatment algorithm is as follows: For T_1N_0, lesions without adverse histologic features (lymphovascular invasion or poor differentiation) local excision alone without adjuvant therapy is adequate. For T_1N_0, lesions with adverse histologic features, local excision must be combined with postoperative chemoradiotherapy (histologic features are rarely available on preoperative, endoscopic biopsy). For T_2N_0 tumors, local excision should be combined with preoperative or postoperative chemoradiotherapy. T_3N_0 patients are candidates for local excision only if major comorbidities preclude radical surgery or patients refuse a radical approach. Node positive patients (N_1 or N_2) are not candidates for curative local excision as mesorectal lymph nodes cannot be reliably removed transanally.

Traditional criteria for local excision (<10 cm from dentate line, <4 cm in diameter, <40% of rectal circumference) no longer apply due to more sophisticated, yet imperfect, staging and more advanced surgical techniques, such as Transanal Endoscopic Microsurgery (TEM).

Transanal Techniques

Once the decision to perform local excision has been made, traditional surgical principles apply as they do in all surgery. The goals are very straightforward, (1) remove the tumor with negative resection margins, (2) restore normal anatomy to the fullest extent possible, (3) minimize morbidity and mortality, and (4) minimize any impact on long-term function. Once a patient has been selected for local excision, one cannot change the tumor characteristics or stage; one can only affect the quality of surgical resection. Positive resection margins result from inadequate surgical technique and dramatically increase the risk of local recurrence and treatment failure. In order to perform a successful local excision, there must be good exposure and access, visualization must be optimum, and surgical technique precise. In addition, these must be accomplished with minimal impact on postoperative function. Four techniques are described in the ensuing paragraphs, TAE, Kraske technique, York–Mason or transsphincteric, and TEM. Traditional TAE creates minimal disruption to local anatomic structures, but is applicable only to the very distal rectum, and exposure, visualization, and precision are limited. The Kraske, or transcoccygeal, approach provides better exposure, but is more destructive (i.e., coccygectomy) and has a high fecal fistula rate.[13–15] The York–Mason, or transsphincteric technique, again provides better exposure than TAE, but by definition, disrupts the anal sphincters, and is as associated with high rates of postoperative fecal incontinence. TEM is currently gaining popularity; it provides excellent exposure and visualization throughout the rectum, and offers a precise surgical excision and wound closure. It does, however, require specialized equipment, specialized training, and an adequate volume of cases to become adept.

Transanal Excision

Local excision can be accomplished via a transanal approach for the majority of low rectal cancers. In a prospective study of 48 local excisions for rectal cancer, 33 were performed using a transanal approach.[13] Prior to local excision, all patients should receive a full mechanical and antibiotic bowel preparation. After the induction of anesthesia, the patient is flipped over and placed in the prone-jackknife position, with the buttocks taped apart. A pudendal nerve block should then be administered, which aids in postoperative pain control and more importantly relaxes the sphincter complex. An anal retractor in combination alone or in combination with a retractor with self-retaining hooks is then used to dilate the anus and expose the lesion. Once adequate visualization has been obtained, traction sutures are often placed 1–2 cm distal to the tumor, and the line of dissection is marked on the mucosa using electrocautery. This line of dissection should be approximately 1–2 cm from the border of the tumor circumferentially (Figure 43-1A). If visualization is not initially adequate, serial traction sutures should be used to prolapse the lesion into the field of view. Next, the electrocautery is used to make a full-thickness incision along the previously marked mucosa (Figure 43-1B). The specimen is then oriented accurately for the pathologist (Figure 43-1C). Upon completion of this incision, the perirectal fat should be visible beneath the lesion to confirm a full-thickness excision. For anterior lesions, care must be taken not to injure the back wall of the vagina in females, or the prostate or membranous urethra in males. The lesion is then excised leaving visible perirectal fat at the base of the lesion. The defect in the bowel
FIGURE 43-1. **A–C** Transanal excision. **A** A transanal excision is performed by marking out a 1 cm or greater margin around the tumor. **B** A full-thickness excision is then performed to obtain adequate radial as well as lateral margins. **C** The specimen is then oriented accurately for the pathologist.

wall is then closed transversely using interrupted 3–0 polyglycolic sutures.

The complications most closely associated with transanal excisions include urinary retention, urinary tract infections, delayed hemorrhage, infections of the perirectal and ischiorectal space, and fecal impactions. However, the overall incidence of these complications is quite low, and the mortality rate is 0% in most series.

Transcoccygeal Exision

The transcoccygeal approach was used historically over the transanal approach for larger, more proximal lesions. It was originally popularized by Kraske who found it beneficial when operating on lesions within the middle or distal third of the rectum. This approach is especially useful for lesions on the posterior wall of the rectum, but can certainly be used for anterior or lateral lesions as well. In this series, the transcoccygeal approach was used, when the distal margin was approximately 4.8 cm from the dentate line as compared to 3.0 cm for the transanal approach.[13]

All patients should undergo a full antibiotic and mechanical bowel preparation the day prior to surgery. The patient is again placed in the prone-jackknife position with the buttocks taped apart after the induction of general anesthesia. The tape is released for closure in order to facilitate the approximation of the subcutaneous tissues and skin. Unlike the transanal approach, a pudendal block is not required, as the sphincters do not require relaxation. The patient is prepped and draped in a sterile fashion with povidone–iodine solution, and an incision is made in the posterior midline adjacent to the sacrum and coccyx down to the upper border of the posterior aspect of the external sphincter. The coccyx, which along with the anal coccygeal ligament lies immediately deep to the skin and subcutaneous tissue, is removed to improve exposure. In order to do so, the anal coccygeal ligaments and other attachments are cauterized from each side and from the lower edge of the coccyx. The dissection then proceeds along the undersurface, anterior edge, of the coccyx until a cutting wire can pass through the sacral coccygeal joint. The coccyx is then removed with occasional bleeding from an extension of the middle sacral artery, which is easily controlled with electrocautery. The levator ani muscles are now visible at the base of the wound and should be separated in the midline, exposing a membrane that resides just outside of the perirectal fat. Division of this membrane allows for complete mobilization of the rectum within the intraperitoneal pelvis.

For posterior based lesions, the distal margin of the tumor can be palpated via a rectal examination, and then the mesorectum and rectum are transected at a point 1–1.5 cm distal to the tumor (Figure 43-2). The excision is then completed with a 1 cm margin surrounding the lesion. For posterior lesions, the transcoccygeal approach allows for the removal of perirectal nodes that lie in the surrounding
FIGURE 43-2. Transcoccygeal excision. For posterior lesions using a transcoccygeal or "Kraske" approach, one can palpate the lower border of the tumor to ensure an adequate distal margin.

mesorectal tissue. For anterior lesions, a posterior proctotomy is made, and then the lesion is approached under direct vision, again excising the lesion down to the perirectal fat with a 1 cm margin (Figure 43-3). Following removal, the specimen is reoriented for the pathologist and all the rectal incisions are closed in either a longitudinal or transverse manner in order to avoid narrowing of the rectum, using an absorbable suture. An air test should be performed, filling the operative field with sterile saline, and insufflating air in the rectum in order to check for air leaks in the suture line. Once these air leaks are controlled, the levator ani is reapproximated in the midline, and the anal coccygeal ligament is reattached to the sacrum. The operation is completed with the closure of the skin and subcutaneous tissue.

An unfortunate complication of this procedure is the development of a fecal fistula that extends from the rectum to the posterior midline incision. The incidence of this complication ranges from 5 to 20%,[13–15] and most heal after temporary diversion of the fecal stream via a loop ileostomy or colostomy. For this reason, the Kraske approach is used much less frequently than other methods for local treatment.

Transsphincteric Excision

The transsphincteric approach developed by York and Mason involves the complete division of the sphincters and the posterior wall of the rectum. Patients undergo an antibiotic and
FIGURE 43-3. Transcoccygeal excision. Anterior lesions need to be approached by first making a posterior proctotomy and then excising the lesion through the rectum. The anterior and posterior walls of the rectum then need to be repaired, usually in a transverse manner in order to maintain the lumen diameter.

mechanical bowel preparation on the day before surgery. General anesthesia is chosen for the operation. The procedure starts similarly to the Kraske transcoccygeal approach; except the levator ani and the external sphincter muscles are divided in the midline. These muscles are carefully tagged, so matching sutures can be reapproximated exactly at the end of the procedure. Care must be taken to remain in the midline in order to avoid the nerve supply to the sphincters that lie in a posterolateral position bilaterally. Once the lesion is removed, the rectum, sphincters, and overlying musculature are closed in a careful stepwise manner. This procedure has an increased risk of incontinence secondary to sphincter dysfunction. Since the exposure provided from this approach is similar to that from the Kraske procedure, which carries less of a risk of incontinence, there are very few indications for this technique.

Transanal Endoscopic Microsurgery

TEM was developed by Gerhard Buess and the Richard Wolf Medical Instruments Company in 1983 in Germany. Originally designed for the removal of large rectal polyps beyond the reach of traditional transanal excision, its indications eventually expanded to include the excision of early stage rectal cancers.

TEM is essentially the earliest natural orifice transluminal endoscopic surgery (NOTES). It utilizes endoluminal insufflation to create rectal distension and exposure. Access

is obtained via a proctoscope 4 cm in diameter and either 12 or 20 cm in length, which allows for resection of lesions anywhere in the rectum. Visualization is provided by a special binocular optic passed through the proctoscope which creates three-dimensional viewing. In addition, a laparoscopic camera can be attached to a separate optic with the image being viewed on a standard video monitor.

TEM is a closed system and a faceplate on the end of the proctoscope maintains an airtight seal. Instruments are passed through three-gasket ports, similar to laparoscopy. All instruments are 5 mm in diameter, and >30 cm in length, and include graspers, cautery, needle holders, suction, scissors, and clip appliers.

With TEM, it is possible to resect large lesions throughout the entire rectum and to meticulously suture the ensuing defects closed. Complete sleeve resection of the mid portion of the rectum with primary endoluminal anastomosis is possible and has been done in many instances.

Briefly, the technique is as follows. The lesion and its location are precisely identified and the patient is positioned on the operating room table with the lesion oriented toward the floor. (i.e., prone for anterior lesions, lithotomy for posterior lesions, etc.) This is important as the TEM equipment is designed to operate from "the top down." The proctoscope is inserted, the lesion is located, and the proctoscope is then fixed in place by attaching it to the "Martin Arm," a three-elbowed gadget that attaches to the OR table, locks in place, and keeps the TEM scope fixed (Figure 43-4A, B). Lidocaine with epinephrine is instilled underneath the lesion and 1 cm margins (5 mm for benign lesions) are marked with electrocautery surrounding the lesion. Using cautery, the lesion is then excised circumferentially in the full-thickness plane until it has been completely detached from the surrounding rectal wall (Figure 43-5). Following this, the deep dissection, often to include a significant portion of perirectal fat, is completed and the lesion removed through the open faceplate of the proctoscope. The specimen is pinned on a corkboard to facilitate microscopic evaluation. The defect is then closed transversely to prevent rectal stenosis. The mid-point of the proximal and distal edges of the defect are identified and approximated with a single suture to insure correct orientation and to facilitate transverse closure. The remaining defect is closed from each corner to the middle. Silver clips or "bbs" are used at the beginning and end of all sutures (usually running) in lieu of tying knots as this is tedious in the small operative field (Figure 43-6). Alternatively small, distal rectal, extra-peritoneal defects can be left open, although this is not commonly recommended as it is important to master suturing skills as some defects may be "intra-peritoneal" where failure to close accurately can lead to peritonitis.

Postoperative recovery is usually uneventful, with most patients being discharged directly from the recovery room. Patients experience pelvic pressure and irregular bowel movements for 1 or 2 weeks following surgery, but little pain
FIGURE 43-4. **A** Five mm TEM instruments, including needle cautery, graspers, suction, and needle holder. **B** External view of assembled TEM equipment in use.
FIGURE 43-6. Defect closed in transverse fashion in order to prevent stenosis. Silver "bbs" are used in lieu of tying knots.

unless the resection involves the distal rectum adjacent to the dentate line, which is innervated by the somatically controlled inferior hemorrhoidal nerve.

Complications of TEM are rare, but include transient urinary retention, dehiscence of the operative closure, hemorrhage, perirectal or intraperitoneal infection, and rectovaginal fistulae. Rarely reoperation and even temporary fecal diversion are necessary to treat severe complications.

Follow-up after resection for rectal cancer is essential as local recurrence, if identified early, can be cured with radical resection. History and physical exam and CEA are performed every 3 months for 2 years, and every 6 months for the following 3 years. Flexible sigmoidoscopy is performed at 3 and 9 months following surgery and yearly thereafter. Colonoscopy is scheduled at 1 year and every 3 years regularly. CT scans begin at 1 year postoperatively and are then performed yearly. Long-term, vigilant follow-up is important, particularly after adjuvant radiation, as recurrence may develop up to 10 years postoperatively.

Results

When evaluating results following various treatments for rectal cancer, local recurrence and survival are naturally most important. It is important to also consider surgical morbidity and mortality, functional consequences, and the quality of life. Various local excision techniques can be compared to each other, and/or compared to traditional, radical resection.

Survival following radical resection for rectal cancer as reported by the National Cancer Database is 73% for Stage I; 56% for Stage II; 47% for Stage III, and 6% for Stage IV[7]. As we evaluate survival following local excision, it is essential to remember that not all patients with early stage rectal cancer are cured by radical resection. If a patient undergoes

FIGURE 43-5. Lesion properly positioned for TEM.

a well-performed, oncologically sound radical resection and then recurs, it is traditionally blamed on tumor biology. If recurrence develops after local excision, we assume that recurrence is due to inadequate surgery. While that may sometimes be the case, it is certainly not always the case as judged by the survival data following radical resection.

Many local failures following local excision are thought to arise in undiagnosed metastatic lymph nodes in the mesorectum. If this is in fact the case, then these are truly Stage III rectal cancers which have been under-staged, not Stage I rectal cancers that have recurred. In this situation, the problem lies with under-staging, and subsequent inadequate treatment. This only occurs following local excision (as lymph nodes are excised and evaluated with radical resection) and therefore artificially increases local recurrence rates and lowers overall survival following local excision of "early stage" rectal cancers.

You et al.[16] performed the most extensive study evaluating local excision of early rectal cancers with data obtained from the National Cancer Database. They compared standard resection (SR) (abdominoperineal and low anterior resection) to local excision (LE) and looked at operative mortality, local recurrence, disease specific survival (DSS) and overall survival (OS) for both groups for T_1 and T_2 rectal cancers. A total of 2,124 patients treated between 1994 and 1996 were included; LE 765 (T_1 601, T_2 164) SR 1359 (T_1 493, T_2 866). Overall operative mortality was lower for LE (0.5% vs. 1.8%). Thirty-day mortality was also lower for LE (5.6% vs. 14.6%). For T_1 tumors, overall survival was similar at 8 years (LE 61.7% vs. SR 66.3%, $p = 0.09$). However, local recurrence was significantly higher for LE compared with SR (14.3% vs. 8.5%, $p = 0.007$) at 8 years. Similarly, DSS was worse for LE (93.2% vs. 97.2%, $p = 0.004$). For T_2 tumors, local recurrence again was higher for LE (22.1% vs. 15.1%, $p = 0.01$) but DSS was similar for LE and SR (90.2% vs. 91.7%, $p = 0.95$). OS was worse for LE (67.6% vs. 76.5%, $p = 0.01$) at 5 years.

These data suggest that LE is clearly safer than SR, but at the cost of inferior oncologic outcomes. Yet, when overall survival is evaluated both groups are essentially similar. Despite being a large, exhaustive project, this study has several shortcomings. (1) Many patients included in the LE group did not have R_0 excisions, which would clearly increase the LR rate and decrease the overall survival. In addition, any patient who received adjuvant therapy (chemotherapy or radiation) was excluded from the analysis. Many surgeons would consider chemoradiation a standard component of treatment for any T_2 tumor and selected T_1 tumors treated by LE. Also, the authors did not evaluate the type of LE performed (TAE vs. TEM vs. Kraske vs. York Mason). Finally, no mention is made of the "stage shift" phenomenon, where a small but significant number of T_1 and T_2 tumor treated by LE (but not by SR) were truly Stage III cancers, and had undocumented disease in unresected perirectal lymph nodes.

Ptok et al.[17] compared local and radical resection for low risk T_1 rectal cancer. Similar to the large database study by You, morbidity was lower with LE (9.2% vs. 22.8%, $p = 0.001$), but local recurrence was higher (6% vs. 2%, $p = 0.049$). However, 5-year tumor free survival was similar for both groups. Although the authors divided the LE group into TAE and TEM for demographic purposes, they did not analyze the groups separately when looking at local recurrence or survival.

Garcia-Aguilar et al.[18] reviewed the University of Minnesota experience with local excision of early stage, low-risk rectal cancers. Their series included 82 patients who underwent TAE for T_1 or T_2 rectal cancers with favorable histology (moderately or well differentiated and with no lymphovascular invasion). All included patients had negative resection margins. Recurrence was identified in 18% of T_1 tumors (nine local, one distant, one local and distant recurrence) and 37% for T_2 tumors (eight local, two combined local and distant). Salvage surgery was performed when appropriate. One patient in the T_1 group and two patients in the T_2 died as a result of cancer recurrence. Mean follow-up was 54 months. The authors concluded that local recurrence rates were high, but salvage was often possible with radical resection. Cancer free survival was high for both groups, but long-term outcomes were inconclusive. Interestingly, preoperative staging with endorectal ultrasound, which should ideally improve staging and patient selection, had no effect on outcomes.

Paty et al.[19] at Memorial Sloan-Kettering Cancer Center, evaluated long term follow-up in 125 patients with T_1 and T_2 rectal cancers undergoing local excision. Median follow-up was 6.7 years, local recurrence was 17% for T_1, and 28% for T_2 tumors. Ten-year survival was 74% and 72%, respectively. Positive resection margins were found in 10% (11 of 125) patients. Adjuvant radiotherapy with or without chemotherapy did not influence local recurrence or overall survival, but radiation was used selectively in high-risk patients. Radiation did, however, seem to delay recurrence; 28% of all cancer deaths occurred more than 5 years after initial treatment.

In evaluating multiple studies of traditional local excision for early rectal cancer, several patterns arise. (1) Morbidity, mortality, and functional outcomes are better with local excision. (2) Local recurrence rates are higher following local excision when compared with radical resection. (3) Salvage radical surgery is possible in 30–50% of patients developing local recurrence after local excision. (4) Disease free survival and overall survival are similar following local excision and radical resection for T_1 and T_2 rectal cancers.

Transanal Endoscopic Microsurgery

TEM has been in use since the early 1980s, but only in select centers, particularly in Europe. Over the past 10 years, its role has expanded significantly and its use is now widespread in Europe, Great Britain, and more recently the USA. It has been

advocated as technically superior to TAE, and oncologically favorable results have been reported. Few studies, however, directly compare TEM to traditional techniques. Yet, the limited data is encouraging.

Lin et al.[20] compared TEM to the York–Mason approach in 82 patients with benign and malignant rectal masses. Postoperative pain, hospital stay, and complication rates were significantly higher for the York–Mason approach. With short-term median follow-up of 30 months recurrence was 0% for the TEM group and 3.9% for the controls. This is a small study, but clearly shows the technical superiority of TEM. Christforidis et al.[21] at the University of Minnesota retrospectively compared TEM to traditional TAE in 171 patients (42 TEM, 129 TAE). Negative resection margins were obtained in 98% of the TEM group compared with 84% of the TAE group. Disease free survival at 5 years was slightly better for the TEM group (84% vs. 76%), but did not reach statistical significance. Multivariate analysis identified T-stage, resection margin status, the use of adjuvant therapy, and distance from the anal verge (lower = worse prognosis), but not surgical technique (TEM vs. TAE) as predictive of local recurrence. Moore et al.[22] evaluated 171 patients subject to TEM (82) or TAE (89) at the University of Vermont for rectal adenomas and carcinomas. In the group of patients undergoing resection for cancer, TEM, when compared to TAE, provided an intact, nonfragmented specimen more often (100% vs. 63%), achieved negative resection margins (98% vs. 78%, $p = 0.01$) and was associated with a lower recurrence rate (8% vs. 24%). When only curative resections were considered, recurrence rate for TEM was 3% compared with 22% for TAE. In this study, TEM was clearly technically and oncologically superior to TAE.

Many other studies have reported individual institution's experience with TEM with some comparisons to historical controls. Whitehouse et al.[23] reported on 42 patients undergoing TEM for rectal cancer. Resection margins were positive in 8%. Adjuvant chemoradiation was used at the surgeon's discretion. Local recurrence rates were as follows, T_1 20% (6/23); T_2 22% (2/9); T_3 0% (0/4). Conclusions indicated TEM to be safe but recurrence rates were high.

In a much larger series Guerrieri et al.[24] reviewed 196 patients (51 T_1, 84 T_2, 61 T_3) treated with TEM for rectal cancer. All patients with T_2 or T_3 lesions underwent preoperative radiotherapy, combined with chemotherapy in some instances. All patients achieved negative resection margins (real time frozen section analysis was used when necessary). Follow-up ranged from 12 to 178 months and local recurrence rates were 0% for T_1, 6% for T_2, and 5% for T_3 lesions. Disease free survival was 100% for T_1, 90% for T_2, and 77% for T_3 lesions. Downsizing and downstaging were good prognostic indicators and the authors only found local recurrence in patients with lesions deemed "non-responders" to radiation therapy.

Zacharakis et al.[25] reviewed the St. Mary's experience with TEM for benign and malignant rectal masses. Specifically regarding malignant masses, positive resection margins were found in 3.7% (1/28). No patient received chemoradiotherapy either before or after surgery. Recurrence occurred in 7.1% of T_1, 42% of T_2, and 66.6% of T_3 lesions. TEM alone seemed adequate treatment for T_1, but not for T_2 or T_3 rectal cancers.

Floyd and Saclarides[26] followed 53 patients with T_1 rectal cancer after curative TEM. None had chemotherapy or radiotherapy. Mean follow-up was 2.84 years. Four patients developed recurrence (7.5%). All patients with recurrence were treated with surgical resection, and at the time of publication were disease free.

Maslekar et al.[27] reported their experience with TEM on 52 patients with rectal cancer. T_1 cancers received TEM alone. While TEM was combined with postoperative chemoradiation for select T_2 and T_3 lesions, recurrence rate was 0% for T_1 (0/27), 20% for T_2 (4/22), and 33% for T_3 (1/3); overall recurrence 14%.

Two prospective, randomized trials have compared TEM to radical surgery for early rectal cancer. Winde et al.[28] randomized 53 patients with ultrasound-staged T_1 rectal cancer to TEM vs. anterior resection (TEM 25; LAR 28). Complication rates were significantly higher for radical resection while 5-year survival was similar for both groups at 96%.

Lezoch et al.[29] published 5-year follow-up data from a prospective randomized trial for the treatment of early rectal cancer. Patients with UT_2N_0 biopsy proven, low-grade rectal cancer underwent preoperative chemoradiotherapy (5,040 rads with continuous infusion of 5-FU) and were then randomized to TEM vs. laparoscopic radical resection (APR vs. LAR). Median follow-up was 84 months. Local recurrence following TEM was 5.7% (2/35) and 2.8% after radical resection (1/35). One patient developed distant metastases in each group. The 5-year disease free survival was 94% for both groups. The authors concluded that TEM provided equivalent oncologic results to radical resection.

Experience and outcomes vary significantly from center to center and country to country with regard to TEM in the treatment of early rectal cancer. Several clear points emerge from a cloudy picture. TEM appears to be technically superior to traditional TAE in its ability to produce a nonfragmented specimen with tumor free margins. It is clearly associated with lower morbidity and mortality than radical resection. Patient selection and preoperative staging are essential. TEM alone may be justified for select T_1 rectal cancers, but recurrence rates are prohibitive without adjuvant chemoradiotherapy for T_2 (and T_3) tumors. When compared to radical resection in a prospective, randomized fashion, TEM, in limited data, compares well to radical resection for T_1 cancers. In addition TEM, combined with preoperative adjuvant therapy, again compares well to radical resection with T_2 rectal cancers.

In the USA, a multicenter prospective phase II trial ACO-SOG Z-6041 has been evaluating local excision (TAE and TEM) for UT_2N_0 rectal cancer following 5040 gray combined

with 5 FU and oxaliplatin.[30] Accrual is currently complete but data is not yet available. The results of this study may help clarify the role of local excision and adjuvant therapy for Stage I rectal cancer.

Predicting Lymph Node Metastases

The reasons for local recurrence following local excision of rectal cancer are likely multifactorial, but remain obscure. Clearly, leaving tumor behind at the site of resection (i.e., positive margins) increases the risk of recurrence, and is responsible for many treatment failures. However, many patients with clear margins ultimately develop local recurrence. The current thinking is that these failures may be the result of undiagnosed and untreated metastatic lymph nodes in the mesorectum.

The incidence of lymph node positivity is directly related to T-stage, and is well documented in the literature.[31–33] Interestingly, local recurrence rates following local excision for rectal cancer seem to parallel the likelihood of lymph node positivity stage for stage. Unfortunately, endorectal ultrasound is inadequate to diagnose some patients with positive lymph nodes. MRI is no better.

Metastatic lymph nodes are found in 5–10% of T_1 tumors, 10–20% of T_2 tumors, and 30–50% of T_3 tumors.[32] However, many of these lymph nodes are very small making ultrasound or MRI detection difficult. Andreola et al.[12] looked at metastatic lymph nodes in cancer of the distal third of the rectum following radical resection in 101 patients. Forty-five percent of all metastatic lymph nodes were smaller than 5 mm in diameter. Fourteen percent of all lymph node positive patients had only lymph nodes smaller than 5 mm. Forty-three percent of patients with metastatic lymph nodes less than 5 mm developed systemic recurrence. Clearly small, metastatic lymph nodes are common, are poorly detected by current staging methods, and are important factors in the development of metastatic disease.

Many individuals have looked at multiple factors in an attempt to predict the presence or absence of occult lymph node metastases and local recurrence following local excision of rectal tumors. In an insightful study, Read et al. used residual T-stage following chemoradiation in 644 patients as a predictor for the presence of mesenteric lymph nodes containing tumor.[34] Patients were staged and selected for neoadjuvant therapy with or without chemotherapy. All patients then underwent radical resection with excision of the mesorectum. Postradiation T-stage was determined and then correlated with the presence or absence of metastatic lymph nodes. For postradiation T_0 lesions, the risk of positive nodes was 2%, for T_1 4%, for T_2 23%, and for T_3 47%. These data may be useful in identifying patients with residual lymph node metastases who fail local excision, and hence should undergo radical resection. Further confirmation of the "response to radiation" as a predictor

of successful outcomes is provided by the multicenter study authored by Capirci et al.[35] As part of the Gastro-Intestinal Working Group in the Italian Association of Radiation Oncology, data was gathered on 566 patients with complete clinical response following preoperative chemoradiotherapy. Patients underwent low anterior resection (73%) abdominoperineal resection (22%) and TEM (5%). Complete pathologic response following neoadjuvant therapy was associated with a 1.6% local recurrence rate, disease free survival of 85%, overall survival of 90%, and cancer specific survival of 94%.

Perez et al.[36] in Sao Paolo, Brazil evaluated postneoadjuvant chemoradiation staging as a predictor of lymphatic involvement and recurrence. Only patients with an incomplete clinical response were included for evaluation ($n = 289$). All patients underwent radical resection. Eighty-eight patients had ypT_2 tumors. Lymph node metastases were identified in 19% of this group. The presence of perineural invasion, vascular invasion, and decreased interval between chemoradiation and surgery (12 vs. 18 weeks) were associated with lymph node metastases and tumor recurrence. The presence of tumor in mesorectal lymph nodes was associated with decreased disease-free survival (30% vs. 49%) even after radical surgery. These authors recommended radial resection for all patients with ypT_2 tumors following chemoradiation. The important clinical implication of this data is any patient undergoing local excision following chemoradiation found to have ypT_2 disease, is at high risk for recurrence and should be considered for subsequent radical surgery.

While response to neoadjuvant treatment has been advocated as a predictor of lymph node involvement by some, others have advocated identifying histopathologic factors present in the primary tumor to predict the presence of metastatic lymph nodes in the mesorectum.

Kikuchi et al.[37] evaluated the depth of submucosal tumor spread (sm level) as a predictor of lymphatic metastases and adverse outcome following endoscopic polypectomy in 182 patients. They identified polyp configuration (pedunculated vs. sessile), polyp location (rectum vs. colon) and sm level as predictors of adverse outcome. Conversely, Rasheed et al.[38] failed to find sm level predictive of lymph node involvement in 55 T_1 rectal cancers.

Park et al.[39] analyzed 90 patients with early colorectal cancer and found lymph node metastases in 8.9%. Lymph node metastases were associated with deep sm invasion, lymphovascular invasion, vessel configuration, absence of a residual adenomatous component, and unfavorable histologic grade. Similarly, Choi et al.[40] evaluated 168 patients with early colorectal cancer who underwent curative bowel resection. They again identified sm 3 invasion and poor differentiation as predictive of lymph node metastases. They, however, also identified tumor cell dissociation (TCD), solid cancer cell clusters and groups of dissociated cancer cells at the tumor front, as predictive of lymph node metastases. (TCD appears to be similar to tumor budding).

Tominaga et al.[41] at the National Cancer Hospital in Tokyo, Japan evaluated 155 submucosal colorectal cancers looking for histopathologic factors associated with lymph node metastases. Twelve percent of patients were found to have lymph nodes containing cancer. On multivariate analysis, lymphatic invasion and high-grade focal dedifferentiation at the submucosal front were predictive of lymph node metastases. No patients with minimal submucosal involvement (<1.3 mm) had cancer in regional nodes. Sakuragi et al.[42] in evaluating 278 early rectal cancers, found the depth of submucosal invasion and lymphatic invasion predictive of lymph node metastases.

In a slightly different approach, Masaki et al.[43] evaluated tumor budding (single cells or clusters of cells at the invasive margin) grade, lymphovascular invasion, tumor dedifferentiation at the invasive margin, residual adenomatous tissue, and depth and width of submucosal invasion in 76 patients with T_1 colon and rectal cancer. Multivariate analysis found only tumor budding to be associated with nodal disease. The authors created a formula to predict the likelihood of lymph node metastases. $Z = 0.07 \times (\# \text{ budding units}) - 3.726$, where the probability of positive lymph nodes $= 1/1 + e^{-z}$. This formula, in theory, can be used to determine if the risk of radical surgery is greater than the risk of residual lymphatic disease.

In yet another study evaluating risk factors for mesenteric lymph node positively, Yasuda et al.[44] analyzed 86 patients undergoing resection for colorectal carcinoma. Multivariate analysis once again identified vascular invasion and tumor budding to be independent predictors of lymph node involvement. In addition, no patients with submucosal invasion ≤1,000 μm had lymph node metastases.

In a large cooperative British and Irish study, reported by Bach et al.[45] 424 patients undergoing TEM for localized rectal cancer were evaluated for risk factors associated with recurrence. Local recurrence rates were 18.6% for T_1 lesions, 29.3% for T_2 lesions, and 47% for T_3 lesions at 5 years. Recurrence rates were relatively high, but incomplete resection (positive margins) was found in 11% of T_1, 22.5% of T_2, and 42% of T_3 lesions. The authors identified increasing tumor size, the presence of lymphatic invasion, and increasing depth of penetration (as measured by sm levels and T-stage) as independent predictors of recurrence. Surprisingly R_1 resection was not found to be predictive for recurrence.

In summarizing the data from the above series, it appears that several factors consistently put patients at risk for untreated regional lymph node disease following local excision for early rectal cancer. The presence of lymphovascular invasion, increasing sm levels of tumor invasion, tumor budding at the invasive tumor margin, and poor differentiation are relatively consistent predictors of adverse outcome. These histologic criteria should clearly be evaluated and thoughtfully considered when assessing the oncologic adequacy of local excision for early rectal cancers. In the future, perhaps a predictive "histologic score" will be developed to accurately identify patients at significant risk for lymph node metastases. These individuals may benefit from radical resection or more aggressive adjuvant chemoradiation.

Conclusions

Local excision will likely continue to play a significant role in the treatment of selected patients with early stage rectal cancer. TEM is utilized much more commonly due to its ability to access the entire rectum, its superior visualization, and its precise surgical technique. Early results indicate lower local recurrence rates and higher overall survival when compared to traditional techniques of transanal excision. In order to improve cure rates and decrease local recurrence, local staging must improve. Considering the significance of very small metastatic lymph nodes, it is unlikely that ultrasound will continue as the primary staging tool. Perhaps a "functional study" which utilizes tumor metabolism will provide more accurate staging. In addition, a "scoring system" based on anatomic tumor factors (i.e., TNM) combined with histopathologic and genetic factors may be developed to help predict success and failure of local excision.

The future of local therapy for rectal cancer may evolve similar to that of breast cancer treatment. Patients will be staged based on anatomic, histologic, and genetic data, then treated with neoadjuvant chemotherapy and radiation. Local excision, likely TEM, will follow neoadjuvant treatment, and will act as a "staging biopsy." If response to neoadjuvant treatment is deemed adequate, no further therapy will be necessary. However, tumors with a lesser response to therapy will receive radical resection. In this way, major surgery and its associated morbidity and mortality will be reserved for patients who truly require it. The above algorithm is by no means the current standard of care, but many unanswered questions remain and treatment recommendations are in flux. No progress can be made unless we honestly evaluate past treatments, let go of traditional prejudices, and embrace sound scientific research, and be willing to change based on new information.

Surgical Treatment of Rectal Cancer

Ronald Bleday and Nelya Brindzei

Approximately 42,000 patients each year are diagnosed with rectal cancer in the USA. Approximately 8,500 die of this disease. Despite remarkable recent advances in new oncologic agents for the treatment of colon and rectal cancer, cure is almost never achieved without surgical resection. However, the current management of rectal cancer is now more varied and complex because of the new approaches with multimodality therapy and the refinements in surgical techniques. For example, small distal rectal cancers with minimal invasion can be treated with a local excision with or without adjuvant therapy. More proximal or more invasive tumors require a "radical" resection. The two most common procedures are the low anterior resection (LAR) and the abdominoperineal resection (APR). Extended resections are occasionally required for patients with cancers that invade or adhere to adjoining structures such as the sacrum, pelvic sidewalls, prostate, or bladder.

This chapter discusses the surgical management of rectal cancer including a basic review of the preoperative evaluation and how it pertains to surgical planning, the preoperative preparation, the surgical procedures, the biology of rectal cancer as it relates to surgery, the issue of margins, and the technical nuances that need to be appreciated for a successful resection.

Evaluation of the Patient with Rectal Cancer

History

The patient with rectal cancer usually presents to the surgeon after a definitive endoscopic diagnosis. The patient's initial complaint may be rectal bleeding, a change in bowel habits, or a sense of rectal pressure. However, with the increase in surveillance colonoscopy, many patients are completely asymptomatic on presentation. During the initial history, the surgeon should ask about certain symptoms because it will aid in selecting the best therapy for the patient. For example, tenesmus (the constant sensation of needing to move the bowels) is often indicative of a large cancer. Constant anal pain or pain with defecation suggests invasion of the anal sphincters or pelvic floor. Preemptive procedures such as a diverting colostomy may be required in patients with these distal painful cancers. Also, cancers growing into the anal sphincter are not candidates for a sphincter-sparing procedure. Questions concerning a patient's fecal continence should also be discussed before any therapy. Sphincter-sparing procedures can put a tremendous stress on even the most normal of pelvic floors and anal sphincters. A history of significant continence problems should prompt a discussion with the patient concerning quality-of-life issues. Sphincter-sparing surgery in these patients, even if technically possible, often leads to significant fecal soiling, and the patient may be better served with a resection and permanent colostomy.

Physical Examination and Rigid Sigmoidoscopic Examination

A digital rectal examination (DRE) and a rigid sigmoidoscopy are essential to the surgical decision-making process. Both a proper examination and rigid sigmoidoscopy should be performed on the initial patient visit unless the patient has a painful invasive lesion. On DRE, fixation of the lesion to the anal sphincter, its relationship to the anorectal ring (the collection of muscles that make up the sphincters), and possible fixation to both the rectal wall and the pelvic wall can be evaluated. For mid rectal or upper rectal lesions, the DRE and rigid sigmoidoscopy can help determine how much normal rectum lies distal to the lower border of the tumor. With the combination of DRE and sigmoidoscopy at the initial visit, the surgeon can often determine whether a patient is a candidate for sphincter-sparing surgery, whether a temporary diverting ostomy is likely, and what anorectal function will be like posttreatment.

Colonoscopy

A colonoscopy should be performed before surgical resection of a rectal cancer. Colonoscopy allows for confirmation of a malignancy through biopsy and the diagnosis and possible removal of synchronous colonic lesions. Synchronous benign polyps have been reported in 13–62% of cases,m and synchronous cancers have been reported in 2–8% of cases.[1–6] Even if a colonoscopy has been recently performed on a patient, the surgeon should still perform a rigid sigmoidoscopy because estimates of the location of the lesion are often misleading. For example, because of the flexibility of the colonoscope, a lesion that is described as 15 cm from the anal verge can sometimes be a close as 5 cm from the anal verge when evaluated with the rigid scope. Finally, both with a colonoscope and rigid sigmoidoscope, one should describe the distance from the lower border of the lesion to a standard distal landmark. The National Cancer Institute (NCI) consensus group recommends the use of the "anal verge" as the starting point for measuring distance; however, this anatomic landmark is variable. An alternative is to use the dentate line as the zero point and measure the distance from the lower border of the lesion to the proximal border of the anorectal ring. This distance is essentially a measure of the maximal amount of rectum that one can resect before considering an APR.

Preoperative Staging

Preoperative staging of a patient with a rectal cancer is becoming essential in the decision-making process as adjuvant modalities become increasingly used preoperatively. Also, the range of surgical procedures that can be offered to a patient is in part dependent on the preoperative imaging. For a basic evaluation, all patients should receive a chest X-ray or chest computed tomography (CT) scan to exclude pulmonary metastases. One can obtain a carcinoembryonic antigen (CEA) level. If increased preoperatively, the CEA level should decrease to the normal range after treatment. CEA can then be followed postoperatively to detect a recurrence. Most other laboratory evaluations obtained preoperatively are useful for determining pertinent medical problems, but are not very helpful in staging. By far, the most useful staging for rectal cancer is abdominal/pelvic imaging with CT, magnetic resonance imaging (MRI), or ultrasound (US)

Imaging for Rectal Cancer

Pretreatment abdominal and pelvic imaging of the patient with rectal cancer is necessary in this era because of the increasing value of preoperative adjuvant therapies. Therapy differs depending on stage, depth of invasion into the rectal wall within a stage, size of lesion, and location of the tumor. In particular, distal and mid rectal cancer treatment management will differ depending on the preoperative staging and

imaging. For upper rectal cancers, imaging to determine stage will often not influence the treatment plan. Many of these patients with upper rectal tumors will benefit from an LAR regardless of the stage and may not require neoadjuvant therapy as often as low and mid rectal cancers.

Computed Tomography Scan

Differing opinions exist as to whether a CT scan is a useful routine assessment modality in a patient diagnosed with a rectal cancer. Some would argue that for routine, uncomplicated malignancies, a CT scan is generally not necessary, since the information obtained will not usually affect the treatment plan. This concept is probably more applicable to patients with colon cancers versus patients with rectal cancers. For rectal cancer, there may be some merit to a baseline preoperative CT scan for advanced lesions. CT scanning is quite accurate in assessing rectal tumors that have invaded adjacent organs. However, for assessment of small primary lesions, CT scanning has many limitations. CT scans do not effectively visualize the layers of the rectal wall and so do not help in evaluating the extent of rectal wall invasion of an early cancer. The overall accuracy of CT scanning in determining depth of invasion is approximately 70%. Additionally, CT scanning is limited in its ability to determine the presence or absence of lymph node metastases. Overall accuracy with CT scanning for assessing lymph nodes in rectal cancer is only 45%.[7–11]

The most current CT scanning, especially with dynamic contrast infusion, has a high accuracy rate in detecting liver metastases. However, abdominal US, similar to CT scan, can also detect occult liver metastases and should be used when the information obtained would alter therapeutic decisions.[12] MRI is also very useful in evaluating the liver before resection.

Endoluminal Imaging

Endoluminal imaging in the form of endoluminal US and endoluminal MRI has become extremely useful in the accurate preoperative staging of a rectal cancer. These modalities allow for more precise determination of the depth of invasion and the presence or absence of mesorectal lymph node metastasis. The knowledge of these factors is critical in determining the sequence and type of therapy for any given rectal cancer.

Endoscopic US is performed with a probe that is inserted into the rectum via the anus. The patient usually takes a small preparation to clear the rectum of stool prior to the US. A water-filled balloon is inflated and pressed against the rectal lesion. A 7.0- to 10.0-MHz transducer is then used to delineate the layers of the bowel wall into five distinct lines. Localized cancers involving only the mucosa and submucosa can therefore be distinguished from those tumors that penetrate the muscularis propria or extend through the rectal wall into the perirectal fat.[13] A modified TNM classification has been proposed,[14,15] in which a US stage T1 lesion

(uT1) denotes a malignancy confined to the mucosa and submucosa, a uT2 lesion implies penetration of the muscularis propria, but confinement to the rectal wall, a uT3 lesion indicates invasion into the perirectal fat, and a uT4 lesion denotes a primary rectal malignancy that invades an adjacent organ. Studies have compared endorectal US (ERUS)[16,17] to DRE[17] and have found the US much more accurate. A recent meta-analysis evaluating all ERUS studies from 1980 to 2008 showed that accuracy was high (88–95%). The sensitivity and specificity of ERUS to diagnose stage T1 cancer were 87.8 and 98.3%, respectively. For stage T2, ERUS had a sensitivity and specificity of 80.5 and 95.6%. For stage T3, ERUS had a sensitivity and specificity of 96.4 and 90.6%, respectively. In diagnosing stage T4 cancer, ERUS had a sensitivity of 95.4% and a specificity of 98.3%.[18]

ERUS is less useful in predicting lymph node metastases with a sensitivity of 73.2% and a specificity of 75.8%.[19]

Endosonographically identified malignant lymph nodes are generally more hypoechoic in perirectal tissues.[20] However, these results are only seen with experienced operators. The disadvantage of ERUS is that it is operator dependent and is less accurate for bulky disease or advanced rectal cancer due to depth of penetration.

Two methods of MRI can be used for the evaluation of rectal cancer. One can use the endorectal coil (ecMRI) or the surface coil MRI. The use of the MRI, either the endorectal or the surface coil, may offer some advantages compared with ERUS. First, it permits a larger field of view. Second, it may be less operator and technique dependent. And third, using the MRI may allow for the study of stenotic tumors.[21–24] Similar to ERUS, endorectal MRI (eMRI) can stage small-volume nodal disease and subtle transmural invasion. In general, eMRI has been more helpful in the assessment of perirectal nodal involvement than T stage. One reason is that MRI can identify involved nodes on the basis of characteristics other than size.[25] Reported accuracy rates of MRI for nodal staging range from 50 to 95%.[24–27]

Several series have compared the preoperative staging accuracy of ecMRI to ERUS in patients with rectal cancer.[24,26–28] In a report of 89 patients, the overall accuracy for T staging was similar (81%) for ecMRI and ERUS compared with only 65% for CT.[29] The accuracy for N staging was equally poor among the three modalities (63, 64, and 57% for ecMRI, ERUS, and CT, respectively). Somewhat similar results were noted in a series of 49 patients.[28] Transmural penetration was predicted by ecMRI with equal sensitivity (89%), but higher specificity (65 versus 33%) than ERUS. With both techniques, the predicted N stage had a relatively low correlation with pathologic N stage (45 versus 53%). In one report of 21 patients, ERUS seemed to be superior to ecMRI for determination of pathologic T stage (accuracy 83 versus 40%) because of better differentiation between T1 and T2 tumors. The accuracy for detecting perirectal tumor infiltration was 80% for ecMRI versus 100% for ERUS.[27]

The ecMRI is less operator dependent, and in answering the critical question of whether a patient has Stage I versus Stage II or Stage III disease, ecMRI was 88% accurate. Those patients who were not staged correctly were usually overstaged and not understaged.

Double-contrast MRI may permit more accurate T staging of rectal cancer by allowing better distinction among mucosa, muscularis, and perirectal tissues.[30,31] The specificity and sensitivity of ecMRI to predict infiltration of the anal sphincter was 100 and 90%, respectively. However, N staging was not improved with this approach; the sensitivity and specificity for nodal disease was 68 and 24%, respectively.

Phased-array surface coil MRI may prove to be the option of choice for staging of more advanced rectal cancers. The technique has been useful in predicting the likelihood of a tumor-free resection margin by visualizing tumor involvement of the mesorectal fascia.[32] However, it is less accurate for prediction of the correct T stage. Currently, we use this MRI technique along with CT scan of the abdomen and pelvis as our baseline imaging for all rectal cancers.

Preparation of the Rectal Cancer Patient for Surgery

After the diagnosis and staging of a rectal cancer, a decision needs to be made regarding optimal method of treatment. The surgical approach is dependent on the location of the tumor, its depth of invasion, and whether, in the preoperative evaluation, metastases have been discovered. If the patient is a candidate for a local excision or for a radical resection, the patient needs to be prepared for the procedure and the anesthetic so as to minimize perioperative and postoperative complications. Particular attention needs to be given to the patient's medical comorbidities. Unique to colon and rectal surgery is the use of a bowel preparation.

Bowel Preparation

There were multiple studies questioning the benefit of a bowel preparation in colorectal surgery. The rationale for a bowel preparation is that it improves visualization of luminal surfaces and reduces fecal flora, which possibly translates into reduction of anastomotic and infectious complications. Cochrane database review study published in 2005 showed no difference in terms of mortality, wound infection rates, extraabdominal complications, and reoperations in bowel preparation group versus nonbowel preparation group. It did, however, show statistically significant increased incidence of anastomotic leak in bowel preparation group (6.2 versus 3.2%, $p = 0.003$). The difference was not statistically significant upon stratification of the groups based on the site of the surgery.[33] More recent RCTs published in 2007 did not show a difference in anastomotic leaks (4.8 versus 5.4%) or other complications.[34,35] The most recent meta-analysis study

published by Pineda et al.[36] showed no difference in terms of anastomotic leak (4.2 versus 3.5%) or wound complications (9.9 versus 8.8%). Despite these studies, bowel preparation is still widely practiced by many surgeons.

Currently, there are several methods used to mechanically cleanse the large intestine. These methods include a diet of clear liquids 1–3 days before surgery combined with one of the following: laxatives, enemas, whole-gut irrigation with saline via a nasogastric tube, mannitol solutions, polyethylene glycol (PEG) electrolyte lavage solutions, or PEG-based tablets. In a 1990 survey of colon and rectal surgeons, almost two-thirds preferred the PEG solutions for their patients because of the reliability of the cleansing results.[37] Many surgeons today continue to use these PEG solutions as a bowel preparation. Despite these recent studies, we would still recommend some type of colonic cleansing before surgery because it is easier to manipulate the bowel if it is not filled with stool. It should be emphasized that one should not force a preparation on a patient because the benefits may be minimal. Furthermore, the choice of preparation should be selected depending on the individual. For instance, large-volume lavage solutions should not be used in patients with gastric emptying problems such as gastroparesis caused by diabetes. Saline laxatives are often phosphate- or magnesium-based and should not be used in patients with renal failure.

Antibiotic Prophylaxis

Antibiotic prophylaxis is used to decrease the incidence of postoperative septic complications, as mechanical cleansing decreases the total volume of stool in the colon but does not affect the concentration of bacteria per milliliter of effluent.[38] Traditional prophylaxis uses an oral regimen known as the Nichols/Condon preparation. This regimen consists of neomycin 1 g and erythromycin base 1 g by mouth at 1:00 p.m., 2:00 p.m., and 11:00 p.m. on the day before surgery.[39] Many surgeons have substituted metronidazole 500 mg for the erythromycin base because it is bacteriocidal against a greater percentage of gut anaerobes.

Most surgeons use perioperative systemic antibiotics instead of oral antibiotics for antibiotic prophylaxis. Regimens need to include coverage for both aerobic and anaerobic gut bacteria. For long procedures, redosing should be considered depending on the serum half-life of the antibiotics used. Some have argued that double prophylaxis with both oral and intravenous antibiotics is of benefit in immunocompromised patients or in patients in whom the dissection is below the peritoneal reflection.

Other Perioperative Issues

Besides the mechanical and antibiotic preparation of the bowel, all patients are prepared in the usual manner for major surgery. Blood loss is usually quite minimal for most elective colorectal surgery, and typically patients are not asked to donate autologous blood. Cardiac, pulmonary, and nutritional evaluations are performed when necessary. Perioperative systemic antibiotic coverage is expanded in patients with high-risk cardiac lesions such as prosthetic heart valves, a history of endocarditis, or a surgically constructed systemic-pulmonary shunt, and with intermediate-risk cardiac lesions such as mitral valve prolapse, valvular heart disease, or idiopathic hypertrophic subaortic stenosis.[38] Intravenous ampicillin 2 g and gentamicin 1.5 mg/kg are given 1/2–1 h before the procedure and for at least one postoperative dose. Oral anticoagulation is stopped and patients are placed on intravenous anticoagulation or on Lovenox® approximately 5 days before surgery. The heparin or Lovenox® is then stopped at the appropriate time before surgery (8 or 12 h, respectively). Depending on the individual risk of the patient and the extent of the operative dissection, anticoagulation is restarted as early as 8 h after surgery, but without a bolus. Careful monitoring of the patient's hematocrit and partial thromboplastin time is necessary if early reheparinization is instituted.

Anatomic and Biologic Issues

Surgical Anatomy

The type of operation that can be offered to a patient with rectal cancer depends not only on the tumor's stage but also on its location as this may determine resectability and sphincter preservation or sacrifice. The NCI consensus on rectal cancer recommended localizing the tumor relative to the anal verge, which is defined as starting at the intersphincteric groove. Another important landmark defining the upper limit of the anal canal is the anorectal ring. From the surgeon's perspective, the top of the anorectal ring is the lower limit of a distal resection margin. A large, full-thickness cancer needs to be located high enough above the top of the anorectal ring to allow for an adequate distal margin if sphincter preservation is contemplated. If the dissection is to be carried lower toward the dentate line, then the tumor must be confined to the mucosa, submucosa, and superficial layer of the internal sphincter.

Biologic Issues

It is important to understand the clinical biology of rectal cancer. "Clinical" biology means the typical pattern of growth and natural history of the spread of the disease. Studies have shown that colon cancer frequently arises in adenomatous polyps of the colon or rectum. Also, there is a 13–62% incidence of polyps in patients with carcinoma of the colon or rectum.[40–43] The variation observed in the incidence of coexisting adenomas with carcinoma of the colon or rectum depends in part on the method of study.[1,2] Whatever method used to study the issue, one can clearly say that the vast majority of carcinomas arise in preexisting adenomas.[44–46] In preparing a patient for surgery, the surgeon

should have the colon completely evaluated preoperatively so as to be able to operatively treat any synchronous disease that cannot be endoscopically removed.

The biology of lymph node metastases with invasive rectal cancer is important to note and is somewhat different from that of other solid tumors such as breast cancer. Gabriel et al.[47] reported in 1935 that colorectal cancers tend not to have "skip" metastases. Rectal cancers usually proceeded in an orderly sequence from the adjacent mesorectal nodes up the lymphatic chain to the upper extent of the mesentery along the inferior mesenteric artery (IMA) and vein systems. From the surgeon's perspective, this usually predictable progression means that early intervention along with proper locoregional resection will cure most cancers. As part of a multimodality team that now treats most solid tumors, it must be emphasized to our medical colleagues that a rectal cancer is not a systemic disease from the first abnormal cell division. Aggressive local therapy in the form of an adequate resection is still the "anchor" to any therapy.

Surgical therapy may need to be customized in patients with certain polyposis syndromes or in cancers associated with inflammatory bowel disease. With both of these conditions, a total proctocolectomy needs to be performed. Sphincter preservation can be considered in certain patients; however, it should be recognized that any mucosa left intact is at an increased risk of developing cancer. The anal transitional zone needs to be biopsied to identify dysplasia. If dysplasia is present, then a proctocolectomy with end ileostomy needs to be performed.

Surgical Procedures: Principles

Resection of the bowel with primary anastomosis was not a common phenomenon until the late 1940s. Before that time, surgery of the colon and rectum usually meant a permanent stoma.[48] Recent advances have been made in the surgical techniques for rectal cancer. The result is that primary resection and anastomosis without a colostomy or ileostomy are now the rule rather than the exception.

Palliation should be the goal in a patient for whom curative resection is not possible. If the patient is a reasonable operative risk and the extent of metastatic disease is minimal, then complete but palliative resection of the primary tumor leads to a better quality of life and prevents many of the distressing symptoms of an advanced primary lesion such as obstruction, bleeding, and pain. If the primary lesion is not resectable, then diversion of the fecal stream can significantly improve the patient's immediate status. However, nonoperative therapy should be considered when there is significant metastatic disease and the primary tumor is relatively small and uncomplicated. In these cases, a colonic stent can be used if the patient needs to be relieved of an significant partial obstruction. Placement of a stent, however, is just a temporizing maneuver. If the patient responds to chemotherapy after a stent is placed, then a more definitive diversion or resection can be reconsidered in the otherwise healthy patient. As highlighted in a study from Memorial Sloan-Kettering, resection of a primary tumor in a patient with metastatic disease did not prolong overall survival. However, one has to individualize the therapy to each situation. Further, greater response to chemotherapy or the ability of new chemotherapy regimens to stop progression of disease will force us to reevaluate this clinical scenario on an ongoing basis.

Variability in Outcome Based on Surgeon and Hospital Volume

The cancer resection margin in the extraperitoneal rectum is limited by the bony confines of the pelvis, as well as by the proximity of adjacent anterior organs. In some cases, locoregional recurrence may be inevitable. However, locoregional failure may also result from incomplete surgery. There is accumulating evidence of variability among surgeons in local recurrence rates for stage-matched rectal cancers. McArdle and Hole[49] presented a review of 645 patients undergoing colorectal cancer resection at the Royal Infirmary in Glasgow. They observed significant variability in patients' postoperative morbidity, mortality, and ultimate survival, depending on the surgeon. The proportion of patients undergoing a curative resection varied from 40 to 76%, operative mortality from 8 to 30%, local recurrence from 0 to 21%, and anastomotic leak rates from 0 to 25%.

Hospital volume can also have an impact on colostomy rates, postoperative mortality, and overall survival as shown in a series of 7,257 patients diagnosed with Stage I–III rectal cancer between 1994 and 1997.[50] When hospitals with the highest quartile of volume (more than 20 procedures annually) were compared with those with volumes in the lowest quartile (fewer than seven procedures annually), there were statistically significant differences in colostomy rates (29.5 versus 36.6%), 30-day postoperative mortality (1.6 versus 4.8%), and overall 2-year survival (83.7 versus 76.6%).

The ability to perform sphincter-sparing surgery is also affected by hospital volume. In the USA Intergroup 0114 trial of 1,330 patients with Stage II or III rectal cancer participating in an adjuvant treatment trial, APR rates were significantly higher in low-volume hospitals (46 versus 32% at lowest and highest volume hospitals, respectively).[51] Low hospital surgical volume was only an important predictor of inferior overall or recurrence-free survival in patients who did not complete their planned adjuvant chemoradiotherapy.

Total Mesorectal Excision

Total mesorectal excision in conjunction with an LAR or an abdominal perineal resection involves precise sharp dissection and removal of the entire rectal mesentery, including that distal to the tumor, as an intact unit.[52] Unlike conventional

blunt dissection, the rectal mesentery is removed sharply under direct visualization emphasizing autonomic nerve preservation, complete hemostasis, and avoidance of violation of the mesorectal envelope. Its rationale is underscored by the hypothesis that the field of rectal cancer spread is limited to this envelope and its total removal encompasses virtually every tumor satellite. The reduction of positive radial margins can be reduced from 25% in conventional surgery to 7% in cases resected by TME. Furthermore, Adam et al.[53] showed that patients with positive radial margins were three times more likely to die and 12 times more likely to have local recurrence than patients without radial margin involvement.

Conventional surgery violates the circumference of the mesorectum during the blunt dissection along undefined planes. This leaves residual mesorectum in the pelvis. The higher rate of pelvic recurrence in conventional surgery is a reflection of inadequate resection and residual viable tumor burden within the pelvis. Several surgical teams using the TME technique have reported local failure rates ranging from 5 to 7% for Stage II and Stage III cancers.[52–56] By contrast, the North Central Cancer Treatment Group, NCCTG, control arm consisting of surgery plus radiotherapy had a local failure rate of 25%, and the addition of chemotherapy only decreased the local failure rate to half of that value.[57]

Fortunately, improved local control seems to be translatable into improved overall survival. Survival ranges from 68 to 78% are observed among large published series when this technique is applied.

The meticulous dissection, however, is not without consequence. Prolonged operative time and increased anastomotic leak rates are noted. Anastomoses 3–6 cm from the anal verge have led up to 17% leak rates such that many centers routinely fashion a protective diverting stoma.

Conventional rectal surgery is associated with a significant incidence of sexual and urinary dysfunction. Presumably, this problem is related to damage to the pelvic autonomic parasympathetic and sympathetic nerves by blunt dissection forces.[58] Postoperative impotence and retrograde ejaculation or both have been observed in 25–75% of cases particularly if lateral-wall lymphadenectomy and splanchnic nerve resection are performed. By contrast, after TME with its careful nerve-sparing dissection, impotence has been reported in only 10–29% of cases. A recent prospective study has confirmed that autonomic nerve preservation yields good results in terms of morbidity and functional outcome.[59]

There are well-recognized points during the rectal dissection where nerve injury can occur. The most proximal is the sympathetic nerve plexus surrounding the aorta. These sympathetic nerve trunks are also prone to injury near the pelvic brim as the bifurcate to each side of the pelvis. Intact nerves should look like a "wishbone" near the sacral promontory after a proper dissection. The clinical consequence of an isolated sympathetic nerve injury is retrograde ejaculation. If one proceeds with a dissection beneath the presacral or pelvic fascia from the sacral promontory around to the lateral

pelvic sidewall, then one can injure both parasympathetic and sympathetic nerves, which can result in impotence and bladder dysfunction. In the lower part of the mid rectum, the hypogastric plexus and nervi erigentes can be injured in the anterolateral pelvis. A radial dissection well outside the lymphovascular bundle, which lies adjacent to the nerve and nerve plexus, can also lead to a mixed parasympathetic and sympathetic injury. This bundle and the nerve structure are typically located just lateral to the seminal vesicles in a man or the cardinal ligaments in a woman. Finally, a dissection anterior to both layers of Denonvillier's fascia in a man can also put at risk the nerve and nerve plexus.

To date, all data are from prospectively gathered series and comparisons with historical controls. There are no randomized control data clearly showing benefits in terms of disease-specific and overall survival in patients undergoing TME as opposed to more conventional resection.

Adjuvant therapy has recently been shown to improve the results of TME surgery. In a two-arm, randomized study comparing TME with or without preoperative radiotherapy for resectable rectal cancer, patients receiving the combined therapy had a lower rate of local recurrence at 2 years. Subset analysis showed the most significant benefit in node-positive cancers.[60] The "completeness" of the TME also correlated with prognosis.[61] Adjuvant therapy should therefore be considered in patients undergoing TME surgery with Stage II and Stage III disease.

Figure 44-1 demonstrates schematically how the dissection should proceed. Figure 44-2 shows a cross-section of the rectum, the mesorectal fat, and the associated fascia.

Distal Margins and Radial Margins

The extent of resection margins in rectal cancer remains controversial. Although the first line of rectal cancer spread is upward along the lymphatic course, tumors below the peritoneal reflection also spread distally by intramural or extramural lymphatic and vascular routes. When distal intramural spread occurs, it is usually within 2.0 cm of the tumor, unless the lesion is poorly differentiated or widely metastatic.[62–64] Williams et al.[65] in 1983 reported distal intramural spread in 12 of 50 resected rectal cancer surgical patients. It was observed that 10 of the 12 had Stage III lesions. Only 6% had distal intramural spread greater than 2 cm. They concluded a "wet" margin of 2.5 cm was adequate in 94% of the patients. They noted that only five patients (10%) had tumors beyond a 1.5-cm margin, and all five of these patients had poorly differentiated, node-positive cancers. Also, the mortality in this group of patients was attributable to distant metastases, not local recurrence. All of these patients had undergone an APR and had distal margins of greater than 5 cm. Grinnell[62] reported five cases of extramural retrograde lymphatic spread within 1.5 cm in 93 rectal cancers. He also reviewed 28 patients with atypical retrograde lymphatic dissemination all of whom died within 5 years. He concluded that retrograde lymphatic spread was a poor
FIGURE 44-1. Schematic representation of the correct TME dissection versus an incorrect dissection. The dissection should proceed between the mesorectal fascia and the pelvic wall fascia to ensure a "complete" TME.
FIGURE 44-2. Transverse diagram of the structures of the mid rectum. The proper dissection proceeds just outside the mesorectal fat and fascia but with sparing of the neurovascular bundle and hypogastric plexus that is located anterolaterally along the pelvic sidewall. One or both layers of Denonvillier's fascia should be included in males and the equivalent fascial dissection along the back of the vagina in females.

prognostic sign and that more radical operations were not advantageous. Pollett and Nicholls[66] observed no difference in local recurrence rates whether distal margins of <2 cm, 2–5 cm, or >5 cm were achieved. Finally, in two early studies from the British literature, surgical pathology of rectal and rectosigmoid cancer demonstrated the clinical biology of extramural lymphatic spread. In the series by Goligher et al.[67] from 1951, only 6.5% of patients had metastatic glands below the primary tumor, whereas 93.5% had no retrograde spread. Approximately two-thirds of patients with retrograde spread had metastasis limited to within 6 mm of the distal tumor edge, and only 2% had metastasis beyond 2 cm. Dukes[68] published similar results in a study of more than 1,500 patients who had undergone APR.

Further data from a randomized, prospective trial conducted by the National Surgical Adjuvant Breast and Bowel Project demonstrated no significant differences in survival or local recurrence when comparing distal rectal margins of <2 cm, 2–2.9 cm, and >3 cm.[69] As a result, a 2-cm distal margin has become acceptable for resection of rectal carcinoma, although a 5-cm proximal margin is still recommended.[70] The radial margin is more critical for local control.

Based upon these extensive data, a 2-cm distal margin can is generally justifiable over a 5-cm distal margin. Even smaller distal margins may be acceptable in certain patients for whom there is no other option for sphincter preservation. In these cases, a frozen section analysis of the distal margin must be performed to confirm a cancer-free margin.

The discussion concerning the distal margin should not be confused with the issues regarding a TME and the radial margin. It is now clear that the status of the radial margin is perhaps the most critical in determining prognosis. Quirke et al.[71]

in 1986 demonstrated tumor spread to the radial margins of 14 of 52 rectal cancers on whole mount specimens (27%). Twelve of these 14 patients subsequently developed local recurrence, suggesting that local recurrence is largely a result of radial spread. Cawthorn et al.[55] also documented that tumor involvement of the lateral resection margin correlated with poor prognosis; however, it seemed to correlate more with distant spread, and it was not a useful indicator of local recurrence.

Lateral Lymph Node Dissection

A complete clearance of lateral lymph nodes or extended lateral lymph node dissection (ELD) for low-lying rectal cancers with suspected or high risk for lateral lymph node metastasis has become a routine practice in Japan. The practice is based on the existence of lateral lymphatic drainage of the rectum, which TME does not encompass. Lateral lymphatic flow passes from the lower rectum and through lateral ligaments beyond mesorectum and ascends along internal iliac arteries and inside the obturator spaces. The recent study from Japan showed that the incidence of lateral lymph node involvement for low-lying rectal cancer is 16.4%.[72] A recent study from The Netherlands compared the treatment of rectal cancer between Japan and The Netherlands and showed 5-year local recurrence rates of 6.9% for the Japanese ELD group, 5.8% in the Dutch RT + TME group, and 12.1% in the Dutch TME group.[73]

ELD is associated with a much higher rate of urinary and sexual dysfunctions as compared to standard TME. Another study from Japan showed that degree of urinary and sexual dysfunction depended not only on the extent of autonomic nerve resection but also on the extent of ELD in independent fashion.[74]

ELD is a controversial topic, and more studies need to be done on its effectiveness and the benefits versus increased morbidity before it can be recommended as a standard of care. However, in some patients where there are palpable nodes along the pelvic sidewall and along the iliacs, a patient may benefit from this extended dissection.

Selection of Appropriate Therapy for Rectal Cancer

The management of rectal cancer has become increasingly complex. Presently, a surgeon has three major curative options: local excision, sphincter-saving abdominal surgery, and APR. Ideal candidates for local therapy that preserves anal sphincter anatomy and function include small T1 lesions (invasion only into the submucosa) and T2 lesions (invasion into the muscularis propria). As will be discussed, patients with T2 lesions probably should not have surgery alone. Recurrence is high. Preoperative or postoperative adjuvant chemoradiation is of benefit. At present, patients with T3 lesions (invasion into the perirectal fat) are not suitable candidates for local therapy and

should be treated with an appropriate major resection as well as adjuvant therapy in most cases.

Certain clinical features also may have an impact on decisions about the appropriate therapy. Patients with physical handicaps may have significant difficulty in managing a stoma. Body habitus and patient gender influence the surgeon's ability to perform a sphincter-saving operation because of pelvic anatomy. Whereas a sphincter-saving procedure in a multiparous thin female can be straightforward, performing a low anastomosis in an obese male with a narrow pelvis can be extremely difficult. A history of pelvic irradiation or nonrectal pelvic malignancy can make a rectal resection and sphincter preservation more difficult.

In summary, each patient with rectal cancer should be individually evaluated, and a technical plan for their resection is customized to their stage, gender, age, and body habitus (Figure 44-3). With these issues in mind, the technical choices for a radical resection are discussed below. In all of these resections, a TME should be performed. Local treatments are then described in detail.

Techniques of Rectal Excision

Abdominoperineal Resection

The APR was the first radical resection described by Miles in 1908 (reprinted in 1971).[75] Miles set out several principles to be achieved with any radical resection. These principles included:

- Removal of the whole pelvic mesocolon
- Removal of the "zone of upward spread" in the rectal mesentery
- Wide perineal dissection
- An abdominal anus
- Removal of the lymph nodes along the iliacs.

Four of five of these principles are the anchor of our technique even today (the dissection along the iliacs is not routinely done).

Candidates for an APR include patients whose tumors are either into the anal sphincter or are so close to the anal sphincter that a safe distal margin cannot be obtained. Also, there is a small subset of patients with mid rectal tumors but with poor continence who may benefit from an APR, even though they are technically sphincter-preservation candidates. There have been recent reports that obturator/pelvic sidewall lymph nodes are more often involved in patients with very low rectal cancers. It has been suggested that these patients should undergo an extrafascial TME dissection.[72] Although there is some merit to this concept, we describe herein two approaches to APR with TME, excision of the sphincter and levators, and creation of a permanent colostomy. Traditionally, the APR has been done in lithotomy position. Recently, there have been reports of oncologic superiority of
FIGURE 44-3. Treatment options for rectal cancer depending on stage and location. Stage I (T1N0, T2N0 – the cancer is confined to the rectal wall, and no nodes are involved). Distal rectal cancers: T1 (invasion into the submucosa only): Local excision; Radical resection, often an APR; Adjuvant therapy is usually not recommended. Distal rectal cancers: T2 (invasion into the muscularis propria): Local excision with preoperative or postoperative adjuvant therapy; Radical resection without adjuvant therapy, often an APR. Mid rectal cancer: T1: TEM (transanal endoscopic microsurgery); Radical resection, usually an LAR with low anastomosis. A temporary proximal diverting ostomy is often required; Adjuvant therapy is usually not recommended. Mid rectal cancer: T2: TEM with either preoperative or postoperative adjuvant therapy; Radical resection similar to a T1 cancer; Adjuvant therapy is not recommended if a radical resection is performed but is recommended before or after a TEM resection. Upper rectal cancers: T1 and T2: LAR; TEM? Stage II and Stage III cancers [Stage II cancers have invasion into the mesorectal fat (T3) but no involved mesorectal lymph nodes. Stage III cancers are any rectal cancer (T1, T2, or T3) but with involved lymph nodes.] Distal rectal cancers: Preoperative adjuvant therapy is most often recommended followed by a radical resection, usually an APR; If preoperative imaging does not clearly define the stage of the cancer, resection can be done first followed by postoperative adjuvant therapy. Mid rectal cancers: Same as above for distal rectal cancers except an LAR is usually performed instead of an APR. Upper rectal cancers: LAR, with either preoperative or postoperative adjuvant therapy. Stage IV cancers: Treatment for any cancer is dependent on the extent of metastasis. With better surgical and medical treatments for metastatic disease, locoregional control of the primary should be aggressive and similar to the above recommendations except in the most advanced cases. Key: *LE* local excision, *short XRT* short-course radiation therapy given two times a day for 5 days in larger fractions, *ChXRT* long-course therapy given in 30 smaller fractions over 6 weeks in combination with chemotherapy.

cylindrical APR that is performed in prone position.[76] The cylindrical approach closely resembles the original Miles APR.[75,77] The recent paper of West et al. showed that cylindrical APR results in more cylindrical specimen (hence the name) and removes more tissue in the distal rectum and leads to lower radial margin involvement (14.8 versus 40.6%) and intraoperative rectal perforations (3.7 versus 22.8%).[76] The experience in our center shows that cylindrical APR leads to fewer wound complications likely due to better visualization and better skin preparation; operative time remains the same.

Position

For traditional APR, the patient is placed in the lithotomy position. We often elevate the mid and upper sacrum off the bed with a blanket or a towel so that the coccyx is away from the bed and therefore able to be more easily prepped into the field. For cylindrical APR, the patient is placed supine for TME portion of the operation and stoma creation and rotated to prone for perineal dissection. We usually have the second OR table ready with appropriate padding for all the pressure points so that the patient can be easily moved to prone position.

Incision and Exploration

The abdomen is usually entered through a midline incision. In thin patients, the incision can often be kept below the umbilicus. Low transverse incisions can also be performed as long as the ostomy site is not compromised. The APR is also a good application of laparoscopic surgery, as the abdominal portion of the procedure can be performed using laparoscopic techniques with extraction of the specimen through the perineum.

The exploration of the abdomen and pelvis should be the first step after accessing the abdomen. The liver, aortic

lymph nodes, superior hemorrhoidal lymph nodes, iliac lymph nodes, and the pelvis should all be examined. A large tumor burden, particularly multiple peritoneal implants, should lead to a reassessment of the need for resection, and perhaps only a colostomy should be performed.

Mobilization

The sigmoid colon and left colon need to be mobilize to excise the whole pelvic mesocolon and "zone of upward spread." The mobilization begins along the left pelvic brim. The gonadal vessels, ureter, and iliacs are reflected toward the retroperitoneum, and the colon and mesocolon are pulled toward the midline. The left colon is mobilized, but the splenic flexure rarely needs to be taken down. The dissection then is started on the right pelvic brim. Often, one can identify the sympathetic nerve trunks behind the superior hemorrhoidal artery (SHA) as one mobilizes the rectal mesocolon away from the sacral promontory.

Resection and Ligation

After mobilization of the mesentery, the bowel is divided near the sigmoid colon/left colon junction at right angles to the blood supply (Figure 44-4). Because a high ligation of the SHA or of the IMA is planned, the blood supply to most of the sigmoid colon will be compromised. For most cases, a ligation of the SHA flush with the left colic artery should be performed. A higher ligation of the IMA should be performed if there is any question of lymph node involvement outside the pelvis (e.g., palpable nodes along the SHA up to or above the left colic artery). The IMA should be ligated flush with the aorta, and the inferior mesenteric vein should be ligated near the ligament of Treitz. A high ligation may also be required for additional colonic mobilization.

After dividing the bowel, sequential clamps of the sigmoid vessels are placed and the mesentery is ligated and divided. A high ligation is performed of the SHA with care being taken to not injure the ureters, and also to make sure that the sympathetic nerve trunks are preserved.

Total Mesorectal Excision

A successful total mesorectal excision (TME) starts with the proper ligation of the SHA or IMA. As one dissects down toward the sacral promontory, the sympathetic nerve trunks are identified. The dissection plane is just anterior or medial to these nerves. Using the cautery or scissors, the nerves are reflected toward the pelvic sidewall, while the mesorectal fascia surrounding the mesorectal fat is kept as an intact unit. The dissection starts posteriorly and then at each level proceeds laterally and then anteriorly. In the mid rectal area along the lateral sidewalls, one can sometimes see the parasympathetic nerves tracing anteriorly toward the hypogastric plexus. The plexus is usually on the anterolateral sidewall of the pelvis, just lateral to the seminal vesicles in the man

Total Mesorectal Excision including Blood and Lymphatic Vessels
Rectum

FIGURE 44-4. The vascular supply of the sigmoid and rectum. A typical ligation is performed at the junction of the SHA and left colic artery. In patients with a clinical suspicion of positive nodes at the level of the IMA, or if vascular mobilization is needed for the left and transverse colon, a ligation of the IMA is performed at the aorta.

and the cardinal ligaments in the woman. There is often a tough "ligament" that traverses the mesorectum at this point. It theoretically contains the middle rectal artery. However, in a study by Jones et al.[78], this artery is only present to any significance about 20% of the time.

The anterior dissection is perhaps the most difficult. In men, one should try to include the two layers of Denonvillier's fascia. This fascia is composed of peritoneum that has been entrapped between the seminal vesicles and prostate anterior and the rectum posterior (Figure 44-5). In woman, the peritoneum at the base of the pouch of Douglas is incised, and the rectovaginal septum is then separated.

If properly done, the mesorectum begins to appear as a bulky bilobed structure. As one progresses distally beyond the mid rectum, the mesorectal fat begins to attenuate. At the pelvic floor, there is often only a thin layer of mesorectal fat around the bowel.
FIGURE 44-5. Sagittal view of the rectum, bladder, Denonvillier's fascia, and the prostate. The dissection should proceed anterior to one or both layers of Denonvillier's fascia.

Perineal Dissection

In traditional APR, as the abdominal procedure proceeds distally, the perineal dissection can commence. Before the preparation and draping of the patient, the position of the perineum is ensured so as to allow a wide elliptical incision around the anus. The rectum is usually cleared of any stool or residual preparation, and the anus is sewn closed. The incision for the perineal dissection starts anteriorly at the perineal body, goes laterally to the ischiorectal spines, and then finishes posteriorly at the tip of the coccyx. After incising the skin and subcutaneous ischiorectal membrane and fat, the levators are then encountered. The perineal surgeon then coordinates their dissection with the abdominal team in the posterior precoccygeal plane. A pair of long scissors or an electrocautery can be used to divide the ligaments in the posterior midline behind the rectum. Once a connection has been opened, the perineal surgeon places their finger above the levators and "hooks" them down toward the perineal field. The levators are then divided with the cautery. The dissection starts posteriorly and then proceeds laterally and anteriorly. Often, it is best to complete the anterior dissection after the proximal portion of the specimen has been everted out to the perineal surgeon. The remaining attachments in the anterior plane are then divided with the cautery. Once the specimen is removed, hemostasis is ensured with the cautery or absorbable figure-of-8 sutures. Typically, there are vessels that need to be ligated in the crease between the lateral prostate and the pelvic floor.

If a cylindrical APR is planned, the patient needs to be changed to prone position after TME is complete and permanent colostomy is created. The pelvis is elevated on a pillow, and the buttocks are taped apart. The skin incision is marked in elliptical fashion to extend from coccyx to ischial tuberosities to perineal body. The incision is made with knife through the skin and extended down through subcutaneous tissues with electrocautery. At this point, two Gelpi retractors or a Lone Star retractor (Lone Star Medical Products Inc., Stafford, TX) facilitate the dissection. Similar to traditional approach, anococcygeal ligament is broken through with a pair of large scissors or an elctrocautery and which are retracted wide open to create enough space for surgeon's finger to hook the levators, thus facilitating the lateral dissection of the rectum. Care is taken to dissect the levators of pelvic sidewall. After lateral attachments are taken down, the rectum is everted onto the field and by holding the rectum up anterior dissection is complete. Sometimes coccyx can be removed as well in continuity with the main specimen.

After irrigating the pelvis, one reapproximates the residual levators with absorbable sutures, and then the subcutaneous fat, ischiorectal fat, and skin are closed in several layers. Drains in the pelvis can be brought out through the pelvis or via the abdomen.

Ostomy

Ideally, the patient has been preoperatively marked by a certified ostomy therapist. The end of the colon is carefully cleaned of any fat. The skin is divided in a circular shape at the ostomy site. The subcutaneous tissues are split and the fascia is divided in a vertical or cruciate manner. The muscle is split but not divided, and then the peritoneum is incised. The hole is made wide enough to accommodate the bowel and the accompanying mesentery. The bowel should then be brought up through the opening so that it is 1–3 cm higher than the skin and the ostomy is matured.

LAR with Sphincter Preservation

Sphincter-sparing procedures for resection of mid and some distal rectal cancers have become increasingly prevalent as their safety and efficacy have been established. The advent of circular stapling devices is largely responsible for their increasing popularity and utilization. An LAR involves dissection and anastomosis below the peritoneal reflection with ligation of the superior and middle hemorrhoidal arteries. An extended LAR indicates complete mobilization of the rectum down to the pelvic floor with division of the lateral ligaments and posterior mobilization through Waldeyer's fascia to the tip of the coccyx. Additionally, there is dissection of the plane between the anterior rectal wall and the vagina in a female patient and dissection of the plane between the rectum and the prostate in a male patient to a level distal to the inferior margin of the prostate gland. As long as the surgeon can obtain a distal margin of at least 2 cm, an anastomosis can be considered appropriate if technically feasible. Body habitus, adequacy of the anal sphincter, encroachment of

the tumor on the anal sphincters, and adequacy of the distal margin are all factors in determining the applicability of a sphincter-sparing operation.

Coloanal Anastomosis

The ultimate procedure in sphincter-saving operations is the ultra-LAR with coloanal anastomosis. This operation preserves the sphincter mechanism in patients with very low-lying rectal cancer in whom the distal margin is at the minimally acceptable level yet adequate for cancer clearance. These operations are reserved for patients who have a distal rectal cancer that does not invade the sphincter musculature and in whom a standard extended LAR is technically not possible. After an adequate distal margin is achieved, the rectum is transected at the level of the pelvic floor musculature. The remaining anal mucosa between the dentate line and the level of transection of the pelvic floor can then be "stripped," and an anastomosis between the colon and the anus is performed to restore continuity. Alternatively, the procedure can be started at the dentate line with a tubular mobilization of the distal rectum in the intersphincteric groove. This perineal resection can proceed up to the superior margin of the puborectalis muscle before dissecting into the pelvis and connecting with the pelvic and abdominal dissection. The procedure usually requires full mobilization of the splenic flexure, such that the vascular supply of the left colon now based on the middle colic vessels can reach the distal pelvis. The coloanal anastomosis can also be undertaken with a colonic J pouch. Because of the larger capacity of the J pouch construction, anorectal function is thought to be improved, especially early after the surgery. The J pouch is created by folding the distal end of the colon back on itself approximately 5–8 cm and then creating a common channel (Figure 44-6). The actual anastomosis to the anus is then done from the apex of the J in side-to-end manner. An alternative to the colonic J pouch is the coloplasty. This technique is similar in concept to a stricturoplasty. The distal colon is divided in a longitudinal direction for 8–10 cm starting 4–6 cm from the distal edge of the pedicle. The longitudinal incision is then approximated transversely, making a larger reservoir capacity (Figure 44-7). The technique can decrease frequency in the early postoperative period, but it has been associated with an increased number of anastomotic leaks. A proximal diverting stoma is advisable because of the potential for an anastomotic leak or vascular compromise of the left colon. Contraindications to the procedure include the following: baseline fecal incontinence from deteriorated anal sphincter muscles, tumor invasion of the anal sphincter musculature or rectovaginal septum, tenesmus, and technical factors such as body habitus, tumor location, and tumor size. An end rectum to side colonic anastomosis is another option to the commonly used colonic J pouch.
FIGURE 44-6. Construction of a colonic J pouch after an ultra LAR. The distal colon pedicle is folded back on itself to make a "J." A common channel is then created using a stapling device that will staple and divide. A larger reservoir is then created. The J pouch is then anastomosed to the anus using a circular stapler or in a hand-sewn manner.

Laparoscopically Assisted Resections for Rectal Cancer

The application of laparoscopy for the treatment of intraabdominal malignancies including proctectomy for rectal cancer is now being performed. In these operations, part of the procedure is done using the laparoscope, and completion of the procedure is in the traditional manner. In particular, exploration and mobilization of the colon and rectum can be done with the laparoscope and laparoscopic instruments.[79] Ligation of the vascular pedicle is performed with laparoscopic clips, vascular stapling devices, or radiofrequency coagulation devices. The improved optics of laparoscopy can provide a much better view in the pelvis, thus facilitating rectal dissection. In the recent years, there has been an increased use of laparoscopic resection for rectal cancer. Most often, however, the actual resection of the bowel and an anastomosis are still more easily performed in an extracorporeal manner.

The main questions about laparoscopic-assisted proctectomy for colorectal cancer are whether it provides the same TME specimen as traditional open techniques, and whether there is any other unique biologic alteration in the laparoscopic procedure that leads to a change in survival or in recurrence patterns. Concerning the latter point, there have been several reports of unusual wound recurrences at trocar sites in patients undergoing laparoscopic-assisted colectomy. It is of paramount importance that laparoscopic resection follows
FIGURE 44-7. Construction of a coloplasty. The bowel is divided in a longitudinal manner as shown and resutured transversely to create a larger reservoir capacity.

the same oncologic principle as open surgery including precise TME. The recent studies have indicated that there is no difference between laparoscopic and open surgery as far as 3 and 5-year survival,[80,81] radial margin involvement [81], and local recurrence rate.[81,82]

The mean operative time for laparoscopic rectal surgery ranges from 180 to 260 min[80,82], although some studies report similar times to open surgery.[79] The blood loss is usually less. Most of the studies report earlier return of bowel function, decreased hospital stay, and reduction in pain.

The rate of anastomotic leak in sphincter sparing rectal surgery is comparable between two approaches and is approximately 10% and can be as high as 17%.[81] Also, there have been two reports of an increase in erectile dysfunction with the laparoscopic rectal resection versus open surgery.

One of the indicators of feasibility of laparoscopic rectal surgery is the conversion rate, which is found to be between 6 and 15%. It was also noted the conversion is associated with higher operative mortality, higher complication rate, and higher local recurrence rate.

The recommendation from ASCRS is that laparoscopic rectal cancer resection be practiced by expert, trained surgeons in an environment where the outcomes can be meaningfully evaluated. Ultimately, the question may be answered with the current American College of Surgeons Oncology Group (ACOSOG) Trial comparing laparoscopic versus open resection of rectal cancers.

Local Excision Versus Radical Resection

Although the LAR and the APR are the mainstays of therapy for many distal rectal cancers, the radical resection is associated with significant morbidity and mortality. A review of the literature showed that mortality rates for the APR range from 0 to 6.3%,[79,83,86] with some studies having a 61% incidence of postoperative complications.[84] The majority of these complications are urinary dysfunction and perineal wound infections, with rates as high as 50 and 16%, respectively.[85] In our experience, the incidence of major wound complications was 10%.[87] Radical surgery, especially the APR, leads to a significant change in body image and social habits. In a patient survey performed in 1983 by Williams and Johnston,[88] 66% of patients complained of significant leaks from their stoma appliances, 67% experienced sexual dysfunction, and only 40% of patients who were working preoperatively returned to their jobs after their operation. Unfortunately, radical surgery does not guarantee a recurrence-free survival; the 5-year survival rate in the National Cancer Data Base for Stage I disease is 78%.[89] The complication rates, the change in body image with a colostomy, and the improvements in patient selection secondary to innovations in preoperative imaging modalities have led to a renewed interest in local excision of rectal cancers. This topic is discussed in another chapter in the book. The Colorectal surgeon should be well versed in all techniques to remove and resect a rectal cancer either through a radical resection (TME) or via a local excision to give the patient the best options for treatment.

Survival After Rectal Cancer Excision

Overall 5-year survival rates for colorectal cancer have shown improvement over recent decades with the combination of better surgery and adjuvant therapy. Reports from 20 years previous have assured us that a sphincter-sparing surgical approach does not sacrifice survival in selected patients where an adequate margin can be achieved.[90–92] Overall 5-year survival rates after major surgery for rectal cancer are as follows: Stage I, 85–100%; Stage II, 60–80%; and Stage III, 30–50%.[57,66,90,93–99]

Local excision of cancers confined to the rectal wall without lymphatic or distant spread (T1 and T2N0) can achieve cure rates of 80–100%; however, the results published in retrospective trials are extremely unreliable because many studies span decades and have no standard entrance criteria and standard adjuvant therapy policy. In some retrospective studies, local recurrence seemed high, but overall survival was not different than a comparative group of patients who underwent radical resection.[100] Future emphasis on earlier diagnosis, accurate preoperative staging, and appropriate choice of resection procedure, combined with improved adjuvant therapy, should influence favorably overall survival using this conservative technique.

Synchronous Cancers

Synchronous cancers of the large intestine occur with an incidence of approximately 3.5%. Also, synchronous polyps are common with a primary cancer. If one finds two cancers within the colon and rectum, then one must plan an approach to the surgical resection that depends on the location of the two lesions. Certainly, two resections and two primary anastomoses can be performed in large bowel surgery with a complication rate that is similar to that of just one anastomosis.[101] If a patient has a small rectal cancer that is amenable to local excision along with a synchronous cancer of the colon, one can consider a local excision of the rectal lesion followed by primary resection of the colon lesion. It is important, however, to realize that surveillance after local excision of a rectal cancer needs to be more aggressive in monitoring for local recurrence and metachronous cancers or precancers than after resection of single bowel cancer.

Extended Resection for Locally Advanced Colon or Rectal Cancer

Carcinoma of the colon and rectum will sometimes invade adjacent organs or the abdominal wall. Even when such invasion occurs, extended resection of the cancer along with the tissue or organ to which it has adhered can lead to a 5-year survival rate of >50%, provided the surgical margins are tumor free.[102,103] Patients with inflammatory adhesions to contiguous organs have a slightly higher survival rate than patients with malignant infiltration, but the distinction between malignant and inflammatory contiguity often cannot be made until after en bloc resection. The organs that are usually involved with adhesions from colon or rectal cancer include the uterus, small bowel, urinary bladder, and abdominal wall. In general, approximately 5% of patients will present with locally advanced lesions.[103]

Surgical Treatment of Recurrent Colorectal Carcinoma

Recurrent colorectal cancer affects between 12 and 50% of patients with Dukes B or C (T2N0 through T3N1) disease. Although adjuvant treatment has some effect on survival, surgery remains the mainstay in treatment of recurrent disease. Most often, the intent of surgery for recurrent disease is not curative, but to improve survival or to palliate symptoms.

There are three main patterns of recurrence after resection of a primary colorectal cancer. The most common site of recurrence is the liver. However, isolated recurrences can also be seen locoregionally or in the lung. Although 60–70% of patients who die of colorectal cancer have liver metastasis, the liver is an isolated site of recurrence in <20% of patients. Of the latter group, only 5–10% will be candidates for curative hepatic resection.[104]

Locoregional recurrence of rectal cancer has been decreasing over the past two decades. With the use of adjuvant therapy and the wider application of TME, local failure has been reported as low as 3%. However, when a patient develops a local recurrence, it is often not just a suture line recurrence, but a regional recurrence. The workup of these patients requires extensive imaging to identify features of the tumor that would make it unresectable.

Wanebo et al.[105] demonstrated a 25% actuarial 5-year survival after abdominal sacral resection for recurrent colorectal cancer. They concluded that patients presenting after a long disease-free interval could benefit from such a large procedure. Noncurative surgery has only a small role in the treatment of symptomatic pelvic recurrence, particularly with sacral involvement. Newer approaches such as cryoablation of perineal recurrences may replace heroic procedures and may be useful in symptomatic relief of nonresectable pelvic recurrence.

ASCRS guidelines

The American Society of Colon and Rectal Surgeons has published practice parameters for the management of rectal cancer.[106]

Rectal Cancer: Locally Advanced and Recurrent

Robert R. Cima

Introduction

Of patients with newly diagnosed colorectal cancer who will undergo surgery with curative intent as part of their treatment, approximately 5–12% will have tumors that have spread beyond the anatomic landmarks of a standard resection and have invaded adjacent organs or structures.[1–3] The goal of surgery in such cases is a wide, en bloc resection of the tumor and any involved adjacent organ or structure. Of patients who undergo resection with curative intent and receive adjuvant therapy, between 7 and 33% develop isolated local or regional recurrences.[4,5] In up to 20% of these recurrences, resection can be curative.[4,6,7]

Although tumor biology must influence the rate and location of recurrence, no tumor-specific characteristics have been clearly associated with local recurrence. The most important factor that influences tumor recurrence is the stage of disease at presentation.[8] Other factors include obstruction or perforation at presentation, adjacent organ involvement, tumor aneuploidy, increased tumor grade, mucin production, or evidence of venous or perineural invasion. Over the last decade, the adequacy of surgical resection and the use of preoperative chemoradiation have been shown to influence the rate of pelvic recurrence.[9–12] Detailed discussion of these aspects of rectal cancer treatment is addressed elsewhere in the textbook. The focus of this chapter is to discuss the evaluation, operative management, and multimodality treatment of patients with locally advanced rectal cancer. Since the preoperative evaluation, operative approach, and often the perioperative oncologic therapy are similar for primary locally advanced and recurrent rectal cancer, they are discussed together. The outcomes for the different approaches are evaluated later in the chapter.

Locally advanced primary rectal cancers include tumors that are T4 N1-2 MX at the time of initial presentation. They are often associated with a higher rate of metastatic disease at the time of diagnosis and have a poorer overall prognosis than earlier stage disease.[8] T4 tumors are found to be fixed by physical examination or to be invading adjacent organs or structures by diagnostic imaging studies. For T4 tumors, standard surgery alone offers a limited chance of significant local tumor control and/or long-term survival. In cases where an extended en bloc resection cannot be performed to achieve complete resection, patient survival is dismal: after no treatment or after palliative surgery, mean survival time is less than 1 year.[13]

Multimodality therapy incorporating radiation, chemotherapy, and surgery should be used to achieve local tumor control and to prevent or control systemic tumor dissemination, thereby improving patient survival for patients with locally advanced primary or recurrent colorectal cancers. To achieve these goals, appropriate surgery is combined with external-beam radiation (EBRT), and, under ideal circumstances, intraoperative radiation therapy (IORT) and adjuvant or neoadjuvant chemotherapy.

Patients with isolated hepatic or pulmonary metastasis from a rectal cancer are known to have reasonable survival after surgical treatment; however, survival with an isolated, untreated, locoregional, rectal cancer recurrence is quite poor.[14,15] Most of these patients develop disabling complications, including severe pain from bony or nervous tissue involvement, urinary obstruction, fecal obstruction or incontinence, or persistent bleeding. Nearly 90% of rectal cancer recurrences after surgery alone occur in the central or posterior pelvis, and 19% occur at the anastomosis.[16] Stage T4 primary tumors are significantly associated with relapse in the anterior pelvic region.[16] External-beam radiation alone or combined with systemic chemotherapy may result in temporary improvement of symptoms, but the 5-year survival rate is less than 5%.[14,15] Surgical palliation without the addition of systemic chemotherapy and radiation therapy adds little to the overall survival. For these patients, length of survival is perhaps less important than quality of life.

A patient who presents with a locally advanced primary or recurrent rectal cancer must be thoroughly evaluated for the presence of extrapelvic disease. If extensive extrapelvic disease is found, the degree and scope of surgical resection should be changed from one of curative intent to palliation.

An exception may be considered in younger patients with no significant comorbidities in whom a single, isolated, resectable hepatic metastasis is found. However, if a patient has multiple sites of spread or significant comorbidities, extensive surgery involving multiple structures is not warranted, as the chance for cure is quite small. Whether a patient is a candidate for surgery is influenced by a number of factors, including the patient's overall physical condition and comorbid diseases and the extent of spread and fixation of the tumor outside of the rectum.

Preoperative Evaluation and Patient Selection

Complete resection of a locally advanced primary or recurrent rectal cancer is a significant undertaking. Complete resection may be technically possible in some patients, but if their overall physical condition does not make them an appropriate candidate, surgical palliation combined with chemoradiation is the more prudent course of action. To be considered for a complete resection, the patient should be in generally good health. Any significant cardiac or respiratory conditions should be thoroughly evaluated and treated. Patients who are in poor health, or who will not be able to tolerate multimodality therapy combined with complete surgical resection, or have an ASA classifications of IV–V are not considered acceptable surgical candidates. Nearly as important as their physical condition is consideration of the patient's motivation and emotional preparedness for undergoing this extensive treatment. They should be thoroughly informed about and accepting of the short-term and long-term risks associated with the surgery, as well as possible subsequent surgeries or interventions required for postoperative complications.

If the patient is deemed an acceptable candidate for surgery, the next step is evaluation for the extent of local spread and the possibility of extrapelvic spread. A detailed history should be obtained. Symptoms that may suggest metastatic disease, such as back or bone pain outside of the pelvis, new respiratory symptoms, or headaches need to be carefully examined. A thorough physical exam, with particular attention placed on the rectal and vaginal exam, needs to be performed, and any fixation of the tumor to rigid pelvic structures needs to be assessed. Complete endoscopic evaluation of the colon needs to be performed, if technically possible, to rule out the presence of a synchronous lesion. Endoluminal ultrasound of the rectum may be combined with this evaluation in cases of recurrent disease to determine if there is a discrete mass adjacent to the intestine that might be amenable to endoscopic biopsy. Imaging should be repeated before surgery is considered and compared to similar previous studies to give some reassurance that there has been no progression or spread of the disease that might change or preclude any surgical intervention. The abdomen and pelvis need to be evaluated with a double-contrast (intravenous and oral) computed tomography (CT) scan to exclude extrapelvic spread and to assess the extent of possible resection. CT scans are generally reliable for identifying the extent of disease and adjacent organ involvement but are less discriminating for predicting local tumor resectability.[17] Any suspicious hepatic lesion should be examined with ultrasound. If the lesion is worrisome for metastatic disease, it should be biopsied. Questionable findings on the chest X-ray film should be further investigated. Any worrisome lesion that is technically accessible should be biopsied percutaneously.

Although the above tests are the standard evaluation for diagnosing recurrence and excluding extrapelvic spread of the tumor, other more tumor-specific tests have been proposed as adjuncts. Magnetic resonance imaging (MRI) might be more accurate than conventional CT scanning for detecting recurrences in the pelvis or elsewhere in the abdomen because of better image resolution. However, similar to CT scans, MR images provide only anatomic details and may not be any better at distinguishing tumor recurrence from scar in a postoperative field, particularly after pelvic irradiation. To overcome this limitation, a metabolic-based imaging modality such at positron emission tomography (PET) has been studied.[18–22] Colorectal cancer is known to rapidly metabolize fluorine-18 fluorodeoxyglucose (FDG), which therefore can be used as a metabolic label to detect tumor deposits, not only in the pelvis, but also throughout the entire body. Numerous nonrandomized studies have shown that FDG-PET imaging for recurrent colorectal cancer has a significantly higher sensitivity and specificity than CT scanning. When CT scanning was compared with FDG-PET imaging in postoperative patients with colorectal locoregional recurrences, the sensitivity of FDG-PET was significantly higher than CT plus colonoscopy (90 vs. 71%, respectively), although the specificities were similar (92 vs. 85%, respectively).[23] FDG-PET imaging has been shown to maintain this high sensitivity and specificity, 84 and 88%, respectively, even in the setting of the previously irradiated and postoperative pelvis.[18] Thus, FDG-PET might be a useful tool in the postoperative patient in whom there is a suspicion of recurrence but equivocal CT findings, and in whom extensive reoperative surgery might be of extremely high risk.

Even the combination of physical examination and radiographic studies may not be able to prove that there is a pelvic recurrence of a rectal cancer, especially if the patient has undergone a previous pelvic operation or pelvic irradiation. We generally accept three ways of differentiating postoperative changes from tumor. The first is to document a change in the lesion, such as increase in size over time; the second is invasion of the adjacent organs; the third is histological evidence obtained from endoscopic, CT-, or ultrasound-guided biopsies of the suspicious tissue. However, occasionally, pelvic disease is suspected from a rising CEA or development of symptoms without any definable anatomic change on exam. In such situations, histologic proof should be vigorously sought.

Exploratory pelvic surgery should be strongly discouraged, as it poses an extreme risk to the patient and makes future evaluation of the pelvis even more difficult.

Determining Tumor Resectability

Locally advanced primary or locoregional recurrences of rectal cancers can extend to involve any of the pelvic organs or rigid bony structures of the pelvis. Resectability is based upon the anatomic location and what other structures are fixed to the lesion. Although there are other schemes for assessing resectability, we use the following one to classify our patients who are being considered for possible resection. The tumor is classified as F0 when it is not fixed to any pelvic organ or structure, FR when the tumor is fixed but resectable, and FNR when the tumor is fixed and not resectable. FR is further subdivided by noting the anatomical extent of the fixation (anterior, posterior, and lateral).[24] The anatomic extent of the tumor determines the scope of the required resection. For example, anterior fixed lesions may require a hysterectomy, vaginectomy, a partial or complete cystectomy, or prostatectomy, whereas lesions that are fixed posteriorly may require a sacrectomy (Figures 45-1–45-3).

Although we have found this classification scheme to be extremely useful, it does not reliably predict resectability before surgery because new findings may be discovered at operation. However, in our experience, some factors are clearly associated with an unresectable tumor (Table 45-1). Any circumferential tumor that extends to the pelvic sidewall is considered unresectable. Evidence of bilateral ureteral obstruction is a very worrisome finding. Unless there is focal infiltration of the bladder trigone causing bilateral ureteral obstruction, this finding usually indicates that a bulky tumor has invaded both lateral pelvic sidewalls. This means that the disease is present at the level of the pelvic inlet, making complete resection impossible. Finally, S1 and S2 nerve root involvement or evidence of invasion of the sacral bone at the level of S1 and S2 indicates an unresectable tumor. A sacrectomy proximal to S2 results in sacroiliac joint instability and although internal fixation is possible, it is not warranted for cases of locally recurrent rectal cancer. Pain from nerve root involvement with tumor occasionally needs to be differentiated from sciatic nerve compression. Nerve compression symptoms may completely resolve after pelvic irradiation and chemotherapy. On the other hand, persistent buttock and perineal pain usually resulting from tumor expansion and in growth is a more ominous symptom.

Multimodality Therapy for Advanced or Locally Recurrent Rectal Cancer

Surgery with curative intent is the mainstay of treatment for advanced or locally recurrent rectal cancer. However, surgery alone results in a high rate of local and distant failure.[13] To improve outcomes, surgery is combined with multimodality therapy, radiation, and chemotherapy. Radiotherapy is used to improve local control and systemic chemotherapy is used to treat possible disseminated disease.

Although EBRT may relieve symptoms and pain resulting from a large primary or recurrent rectal tumor, it alone does not offer a significant chance of cure.[25] However, when it is combined with sensitizing chemotherapy, the probability of achieving a resection with negative margins and the rate of local tumor control increases.[26–33] In the setting of a locally advanced or recurrent rectal cancer, centers have combined multimodality therapy with intraoperative radiotherapy – either as electron-beam radiation therapy, high-dose rate brachytherapy, or traditional perioperative brachytherapy to further improve patient outcomes.[34–41] These forms of locally directed radiation reduce toxicity by limiting normal tissue exposure and deliver a high biologically equivalent dose to the localized area of the tumor.

In general, patients who never received prior pelvic radiation therapy, a full course of external-beam radiation (5,040 cGy) is administered with concurrent 5-fluorouracil chemotherapy. Often, patients with recurrent rectal cancer have previously received a full course of pelvic external-beam radiation. We treat such patients with an additional course of 2,000 cGy of external-beam radiation combined with additional 5-fluorouracil chemotherapy before repeating pelvic surgery. A recent multicenter study has shown that hyperfractionated preoperative chemoradiation can be safely administered in recurrent rectal cancer patients who have previously received pelvic radiation.[42] The overall tumor response rate was 44.1%. Furthermore, there was no increase in postoperative complications as compared to patients who did not receive the hyperfractionated therapy. Therapeutic synergy between external-beam and intraoperative radiation reaches its peak within 8 weeks of completion of external-beam therapy. The disease is restaged both clinically and radiographically 4 weeks after completion of the external beam and chemotherapy course. If there is no evidence of disease progression in the pelvis or extrapelvic metastasis, the patient is scheduled for surgery within the next 4 weeks.

Surgery

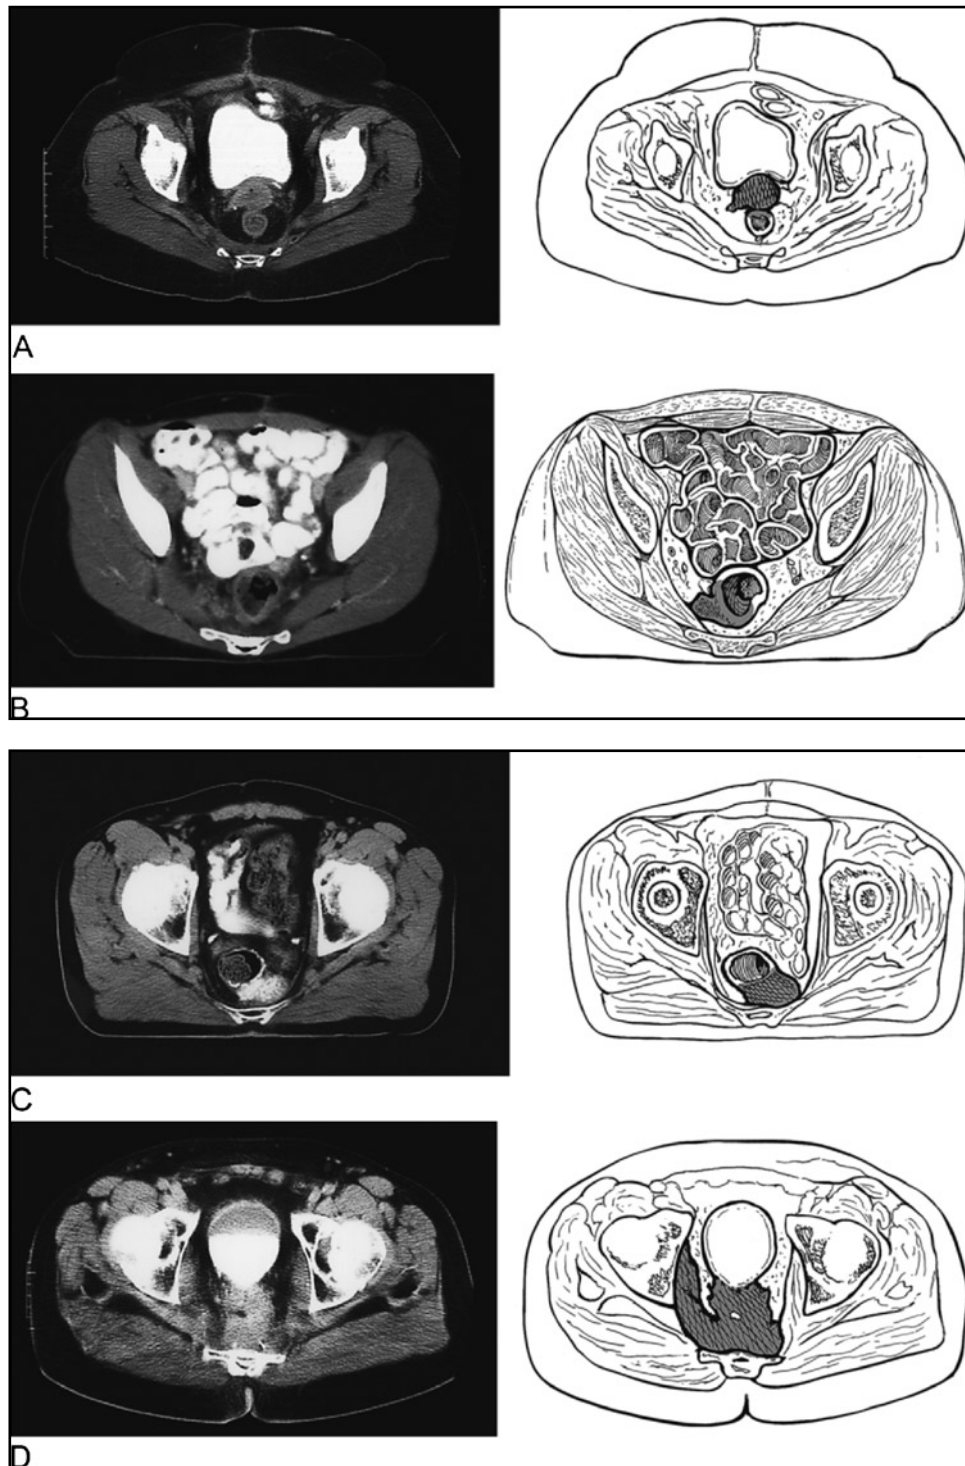
Before surgery, the magnitude of the operation and the possible complications are discussed in depth with the patient and family members. In cases of large locally advanced primary rectal cancers, the sphincter mechanism is preserved. In recurrent cancers, there is little role for an attempt at sphincter preservation, as the risk of complications or poor functional outcomes is quite high. Therefore, the patient must be accepting of a permanent colostomy. In addition, the resection of adjacent structures or organs and the functional implications and reconstruction alternatives, such as an ileal


FIGURE 45-1. **A** A primary T3N0M0 rectal cancer treated with a lower anterior resection without adjuvant therapy. The anterior recurrent tumor fixed at the base of the bladder was treated with preoperative chemoradiation and then resected with IORT. **B** After a primary low anterior resection for T2N0M0 rectal cancer without adjuvant therapy, this patient developed a lateral pelvic recurrence. After preoperative chemoradiation, the patient underwent an abdominal resection with negative margins. **C** A recurrence after a T3N0M0 lesion treated with postoperative chemoradiation therapy was found to invade the sacrum. After additional EBRT and chemotherapy, IORT combined with an en bloc resection of the tumor and distal sacrum was performed with negative margins. **D** A massive recurrent cancer found in the pelvis after an abdominal perineal resection and postoperative chemoradiation. The tumor was fixed to vital pelvic structures and was deemed unresectable (with permission from Nicholls RJ, Dozois RR, editors. Surgery of the colon and rectum. New York: Churchill Livingston; 1997).

FIGURE 45-2. The IORT suite, showing the equipment, the position of the patient on the operating room table, and the linear accelerator.

conduit, need to be discussed. All patients visit with and are marked for multiple ostomies by an enterostomal therapist.

Depending upon the patient's medical condition, they may need admission at the night prior to surgery, although the majority of patients can be admitted on the day of surgery. While the need for a mechanical bowel preparation in a routine colectomy is under debate, we routinely prepare these patients to minimize the potential for contamination. At our institution, all cases of locally advanced or recurrent rectal cancers are scheduled in a dedicated IORT suite. This suite within the OR complex houses the standard operating room equipment, a linear accelerator, and special anesthetic equipment that permits the anesthetized patient to be moved from operating to irradiating positions (Figure 45-2). In addition, remote controls are used to monitor the patient outside the suite while radiation is given. The patient is placed in the lithotomy position with both arms tucked and the legs supported in Allen stirrups. Special care is taken to ensure that the arms are well padded and in a neutral position to avoid any nerve injury. The calves are positioned and padded to avoid any pressure from directly resting on the stirrups, since the lengthy operation may result in compartment syndrome and/or venous thrombosis.[43] Bilateral ureteral stents are inserted cystoscopically preoperatively in all patients.

A midline incision is usually made. Transverse abdominal incisions should be avoided, as they compromise the placement of any stomas and may injure the inferior epigastric vessels, the primary blood supply of the rectus muscle. Preservation of the rectus muscle is important in case a transpelvic rectus abdominis flap is required to reconstruct the pelvic floor. If the patient has had prior abdominal surgery, all adhesions need to be lysed. If any of the small bowel is adhered into the pelvis or in a region that might be indicative of tumor, a sample should be sent for intraoperative biopsy. If the bowel is involved with tumor, then that portion of the small bowel needs to be resected with the rectal tumor en bloc. Once all adhesions have been lysed, the entire abdomen needs to be thoroughly explored for evidence of extrapelvic tumor deposits. The liver, omentum, retroperitoneum, peritoneal lining, and the area of any prior surgical incision should be carefully examined for metastatic disease. Any suspicious finding should be biopsied and analyzed by frozen section. The presence of extrapelvic disease would be a contraindication to radical resection. Very rarely, exceptions may be made in a young patient who has limited pelvic and liver disease; in such cases, the pelvic recurrence and secondary liver tumor are resected simultaneously.

A self-retaining retractor is placed and the small bowel is packed into the upper abdomen to facilitate pelvic exposure. As pelvic irradiation or prior pelvic surgery would have induced significant fibrosis in the tissues of the pelvis, we begin the dissection at the level of the aortic bifurcation. Starting at this level allows us to enter a virgin fascial plane, which aids in the posterior dissection to the level of the pelvic floor. Similarly, the ureters are identified before they enter the pelvis and are then mobilized along their length along the pelvic sidewall and into the bladder. Identifying the ureters all the way to their insertion into the bladder is important
FIGURE 45-3. **A** The assortment of the Lucite tubes used to direct the electron beam to a fixed site in the operating field to deliver the IOT. **B** Place of a large Lucite tube to deliver the IORT into the pelvis. The tube is fixed in place by securing it to an external support apparatus attached to the operating table.

TABLE 45-1. Symptoms or findings suggestive of an unresectable tumor for cure

Sciatic pain
Bilateral ureteral obstruction
Multiple points of tumor fixation to the pelvic sidewall
Circumferential involvement of the pelvic sidewall
S1 or S2 bony or neural involvement
Extrapelvic disease

to ensure adequate length if an ileal conduit is required for urinary tract reconstruction.

For rectal cancer recurrences that are not fixed to any pelvic structure (F0), a completion abdominoperineal resection (APR) is required. The scope of the resection is similar to a standard APR, but the pelvic fibrosis induced by any prior surgery would have distorted or eliminated the ideal, relatively bloodless plane between the mesorectum and sacral fascia. The distinction between fibrosis and tumor infiltration into adjacent tissue can be very difficult to discern at the time of the operation. If there is any question about the nature of the tissue, particularly when it occurs outside the realm of planned resection, for example, at the level of the sacral promontory or at the lateral pelvic walls, a frozen section should be analyzed. If tumor cells are seen, a complete resection with negative margins is not feasible. As discussed later, it is in this setting that the use of IORT improves clinical outcomes.

When the tumor is fixed, either anteriorly or posteriorly, the scope of the operation is much larger than for the non-fixed lesion (F0). If the fixed tumor is considered resectable,

we classify it as a FR (fixed, resectable) lesion. For anteriorly fixed tumors, there are different operations that need to be considered, whereas for a primary or recurrent posteriorly fixed tumor, our operation of choice is an en bloc distal sacrectomy.

For the anteriorly fixed lesion, the choice of operation is influenced somewhat by the sex of the patient. In a woman, depending on the level and extent of the tumor, the resection may require only an en bloc excision of the posterior wall of the vagina, with immediate reconstruction. When the upper vagina or lower uterus is involved more extensively, en bloc hysterectomy and posterior vaginectomy would be necessary. A woman who has her uterus in situ usually does not need a cystectomy. However, a man with an anteriorly fixed tumor commonly needs a cystectomy or cystoprostatectomy. A partial cystectomy with a wide margin may be an option for an upper rectal lesion, but the functional results may be poor due to a decrease in bladder size and radiation-induced injury to the bladder. In such patients, an ileal conduit at the time of resection may be preferred to subjecting the patient to a second surgery.

Posteriorly fixed lesions require an en bloc distal sacrectomy. The proximal extent of the resection is to S2-3. A more proximal resection would require internal fixation of the sacroiliac joints to stabilize the pelvis. We consider a resection of this magnitude too extensive for primary or recurrent rectal cancer. Furthermore, when the resection is limited to the S2-3 level, it is generally possible to preserve one S3 root, which is usually sufficient to preserve bladder function. The sacrectomy proceeds through four distinct steps: (1) the anterior resection, (2) the posterior resection, (3) the use of IORT if required, and (4) the reconstruction of the pelvic tissue defect. The abdominal dissection is begun as described previously. The dissection in the posterior plane in carried out to the level of proximal tumor extent along the sacrum. This permits reevaluation to insure that the tumor does not extend above the S2-3 level. If it does, then the rectum is dissected free in the anterior and lateral planes, leaving the point of sacral fixation as the only point of attachment. A sacrectomy that needs to include a resection proximal to S3-4 requires bilateral ligation of the internal iliac arteries and veins. This is done to decrease blood loss during the sacrectomy. Once the rectum is completely freed anteriorly and laterally, all required abdominal wall stomas are created, and an omental or rectus abdominis flap is mobilized and placed into the pelvis, to be used for later reconstruction. Then, the abdominal incision is closed, and the patient is repositioned in the prone-jackknife position. A posterior midline incision is made from the region of the last lumbar vertebrae to the coccyx. The gluteal muscles are dissected free of the sacrum and the proposed site of transection is identified. The important nervous structures to the lower pelvis and extremities, the pudendal and sciatic nerves, respectively, are identified and preserved. With the assistance of our orthopedic or neurosurgical colleagues, the sacrum is transected and the dural sac

is closed. The defect is closed either over an omental flap or over the mobilized rectus abdominis flap. As the resulting tissue defect can be quite sizable, local muscle flaps may need to be mobilized to close the defect. Multiple closed suction drains should be used, as any pelvic fluid collection can easily become infected and lead to wound breakdown. The wound complications and breakdown in this heavily irradiated field are not uncommon and occur in as many as 65% of patients who undergo radical resection with concurrent IORT.[44] These postoperative wounds often require transfer of nonirradiated, well-vascularized tissue-like muscle flaps to heal if that transfer was not done at the initial operation.

Postoperatively, these patients are managed quite conservatively as prolonged ileus and urinary retention is quite common. Given the high risk of venous thromboembolism, these patients are given unfractionated heparin three times a day, and use of mechanical compression devices and mandatory early ambulation are enforced.

Use of Intraoperative Radiation Therapy

In cases of close margins, known microscopically positive margins, or minimal gross unresectable disease in the pelvis or after the sacrectomy, our policy is to use intraoperative electron-beam radiation therapy (IORT). To give IORT, a Lucite cylinder is positioned in the pelvis to target the at-risk area. The patient is then positioned under the linear accelerator. One thousand to 2,000 cGy is delivered, depending on the extent of margin involvement. A dose of 1,000 cGy is recommended for minimal residual disease; 1,500 cGy is given for gross residual disease less than 2 cm, and 2,000 cGy is reserved for unresectable or gross residual disease more than 2 cm. The IORT dose that can be given should take into account the total of any prior external-beam radiation that has been administered.

Although we only have experience with electron-beam radiation therapy, other institutions have used other ways of delivering intraoperative or prolonged local radiation therapy. At Memorial Sloan-Kettering, a combined-modality treatment protocol uses high-dose intraoperative brachytherapy (HDR-IORT).[34] The radiation is delivered via an array of catheters that are imbedded in a flexible rubber pad. This pad is then sutured to the area of concern and other normal tissues are packed away and protected. The catheters are connected to a high-dose rate ^{192}Ir source. After the total dose is delivered, the pad is removed and the operation proceeds. Another approach is to use perioperative brachytherapy as a way to combine local delivery of radiation with extended surgery.[35–38] With this method, brachytherapy catheters are loosely secured to a mesh material that is then secured to the region of interest. The operation is completed and the ends of the catheters are brought out through separate skin incisions and secured to the skin. Then, usually between postoperative day 3 and 5, removable radioactive elements are placed into

the brachytherapy catheters. Once the desired total dose is delivered, the catheters are removed at the bedside without the need for sedation or anesthesia. These techniques do not require a dedicated OR with a linear accelerator to administer radiation regionally and may therefore expand where this type of surgery can be performed. One possible disadvantage with the use of the postoperative brachytherapy catheters is that it is difficult to protect normal tissue, particularly the small intestine, once the operation is complete. However, these alternative methods for delivering local radiation therapy, when combined with extended surgery and chemotherapy, seem to result in morbidity and survival outcomes that are comparable to our experience with intraoperative electron-beam radiation therapy.

Results of Multimodality Treatment for Advanced Primary or Locally Recurrent Rectal Cancer

Disease recurrence and survival in patients with rectal cancer is highly dependent upon the stage of disease and the mode of treatment. In recent reports, the combination of preoperative external-beam radiation and total mesorectal excision surgery for resectable rectal cancer resulted in a recurrence-free rate of 94% for Stage II and 85% for Stage III tumors.[45] However, more locally advanced rectal cancers often have a higher recurrence rate.[46] Although the cause of death in these patients is commonly due to systemic disease, a mortality rate of 16–44% has been attributed to isolated local failure.[47,48] Also, advanced primary disease and recurrences in the pelvis are associated with significant pain, bleeding, and urinary or neurologic complications that often dominate the clinical picture and affect the patient's quality of life.[14] Traditionally, palliative pelvic radiation has been used, but it often only provides short-term palliation of symptoms or of local disease progression.[14,49] To better address the significant symptoms associated with advanced primary or recurrent rectal cancer and to perhaps improve survival, a number of institutions have used multimodality therapy, including preoperative chemoradiation, extensive surgery, and intraoperative-directed local radiation therapy.

For patients with advanced primary rectal cancer, studies have shown the benefit of combined preoperative chemoradiation followed by radical surgery. In a retrospective review of 60 patients with primary locally advanced rectal cancers, 81% were able to undergo curative resection.[28] Their overall 2-year survival was 91%, and their local regional recurrence rate was 7.5%. In another study, preoperative chemoradiation with extensive surgery improved overall survival and control of pelvic disease compared to preoperative radiation therapy alone.[39] In that study, the use of IORT improved local control in patients with microscopic residual disease or clinically fixed tumors. None of the patients treated with IORT developed local failure in the pelvis. Similar findings of improved local control and survival were reported in a series of patients with primary advanced rectal cancers who were given high-dose-rate intraoperative radiation therapy (HDR-IORT).[40] These 22 patients with primary unresectable rectal cancer underwent multimodality therapy including preoperative chemotherapy, external-beam irradiation, and extensive surgery with intraoperative brachytherapy, which led to actuarial 2-year local control of 81%. Local tumor control was 92% for patients who underwent resection with negative margins vs. 38% for those with microscopic positive margins. The overall 2-year actuarial disease-free survival rates were 77% for patients with negative margins and 38% for patients with positive margins. In summary, a number of reports of patients with locally advanced primary rectal cancer who were treated with intraoperative radiation and surgery have shown an overall improvement in local control compared to historical controls.

Surgery alone has been used to treat recurrent rectal cancers. In Garcia-Aguilar and colleagues reported a series of 87 patients with recurrent rectal cancer.[50] Sixty-four patients underwent surgical exploration, and only 42 were able to undergo resection with curative intent. The estimated 5-year survival rate for patients who had curative-intent surgery was significantly better than that for patients who had only palliative or no surgery (35 vs. 7%). In most series, recurrence and survival rates for patients with recurrent rectal cancer treated with surgery alone are less than those for patients with primary advanced rectal cancer, but are still better than historical data for patients treated with palliative therapies. In general, patients treated with multimodality therapy including preoperative or intraoperative radiation therapy experience 3-year local control rates ranging from 25 to 78%, and long-term survival has been reported to be between 25 and 40%.[30–33,51–58] The most consistent findings from all of these reports is that the most predictive factor associated with a better outcome, decreased local recurrence, cancer-specific and overall survival is an R0 resection. The presence of microscopic positive or grossly positive margins markedly reduces survival.

The institution with the largest reported experience using multimodality therapy including IORT for recurrent rectal cancer is the Mayo Clinic. Between 1981 and 1996, 394 patients were treated, 90 of whom had unresectable local or extrapelvic disease at the time of surgical exploration.[51] Although 304 patients underwent resection of the recurrent tumor, only 138 (45%) underwent a histologically confirmed curative resection. The 166 remaining patients had a palliative operation because of either gross ($n=139$) or microscopic ($n=27$) residual cancer in the pelvis. Nine percent of the patients who had surgery with curative intent underwent extended resections (i.e., sacrectomy, pelvic exenteration, cystectomy with ileal conduit) due to the advanced nature of the tumor. These patients were prospectively monitored to determine long-term survival and the factors influencing survival.

The 1-year, 3-year, and 5-year survival rates for the 304 patients were 84, 43, and 25%. The median survival time was 31 months. The 5-year survival rate was greater after curative surgery (i.e., negative histologic margins) than after palliative surgery (37 vs. 16%, $P < 0.001$). The presence of gross residual disease in patients who underwent nonpalliative resections resulted in decreased survival compared to those patients with microscopic residual disease. However, survival for patients who had extended resections was not significantly different than that for patients who had a limited resection (28 vs. 21%, $P = 0.11$, respectively). Logistic regression analysis found several independent factors that contributed to the ability to perform a curative resection. On univariate analysis, an initial surgery with end colostomy or painful recurrence was associated with having palliative surgery. On multivariate analysis, increasing number of tumor fixation sites was associated with a palliative resection. These factors also affected overall survival; patients with pain and more than one site of fixation had significantly lower survival rates. The best 5-year survival rates were in patients who had nonfixed tumors (41%) or asymptomatic recurrences (41%). Other institutions that have used a multimodality approach that included some form of intraoperative radiation have reported similar improvements in local recurrence and survival.[55–58]

Patients whose tumors can be resected with negative margins often have better outcomes. Because of this, some investigators have questioned the routine use of the intraoperative, locally directed radiation therapy.[59] Recently, Wiig and colleagues[60] have reported a nonrandomized prospective study evaluating the value of IORT in reoperative surgery for recurrent rectal cancer. The estimated overall 5-year survival was 30%. However, patients who had an R0 resection had a 60% survival compared to 25 and 0% for R1 and R2, respectively. The use of IORT did not improve survival or local recurrence when controlling for R-stage resection. However, other reports indicate that IORT improves local control and survival even in patients with R1 resections when compared to most control series of patients.[52] In addition, many series report that pelvic recurrences after multimodality therapy that included IORT occur outside the intraoperative radiation field. In the most recent study to look specifically at the rate of local recurrence after the use of high-dose-rate brachytherapy, significantly more recurrences occurred outside of the IORT field than within the radiation field.[58] In that series, the time to pelvic recurrence was 16 months in patients who had a pelvic recurrence outside the radiation field, and 31 months in patients who had a pelvic recurrence within the radiation field; however, the difference was not statistically significantly ($P = 0.07$). To specifically address the benefit of adding IORT to the combined multimodality treatment of patients with advanced primary or recurrent rectal cancer, a prospective randomized trial would be required. However, this would be a difficult undertaking given the relatively few institutions capable of delivering this complex therapy, the variations in different intraoperative radiation techniques, and the relatively limited number of patients for whom this therapy is appropriate. For now, most studies, although retrospective and often based on single institutions, suggest that combined multimodality therapy that includes IORT provides the best chance for cure for patients with locally advanced or recurrent rectal cancer.

Perioperatively related mortality was very low in patients who undergo this multimodality treatment (0.3%).[51] Unfortunately, the treatment-related morbidity is relatively high. In one series of 304 patients who underwent surgery with curative intent, 96 (32%) required prolonged hospitalizations, 78 (26%) of whom required readmissions and/or additional surgical procedures. The most frequent complications included pelvic abscesses (6.6%), bowel obstructions (5.3%), enteric fistulas (4.3%), and perineal wound complications (4.6%).[51] The complication rate was significantly higher in patients who underwent extended surgical resections and in patients who had recurrences fixed in more than two sites in the pelvis. These findings underscore the need for thorough preoperative patient selection to ensure that the patient is fit enough to tolerate the surgery and the potential complications and that there is no evidence of disease outside of the region of resection.

Palliative Care for Advanced or Recurrent Rectal Cancer

Patients who present with locally advanced or recurrent rectal cancer must first be evaluated with the intent to cure. An equally important consideration is palliation of symptoms if a cure does not seem to be achievable. The local effect within the pelvis of an advanced or recurrent rectal cancer drives the need to address control of symptoms. These symptoms often include rectal bleeding, rectal obstruction, urinary obstruction due to local invasion, and severe pain related to invasion of the pelvic sidewall or direct invasion of pelvic nerves. Over the past decade, the choice of palliative options has expanded, and the choice of option requires careful consideration of the presenting symptoms, possible future symptoms, extent of local and distant spread of the disease, and the overall physical condition of the patient.

Palliative interventions may be broadly classified as noninvasive, minimally invasive, and surgical. The primary noninvasive palliative option is radiotherapy. In patients who have never received pelvic radiation, a full course of external beam irradiation may be a very effective treatment for bleeding, pelvic pain, and near obstruction. The use of external-beam radiotherapy may result in palliation of severe pelvic pain in 50–90% of patients.[61,62] However, virtually all patients will experience progression of the tumor and recurrent symptoms before they die. Lingareddy and colleagues[49] have shown that there is a significant use for palliative reirradiation in treating recurrent rectal cancers. In their study of 52 patients with recurrent rectal cancer, pelvic reirradiation

resulted in complete palliation of bleeding, pain, and mass effect in 100, 65, and 24% of cases, respectively. The median initial radiation dose to the pelvis was 50 cGy; the median reirradiation dose was 30 cGy. Most patients had palliation of their symptoms until their deaths. Grade 3 and 4 toxicities were seen in 23 and 10% of patients, respectively. The 2-year overall actuarial survival was 25%.

Minimally invasive approaches to palliation usually involve mechanical means to reduce symptoms related to pelvic tumors. These include ureteral stents to alleviate urinary obstruction and expandable metal colonic wall stents or the use of lasers to relieve rectal obstruction. Self-expanding metal stents (SEMS) are useful for the nonsurgical management of rectal obstructions, bleeding, and malignant fistulas.[63] In a review of the literature, palliation with SEMS was achieved in 90% of patients.[64] In the largest series to report on SEMS for malignant rectal obstructions, stents could be deployed successfully in 36/37 patients with rectal obstructions,[65] and 28 had good long-term results with no need for subsequent intervention.[65]

Endoscopic lasers are an alternative to SEMS. The neodymium yttrium argon garnet (Nd:YAG) laser is the most commonly used. Endoscopic laser treatments remove the tissue from the lumen by coagulative necrosis or immediate tissue vaporization, depending on the amount of energy applied. Palliation of symptoms and marked improvement in quality of life is achieved after repeated laser sessions (usually 2–5) in 80–90% of patients.[66,67] Unfortunately, laser therapy does not appear to be a durable treatment. Effective palliation declines as patients survive longer; successful palliation at 1 year was only 42%.[68]

There is no data on the use of palliative resections in patients with locally advanced or recurrent rectal cancer. However, a report from Memorial Sloan-Kettering has evaluated the role of palliative resection in 80 patients with Stage IV rectal cancer.[69] Twenty-four percent had clinical evidence of obstruction and 94% had either T3 or T4 lesions. None had received prior surgery or radiation therapy. They underwent radical resection of the primary lesion and surgical treatment of solitary hepatic metastasis, if present. There was one death, a 15% postoperative morbidity, and a 20% colostomy rate. The overall local recurrence rate was 6%, the actuarial local control at 2 years was 94%, and the median survival was 25 months. This study shows that in appropriately selected patients with stage IV disease and complicated or advanced rectal cancer, surgical resection of the primary tumors can achieve very reasonable oncologic results and provide good palliation of symptoms related to the tumor.

Summary

For patients with advanced primary or recurrent rectal cancers, the only hope of cure requires a coordinated multidisciplinary approach to treatment. In general, EBRT, chemotherapy, extensive surgery, and the use of directed IORT appears to improve local control and survival. Surgery in these patients carries a higher morbidity rate than surgery for primary rectal cancer but one that is acceptable in appropriately selected patients. Before proceeding with multimodality therapy, patients should be thoroughly evaluated for the presence of disseminated extrapelvic or metastatic disease, which would, in most instances, preclude a curative operation. Experience indicates that isolated anterior or posterior fixation of the tumor does not preclude a curative resection. In these cases, en bloc resection of involved organs or bony structures can result in resection with negative margins. However, tumors fixed to the lateral pelvic sidewall, fixed at multiple points, or fixed circumferentially are often unresectable or incurable. Available data from many institutions indicate that multimodality therapy for advanced primary or recurrent rectal cancer results in better local control and higher survival rates than palliative therapy.

Colon Cancer

The stage of disease at presentation is the most important predictor of outcome for colon cancer patients. Stage I (T1-2N0M0) disease carries an excellent prognosis of up to 95% 5-year survival rate after resection, and surgical treatment alone is considered sufficient; adjuvant treatment is not indicated.[1] Patients with stage II disease (T3-4N0M0) also have excellent 5-year survival, averaging 70–80%, but a subset of high-risk patients have poorer prognosis.[1] As such, it has been suggested that some stage II patients may benefit from adjuvant therapy, but the role of treatment in this patient population remains controversial. In contrast, adjuvant treatment repeatedly has been shown to improve survival for stage III (TanyN1-2M0) disease.

Adjuvant Chemotherapy for Stage II and III Colon Cancer

Nodal status is the single most important prognostic factor in colon cancer. Overall 5-year survival after curative surgery for stage III colon cancer ranges from approximately 40–60%.[2] Recurrences are often systemic, hence the need for adjuvant treatment in these high-risk patients. Because the outlook for patients with stage II disease is considerably better, oncologists have been hesitant to offer adjuvant therapy to these patients. Nevertheless, some stage II patients will develop systemic recurrence, and a number of trials have attempted to address whether adjuvant chemotherapy is appropriate in these patients.

The efficacy of 5-fluorouracil (5-FU)/leucovorin (LV)-based adjuvant chemotherapy for stage III disease has long been well established and is now considered to be the standard of care in the USA.[3] Historically, single-agent chemotherapeutic agents such as thiotepa or fluoropyrimidines did not prove helpful as adjuvant treatment for colon cancer. Progressively, several combination trials of chemotherapy and immune modulators helped refine the recommendations made for adjuvant treatment. In 1988, the NSABP (National Surgical Adjuvant Breast and Bowel Project) CO-1 trial documented 8% improvement in overall 5-year survival for both stage II and stage III disease when adjuvant chemotherapy with MOF (semustine, vincristine, and 5-FU) was used.[4] In 1989, the NCCTG (North Central Cancer Treatment Group) compared surgical resection alone to levamisole and to 5-FU plus levamisole. 5-FU plus levamisole significantly decreased recurrence rates and improved overall survival, particularly in Dukes' C (stage III) patients.[5] The 1990 Intergroup Trial INT-0035 study subsequently confirmed the efficacy of 5-FU plus levamisole in Dukes' stage C cancer.[6] As a result of these trials, the National Institutes of Health published a consensus statement in 1990 establishing 5-FU plus levamisole as the standard adjuvant therapy for stage III colon cancer.[7]

While the usefulness of 5-FU/levamisole in stage III disease was being confirmed, leucovorin emerged as a beneficial agent for the treatment of metastatic disease. Its applicability to stage II and stage III disease was confirmed by the IMPACT (International Multicenter Pooled Analyses of Colon Cancer Trials) study in 1995; 3-year disease-free survival increased from 62 to 71% ($p = 0.0001$) while overall survival increased from 78 to 83% ($p = 0.029$) in the 5-FU/leucovorin group.[8] The NSAPB C-03 randomized trial of stage II and stage III patients comparing MOF to 5-FU/leucovorin had documented a similar advantage of 5-FU/leucovorin, with a 3-year disease-free survival increased from 64 to 73% ($p = 0.0004$) and an overall survival increased from 77 to 84% ($p = 0.003$) in the 5-FU/leucovorin group compared to MOF.[9]

The relative merits of levamisole and leucovorin as modulators of 5-FU-based adjuvant chemotherapy, and the optimal duration of treatment have been documented in several studies between 1998 and 2000. The NCCTG/NCIC (National Cancer Institute of Canada)[10] study of 915 patients compared 6 months 5-FU/leucovorin; 6 months 5-FU/leucovorin/levamisole; 1 year 5-FU/levamisole; and 1 year 5-FU/leucovorin/

levamisole. Triple therapy for 6 months was as effective as 12 months; and 6-month triple therapy provided superior 5-year overall survival and disease-free survival compared to 5-FU/levamisole. The Intergroup Trial INT-0089 of 3,759 patients compared 1 year 5-FU/levamisole; 5-FU/high-dose leucovorin for 32 weeks; 5-FU/low-dose leucovorin for 6 cycles; and 5-FU/low-dose leucovorin/levamisole for 6 cycles.[11] There were no differences between the four treatment arms with regards to 5-year disease-free and overall survival. The NSABP CO-4 study essentially confirmed these results.[12] The QUASAR Collaborative Group study[13] confirmed the survival advantage provided by leucovorin modulation over levamisole. Based on the results of these studies, the new standard for treatment was changed to 6 months of adjuvant chemotherapy with 5-FU/leucovorin for stage III disease.

While the efficacy and benefits of adjuvant chemotherapy for stage III node-positive disease is unequivocally documented through numerous randomized trials, the role of adjuvant chemotherapy for stage II node-negative disease is still controversial. The data from the early studies which prompted the NIH recommendation for adjuvant treatment in stage III disease did not support a similar recommendation for stage II disease.[5,6] Recent meta-analyses have yielded conflicting results. The IMPACT-B_2 (International Multicenter Pooled Analysis of B_2 colon Cancer Trials) Group published a pooled analysis of five trials conducted from 1982 to 1989 and regrouping 1,016 patients with stage B_2 colon cancer.[14] Relapse rates, all-cause death rates, 5-year event-free survival and overall survival were similar with adjuvant 5-FU/leucovorin compared to controls. Increasing age and poor tumor differentiation were indicators of poor prognosis.[14] A SEER-Medicare cohort analysis of 3,700 patients with resected stage II colon cancer did not reveal any change in 5-year survival in patients having received adjuvant chemotherapy (74% vs. 72%).[15] In contrast, the NSABP concluded that all Dukes' B colon cancers should be offered adjuvant chemotherapy[16] after reviewing data from four very different trials (CO-1, CO-2, CO-3 and CO-4) regrouping 1,565 patients with Dukes' B disease, 2,255 patients with Dukes' C disease, and with widely different treatment and control arms. The authors calculated a 30% relative reduction in mortality for stage II patients having received adjuvant chemotherapy. That meta-analysis has since been widely criticized for its methodological flaws, and the controversy rages on. The likelihood of reaching a resolution on this subject is remote: in order to detect a significant survival benefit among stage II colon cancer patients (who have an estimated 5-year survival of 80%), an adjuvant trial with a no-treatment control arm would require a sample size of 5,000–8,000 patients.[17] At this time, the use of adjuvant chemotherapy for stage II disease remains an unanswered question, mainly because the prognosis for stage II node-negative disease is good overall, and many patients would face unnecessary treatment. For the time being, high-risk patients might be considered for adjuvant treatment on an individual basis or might be entered in a clinical trial.

The observation that the newer chemotherapy agents irinotecan and oxaliplatin are effective in treating stage IV (metastatic) colorectal cancer led to postulation that these agents might further improve survival in stage II and III disease. To assess the efficacy of irinotecan in the adjuvant setting, the PETACC-3 trial randomized over 2,000 patients with stage III colon cancer to 5-FU/LV plus irinotecan or 5-FU alone. In contrast to stage IV disease, no survival advantage was achieved by adding irinotecan to 5-FU (5-year survival was 74% vs. 71%) and toxicity (gastrointestinal and hematologic) was increased.[18] Results for oxaliplatin, on the other hand, are more promising. Recent data from the multicenter international randomized MOSAIC Trial have confirmed that the addition of oxaliplatin to 5-FU/leucovorin (FOLFOX) further decreases the risk of recurrence in stage II and stage III disease by 23%, resulting in a significant improvement in 3-year disease-free survival.[19] This improvement in survival has proven durable in stage III disease and 6-year overall survival recently has been reported to be 73% in the FOLFOX group compared to 69% in the 5-FU group. Toxicity also proved to be acceptable, with fewer than 1.5% of patients experiencing grade 3 peripheral sensory neuropathy.[20] Although initial reports suggested that this benefit would also extend to stage II patients,[21] longer-term follow-up has once again muddied the waters. For stage II patients, the addition of oxaliplatin offered no survival advantage over 5-FU alone. As a result of these recent studies, FOLFOX is now recommended for adjuvant therapy in stage III colon cancer. This regimen may also be useful in select stage II patients, especially those with high-risk features such as T4 tumors, vascular invasion, or poor differentiation, but definitive recommendations must await additional trials.[22]

Targeted Biologic Therapy

Over the past several years, monoclonal antibodies targeting specific tumor proteins have proven useful in treating selected patients with metastatic colorectal cancer. This utility has raised the possibility that these agents may prove efficacious in the adjuvant setting. Antibodies against epidermal growth factor receptor (cetuximab) and vascular endothelial growth factor (bevacizumab) are of greatest interest and several trials are currently accruing patients. The AVANT trial and NSABP C-08 trial both compare standard 5-FU and oxaliplatin-based therapy to standard therapy plus bevacizumab. NSABP C-08 recently has released safety data showing that the addition of bevacizumab is well tolerated.[23] The Eastern Cooperative Oncology Group 5202 is stratifying stage II colon cancer patients based upon loss of heterozygosity and microsatellite instability to test the efficacy of FOLFOX plus bevacizumab. Finally, PETACC-8 and INT No 147 are comparing FOLFOX to FOLFOX plus cetuximab in stage III colon cancer.[22,24] The results of these trials are anxiously awaited.

Radiotherapy

Local recurrence of rectal cancer after surgery with curative intent has always been recognized as a significant clinical problem. Combined chemoradiotherapy has been shown to increase both local control and survival for patients with locally advanced and node-positive rectal cancer (see below).[25] In contrast, although local failure and recurrence after surgery for colon cancer had been described, there long existed an unwritten consensus that treatment failures in colon cancer surgery were primarily systemic rather than local. Thus, no prospective randomized study was devised to provide data on the role of external beam radiotherapy in preventing local recurrence or improving survival after colon surgery. The recognition that selected individuals with colon cancer were at a high risk for local recurrence eventually came from retrospective reviews of patterns of failure after surgery with curative intent. Two large retrospective reviews helped define the risk factors for local recurrence after surgery for colon cancer.[26,27] Loco-regional failure was identified in 19%[26] to 46%[27] of patients overall; at least half of local recurrences were in the original tumor bed. Only 13% of the local recurrences were salvageable surgically.[26] The most important risk factors for local recurrence were (1) pathological staging, with local recurrence rates of 35% in modified Astler–Coller stages B3, C2, or C3 vs. 7% in stages A, B1, and C1[26]; (2) primary tumor localization in a fixed, nonperitonealized segment of the colon, with the highest failure rates in the cecum, descending colon, hepatic or splenic flexures, and sigmoid colon[26,27]; (3) colon carcinoma complicated by perforation or obstruction, with a two- to threefold increase in local recurrence for any given pathological stage.[26]

Identification of individuals at high risk for local recurrence after curative surgery for colon cancer triggered a number of studies on the role of external beam radiotherapy in preventing local recurrence or improving survival after colon surgery. Several disparate single-institutional retrospective studies suggested an improvement in local failure and recurrence rates with adjuvant radiotherapy compared to historical controls.[28–30] Wide variations in radiation techniques and doses, concurrent use and choice of chemotherapy, and patient selection criteria make comparison between studies difficult. Overall, local control rates ranged from 60 to 88%, a significant improvement over controls treated by surgery alone. A single randomized prospective study initiated jointly by the NCCTG and RTOG, comparing chemotherapy alone with F-FU/levamisole vs. combined chemotherapy/radiotherapy closed prematurely because of poor accrual; although no differences were observed in overall survival between treatment arms, the study lacked sufficient statistical power to draw valid conclusions.[31]

At this time, the precise role of adjuvant radiotherapy in the treatment of colon cancer remains undefined. There is no data to support a systematic recommendation for therapy or a well-recognized adjuvant regimen. The potential risks of adjuvant radiotherapy for colon cancer, particularly radiation damage to surrounding organs (e.g., small bowel) are significant. Treatment for individuals deemed at high-risk for local recurrence after curative surgery for colon cancer should be individualized.

Rectal Cancer

Although surgery remains the central treatment of rectal cancer, the overall approach to treatment has changed dramatically over the last three decades. Surgical technique has been refined to become more focused and precise, with specific attention given to a locally more aggressive and meticulous technique. Optimal treatment requires precise local staging as well as evaluation of potential disease spread to distant organs. The modern multimodal therapy approach individualizes rectal cancer care, thus offering the best and most appropriate treatment to every patient. Local and distant staging orients the decision for adjuvant radiotherapy and/or chemoradiotherapy and for available surgical approaches, such as local excision or an abdominal procedure.

Adjuvant/Neoadjuvant Therapy for Stage I Rectal Cancer

Like stage I colon cancer, 5-year survival after curative intent surgery (radical resection) for stage I rectal cancer exceeds 90%.[32] For this reason, adjuvant or neoadjuvant therapy is not recommended for patients who undergo radical resection of T1 or T2N0 tumors.

The morbidity of radical surgery has led some surgeons to consider local (transanal) excision for these early lesions. Advantages of local excision include sphincter preservation in some cases and the avoidance of an abdominal procedure in patients who are medically compromised. Despite these advantages, concern increasingly has arisen as to the oncologic efficacy of local excision. Recurrence after local resection of T1 tumors ranges from 4 to 18%; for T2 tumors recurrence ranges from 27 to 67%.[33–35] For this reason, adjuvant radiation and/or chemoradiation therapy after local (transanal) excision have been suggested as an adjunct to surgery to improve local control and prolong survival. Uncontrolled studies suggest that the addition of adjuvant therapy improves outcome.[34–40] ACOSOG Z6041 currently is accruing patients with T2 rectal cancers in an attempt to determine if preoperative chemoradiation followed by transanal excision will result in disease-free survival equivalent to that seen after radical surgery.[41] For patients in whom medical comorbidities preclude an abdominal procedure, adjuvant or neoadjuvant chemoradiation therapy may be appropriate to improve local control.[42]

Adjuvant/Neoadjuvant Therapy for Stage II and III Rectal Cancer

Combined modality chemotherapy and radiation have long been used as adjuvant therapy for locally advanced (stage II and III) rectal cancer. Several studies demonstrated both improved local control and prolonged survival, and resulted in the 1990 NIH consensus conference recommendation for postoperative chemoradiation therapy in these patients.[7] There is little controversy regarding adjuvant or neoadjuvant therapy for stage III (TanyN1M0) disease. However, advances in surgical technique, such as total mesorectal excision (TME), for locally advanced node-negative cancers (T3-4, N0, M0; stage II) have improved local control with surgery alone, prompting some surgeons to abandon adjuvant therapy in these patients.[43,44] Although the data from these studies are intriguing, other reports have shown that chemoradiation improves local control and survival even in patients who undergo TME.[45] Adjuvant or neoadjuvant therapy is still recommended for all patients with stage III disease and the majority of patients with stage II disease. In well-selected patients with T3 tumors, favorable histology, and negative radial margins, chemoradiation may not be necessary, but larger prospective studies are required before this approach can be recommended.

Radiation Therapy

Initial neoadjuvant radiation has long been considered an important adjunct in the treatment of rectal cancer. A short preoperative course, 20–30 Gy given over 1 week (most commonly used) is biologically equivalent to the traditional postoperative course of 45–55 Gy given over 5–6 weeks. It was long held that neoadjuvant radiation alone only improved local control but did not improve survival. In 1993, the randomized Swedish Rectal Cancer Trial (SRCT) demonstrated that a biologically equivalent short course (25 Gy) of preoperative radiotherapy with surgery within the next week significantly reduced local recurrence from 27 to 12%, and improved 5-year survival rates from 48 to 58% when compared to surgery alone.[46] The main objection to all trials showing improvement in local recurrence and survival rates with radiotherapy, including the SRCT, is that surgical technique was not optimal. The average local recurrence rate in the "surgery alone" arm in all trials discussed in the meta-analyses was 29–30%.[47–49] Although the undisputed major benefits of preoperative radiotherapy remain loco-regional tumor control and decreased local recurrence, several reports have shown that lower local recurrence rates have been achieved in specialized centers using a more meticulous surgical technique.[50–52] Several reports from different countries have confirmed that surgical skill is of utmost importance, thus opening for discussion the real role of radiotherapy when surgical technique is optimized.[53–56]

Those concerns prompted the reexamination of short-course neoadjuvant radiotherapy followed by surgery within 1 week vs. surgery alone in the Dutch trial. All participating surgeons had adopted the technical "gold standard" of total mesorectal excision (TME) before entering patients. In this randomized multicenter study of 1,861 patients with rectal cancer, 2-year local recurrence rates were significantly improved from 8.2 to 2.4% when preoperative radiation was given prior to TME.[52] Five years figures confirm a reduction in local recurrence rates from 11.4% after TME alone vs. 5.6% for preoperative radiotherapy followed by TME but this does not translate into an improvement in 5-year survival rates (van de Velde, personal communication). Thus it seems that neoadjuvant radiotherapy still has a place in the treatment of rectal cancer, even when surgical technique is optimized.[57]

The advisability of adding chemotherapy to preoperative radiation (and therefore to use neoadjuvant combined chemoradiotherapy) is undergoing intense scrutiny. Additional 5-FU-based chemotherapy may theoretically act as a radio-sensitizer at the high cost of increased hematologic and gastrointestinal toxicity. Neoadjuvant chemoradiotherapy is recommended for advanced disease (T4, N0-2), but until recently there was no randomized phase III study comparing neoadjuvant radiotherapy vs. neoadjuvant chemoradiotherapy in resectable rectal cancer (T2-3, N0-2). The EORTC 22921 trial initially reported that the addition of chemotherapy (either pre- or postoperatively) did not substantially improve survival in resectable rectal cancer; however, the survival curves began to diverge several years into the study, suggesting that a subgroup of patients might benefit from chemotherapy.[58] A recent update confirms that chemotherapy in addition to radiation therapy is beneficial for patients who respond well (ypT0-2) vs. those who respond poorly (ypT3-4).[59] Because it is difficult, if not impossible, to predict tumor response to neoadjuvant therapy, most oncologists currently recommend combination chemoradiation therapy.

Adjuvant vs. Neoadjuvant Therapy

Although combination chemotherapy and radiation have been shown to decrease local recurrence and improve survival for patients with stage III rectal cancer and many with stage II rectal cancer, the optimal timing of therapy has been controversial. Preoperative chemoradiation has been advocated based on tumor shrinkage/downstaging, improved resectability, and the possibility of performing a sphincter sparing operation in some patients. In addition, the absence of small bowel adhesions in the pelvis may decrease toxicity.[60–70] However, preoperative radiation therapy may increase operative complications and impairs wound healing.[71–75] Although preoperative endorectal ultrasound and MRI have improved our ability to stage rectal cancer, clinical "overstaging" can be problematic and neoadjuvant therapy may therefore overtreat

patients with pT1-2, N0 tumors. Advocates of postoperative radiation therapy cite more accurate pathologic staging and fewer operative/postoperative complications. However, large, bulky tumors may be unresectable or require a more extensive operation (APR, pelvic exenteration) without preoperative therapy. In addition, postoperative pelvic radiation may compromise function of the neorectum.[76]

According to three recently published meta-analyses, there is no doubt that neoadjuvant treatment is superior to adjuvant treatment with regards to reduction in local failure rates and cancer-specific survival.[47–49] The results of two out of three other trials that specifically studied preoperative vs. postoperative radiotherapy support the conclusions from the meta-analyses. The first report was the Uppsala trial in which short-course preoperative radiotherapy in all patients was compared with postoperative prolonged course only in patients with advanced cancers (stage II and III).[77] The other two trials compare neoadjuvant chemoradiotherapy with adjuvant chemoradiotherapy with same schedules and doses. The results from the NSABP R-03 trial, which closed prematurely because of poor accrual, showed that 44% of patients having undergone preoperative chemoradiation were disease-free at 1 year, compared with 34% of patients who had received postoperative chemoradiation. Results from the German CAO/ARO/AIO-94 trial address the issue of toxicity, postoperative complications, and oncologic outcome. This study randomized 823 patients with T3-4 and/or node-positive rectal cancer to either pre- or postoperative chemoradiation (5-FU-based chemotherapy + 5,040 cGy radiation). An initial report showed equivalent toxicity (11–12%), equivalent postoperative complications (12%), and equivalent anastomotic leak rate (3%).[78] A subsequent report noted that preoperative chemoradiation improved local control (local recurrence = 6% in the preoperative chemoradiation group vs. 13% in the postoperative chemoradiation group). Long-term survival was equivalent in both groups (76% vs. 74%). Interestingly, both short and long-term toxicity were significantly lower in the preoperative chemoradiation group.[79] As such, preoperative chemoradiation is now recommended for all patients with clinical stage III disease and most with clinical stage II disease.

Chemotherapeutic Agents

Like colon cancer, adjuvant and neoadjuvant therapy for rectal cancer has long utilized 5-FU-based regimens. Infusional 5-FU and, increasingly, oral 5-FU (capecitabine) have used as radio-sensitizing agents. Because additional agents such as oxaliplatin have shown synergistic efficacy in the metastatic setting, the addition of this agent to neoadjuvant regimens has been suggested. Two recent phase II studies of oxaliplatin in combination with capecitabine and radiation demonstrated good complete pathologic responses (16 and 24%) with acceptable toxicity (grade 3–4 toxicity

in only 12 and 20% of patients).[80,81] Prospective randomized phase III trials (PETACC-6 and NSABP R-04) are currently underway to assess the efficacy of this approach.[24]

Radiation Dose and Timing of Surgery After Completion of Treatment

Controversy also exists as to the optimal radiation dose and timing of posttreatment surgery. Current regimens in the USA typically give a total of 45–54 Gy of radiation over 4–6 weeks. Surgery is then performed 6 weeks later. Many European centers, in contrast, favor a short course of radiation consisting of five fractions of 500 cGY (total dose = 25 Gy) without chemotherapy followed by surgery within 1–2 weeks. Advocates of the short course of radiotherapy suggest that the lower dose of pelvic radiation will result in fewer complications while maintaining efficacy in tumor control. Earlier surgery theoretically may prevent tumor progression. Detractors counter that the lower dose may not be as efficacious and that immediate surgery does not allow enough time for maximal tumor shrinkage.[82] The Swedish Rectal Cancer Trial has shown that short-course radiotherapy improves local control and long-term survival compared to surgery alone.[83] Similarly, the Dutch Colorectal Cancer Group has shown that short-course preoperative radiotherapy decreases local recurrence and increases survival compared to total mesorectal excision alone.[45] However, there are no studies to date that compare short-course vs. long-course chemoradiation and the majority of radiation oncologists in the USA continue to offer standard 45–54 Gy treatment.

The European experience with short-course chemotherapy followed by early surgery has also led to questions about optimal timing for surgery following preoperative chemoradiation. It has been suggested that delaying resection may improve the clinical response to chemoradiation and lead to a larger proportion of patients having a pathologic complete response (pCR).[84] For this reason, several centers have begun to study the timing of surgery following neoadjuvant treatment. Stein et al.[85] performed a retrospective review of 40 patients who underwent chemoradiation for low rectal cancer followed by resection from 28 to 97 days later. These authors found no difference in tumor response based upon the timing of resection. Moreover, no difference could be detected in peri-operative morbidity. However, definitive conclusions await larger studies.

Chemotherapy Alone

In contrast to colon cancer, chemotherapy alone as adjuvant treatment in rectal cancer remains questionable. Early 1980s underpowered US radiotherapy trials concluded that chemotherapy improved survival compared to surgery alone. Two large randomized trials comprising more than 4,000 patients

have studied the value of chemotherapy vs. surgery alone in colorectal cancer. Rectal cancer patients were included in both studies. Combination 5-FU/levamisole and 5-FU/leucovorin were found to improve survival in colon cancer patients but showed no benefit in rectal cancer patients.[86,87] These results underscore the difference in chemotherapy effectiveness for rectal cancer and colon cancer. The reasons for this are unclear: different tumor profiles or lack of proper surgical technique at the time of these trials may partly explain the results. At this time, adjuvant chemotherapy alone for stage III rectal cancer is not acceptable.

Neoadjuvant Therapy in Unresectable Rectal Cancer

Based on the literature, it is obvious that there is no uniform definition of a nonresectable rectal cancer. For the purpose of this section we will define a nonresectable rectal cancer as a tumor which cannot be resected without a very high risk of local recurrence. These tumors are clinically tethered or fixed, but it is difficult to know whether or not the fixity is due to cancer overgrowth or fibrosis. Such tumors probably involve the rectal fascia, and resection carries a high likelihood of involvement of the circumferential resection margin. Based on available data, patients with such large tumors benefit from long-course preoperative radiotherapy (45–55 Gy over 5–6 weeks) with the aim of downsizing the tumor. Approximately 10–15% of all patients with rectal cancer have an advanced cancer which could be considered nonresectable; half of those patients have no metastases, indicating that there is potential for a curative procedure.[88] Based on tumor characteristics, surgery alone is unlikely to be curative and it is indicated to offer radiotherapy to those patients.

The role of additional chemotherapy has been unclear in this context. There is very little solid evidence from randomized trials using chemoradiotherapy. One older trial from 1969 reports positive results from chemoradiotherapy in locally unresectable rectal cancer.[89] Two other negative trials, published in the late 1980s reported increased toxicity.[90,91] One recent underpowered Swedish trial (2001) showed improved local recurrence rate and overall survival in patients randomized to chemoradiotherapy vs. radiotherapy alone followed by surgery.[92] Several phase II trials have reported a reduction in local recurrence rates and impressive data regarding survival;[93,94] problems with interpretation of case-mix and definition of "nonresectability" make the results of those trials difficult to interpret. One study including 106 patients with unresectable rectal cancer has shown improved local control and survival in patients who receive aggressive multimodality therapy (preoperative chemoradiation, surgery, and intraoperative radiation).[95] Despite the lack of strong evidence, this approach is probably reasonable in selected patients who will tolerate such an aggressive approach. Newer chemotherapeutic agents currently in use or under study for treatment of locally advanced and metastatic colon cancer (especially oxaliplatin) will doubtlessly be evaluated for their usefulness in neoadjuvant and adjuvant treatment of rectal cancer in the near future. Their efficacy and usefulness is unknown at this time.[96]

Neoadjuvant Therapy and Sphincter Preservation

Several series claim that preoperative radiotherapy (and preferably chemoradiotherapy) downsizes tumors to the extent that it is possible to increase the number of patients in whom the sphincters can be preserved.[97–101] There is even a report showing complete response to chemoradiotherapy in some patients with T4 tumors; some of these patients were not operated upon and reportedly remain alive and well.[84]

Caution must be exercised when reading these studies. First, rates of sphincter preservation do not tell the entire story; second, the main criticism of these studies is that modern therapies are compared to historical controls. The dramatic recent changes in surgical technique (TME, staplers) and the modern approach to rectal cancer treatment may partially explain the increased rate of sphincter preservation. We now accept a 5–10 mm distal margin as curative procedure if a stapled anastomosis is done.[102,103] Modern randomized trials must be done to verify the sturdiness of the conclusions. In the French R9001 trial, patients with T2 and T3 tumors received preoperative 39 Gy (13×3 Gy) and were randomized to immediate surgery or surgery 5 weeks after irradiation. Surgeons were asked before any treatment to evaluate the possibility to preserve the sphincters. Delaying surgery for 5 weeks after the end of radiation only slightly increased the rate of sphincter preservation.[104] This small trial indicates that there might be a downstaging and downsizing effect, which in turn might increase the rate of sphincter preservation. Of note, the overall recurrence rate in the trial was 9%, which is considered a high figure; more crucially, the local recurrence rate was 12% among the patients in whom the surgeon had originally planned an APR but changed intraoperatively to a sphincter-preserving procedure because of the downsizing effect of radiotherapy.[104] The German trial (CAO/ARO/AIO) trial had a more positive result. Among 194 patients initially determined to require APR, neoadjuvant therapy allowed sphincter preservation in 39% compared to 19% in the postop adjuvant-treated group.[79] Nevertheless, long-term outcome in the patients who underwent sphincter preservation have not yet been compared to patients who underwent APR.

An important consequence of increased sphincter preservation is poor function. Poor quality of life may be the price to pay for intact sphincters: up to 20% of all patients who undergo a low anterior resection are incontinent of solid stool.[105] This contrasts with reports that patients with a stoma had a better quality of life compared to those with an anterior resection.[86] This must be considered when selecting surgical options for individual patients.

Immunotherapy, Tumor Vaccines, and Gene Therapy

The goal of cancer immunotherapy treatments is to stimulate the body's immune system in order to improve host defense mechanisms against growing tumors. Colorectal cancer immunotherapy strategies have evolved dramatically over the past 30 years. Nonspecific immune stimulation with bacterial cell products (e.g., BCG) and cytokines (e.g., IL-2) has recently been superseded by more specific immune stimulation targeted against colorectal tumor-expressed antigens. While some tumor antigens are present in normal tissues but overexpressed in cancer, other tumor antigens are restricted to cancer tissues. Vaccines stimulate the immune system to recognize and act specifically against these tumor-expressed antigens, through either the humoral or cellular pathway.

Over 25 phase I and phase II studies have explored a variety of vaccines based on whole colorectal tumor cells, virus-modified tumor cells, gene-modified tumor cells, tumor antigen-derived peptides, tumor cell lysates, proteins or carbohydrates, monoclonal antibodies, plasmid or viral vectors encoding tumor antigens, and dendritic cell-based vaccines. Promising results were observed in some animal models and phase I and II studies, prompting ongoing research efforts.

A few phase III studies have also yielded promising results.[106] Three large studies have looked at the effect of immune stimulation with autologous irradiated tumor vaccine plus BCG in colorectal cancer patients. Hoover et al.[107] randomized 98 patients with colon or rectal cancer to surgical resection alone or surgical resection followed by vaccination with autologous irradiated tumor plus BCG. There was no difference in disease-free or overall survival in 80 eligible patients, but subset analysis showed a significant improvement in disease-free survival for colon cancer patients. The Eastern Cooperative Oncology Group (ECOG) randomized stage II and stage III colon cancer patients to either observation or vaccination with autologous irradiated tumor plus BCG. There was no survival difference between groups, but patients with a marked delayed cutaneous hypersensitivity showed a trend toward better disease-free and overall survival, suggesting that survival correlated with the patient's immune response to vaccination.[108] Vermorken et al.[109] randomized 254 patients operated for colon cancer to either observation or vaccination with autologous irradiated tumor plus BCG immediately post-op, followed by a vaccine booster 6 months post-op. The overall risk for recurrence was decreased by 44% in all vaccinated patients, with a 61% reduction in stage II patients. Vaccination significantly increased recurrence-free survival, and there was a trend toward improved overall survival.[109]

Gene therapy is based on the concept of transferring genetic material into target cells, which would allow for correction of genetic defects in tumor suppressor genes, inactivation of oncogenes, or insertion of treatment-sensitizing genes (such as drug-converting enzymes) or "suicide genes" into the colorectal cells. Correction of p53 mutations, inactivation of k-ras gene product p21, delivery of pro-drug-converting enzymes are currently being studied. The long-term potential for clinical usefulness of these techniques remains to be defined.

Molecular Profiling and Chemoresistance

Increasingly, tumor characteristics are found to influence response to chemotherapy and "personalized" treatment based upon molecular profiling shows increasing promise for increasing response to therapy while decreasing toxicity. Microsatellite instability (MSI) and rates of phenotypic expression of DNA synthesis-associated enzymes recently have been found to predict chemoresistance to 5-FU and irinotecan.[110,111] For example, microsatellite instability appears to confer not only better prognosis but may also predict poor response to chemotherapy, suggesting that patients with MSI-high tumors may not benefit from adjuvant therapy.[112] Similarly, polymorphisms in the enzymes that synthesize and metabolize folate may affect both efficacy and toxicity of 5-FU-based therapy.[113,114] Finally, the observation that k-ras status predicts response to EGFR-targeted therapy in metastatic colorectal cancer has implications for adjuvant therapy.[115,116] This is an area of research which is evolving rapidly, and our increasing knowledge on the impact of molecular characteristics will certainly change the recommendations for adjuvant treatment in the future.

Colorectal Cancer: Metastatic (Palliation)

Elisabeth C. McLemore and Sonia Ramamoorthy

Introduction

Approximately 20% of colorectal cancer patients present with established distant metastases.[1] Metastases are often detectable with noninvasive imaging such as CT scan and MRI that are performed for staging of cancer. A diagnosis of stage IV disease then allows for appropriate operative and oncologic planning. Among these patients there is enormous heterogeneity with respect to sites of disease, extent of disease, symptoms, performance status, and comorbidities. The clinical spectrum at the time of diagnosis ranges from the asymptomatic patient with a single metastatic lesion to the rapidly deteriorating patient with colon obstruction and advanced, multiorgan metastases. While treatment algorithms may exist for some forms of metastatic disease such as a solitary liver lesion, others are still being defined.

Despite considerable progress in the treatment of advanced colorectal cancer, the vast majority of stage IV patients are not curable by current treatment protocols. A recent analysis of data from the SEER population-based database estimates that the 5-year survival rate for stage IV patients diagnosed between 1991 and 2000 was 8%.[2] Despite a low overall cure rate treatment options are available to extend survival and enhance quality of life. Systemic chemotherapy, endoscopic treatments to palliate obstruction, surgical diversion, and surgical resection all have important roles in treatment of stage IV patients. Treatment approaches must be individualized based on the extent and resectability of local and distant disease, the presence or absence of bowel obstruction, performance status, and co-morbidities. For patients with good performance status and minimal symptoms from their primary cancers, standard treatment is systemic chemotherapy, which is well documented to increase survival and quality of life.[3,4] Surgical resection of the primary tumor and if indicated, of the metastatic lesions can provide excellent palliation, and in some cases can provide lasting cure.

First-line therapy with either FOLFOX or FOLFIRI now yields major responses in up to 50% of previously untreated patients, and achieves minor responses or stable disease in an additional 20% of patients.[5] Multiple effective drug combinations are available as well, and second-line chemotherapy has become more effective and more likely to impact survival. Over the past 10 years, the median survival for patients with metastatic disease who are treated with chemotherapy has improved from 12–14 to 21 months.[6] Although cure from chemotherapy alone remains extremely rare, effective chemotherapy combined with aggressive surgery may be increasing the overall cure rate. In this setting, the care of patients with advanced disease has become quite complex. The goal of this chapter is to provide a reference source for surgeons managing patients who present with metastatic stage IV colorectal cancer.

Biology of Metastatic Disease

Metastasis is defined as the spread of malignant cells from a primary tumor to a distant organ. It is estimated that 90% of all cancer deaths are a result of metastasis.[7] The biologic process of metastasis is poorly understood. Numerous clinical and laboratory studies have attempted to define the complex process of metastasis formation. The process relies on properties of the tumors cells, as well as the microenvironment of the primary and secondary sites.[8,9] A series of major events must occur (Figure 47-1).

The first step is tumorigenesis, which occurs after the initial malignant transformation. The tumor proliferates into a small mass of heterogeneous cells that are of varying metastatic or malignant potential. These tumor cells undergo multiple and sequential genetic changes, characterized by the appearance of oncogenes and a decrease in tumor suppressor genes. As the tumor grows beyond 1 mm in diameter and becomes relatively hypoxic, angiogenesis is initiated. The process of tumor angiogenesis is tightly regulated by pro- and anti-angiogenic factors secreted by both the tumor and its environment. As tumors successfully grow, suppressors of angiogenesis are inhibited and pro-angiogenic factors predominate, resulting in neovascularity and further growth of
FIGURE 47-1. Schematic illustrating the multistep process involved in the development of metastasis. (With permission from DeVita VT Jr., Hellman S, Rosenberg SA. Cancer: Principles and Practice of Oncology, 6th ed., Lippincott Williams and Wilkins, copyright 2001).

the tumor.[10] Some tumors may grow by utilizing other existing blood vessels in nearby tissues.

In the next step, some cells will develop an invasive phenotype. Most researchers believe that there is a selection process resulting in the clonal expansion of certain cell sub-populations with growth advantages and invasive properties. Whether this process represents a property of the whole tumor cell mass or true clonal selection of more invasive cell sub-populations is not known, and it is a subject of intense research.[11] Malignant invasion is characterized by down-regulation of cell adhesion, resulting in detachment of the cell from the primary tumor mass and the extracellular matrix. Stromal invasion is accomplished through interactions with the basement membrane, including adhesion, proteolysis, and migration, ultimately resulting in detachment and invasion through the basement membrane. This invasive phenotype also enables these cells to enter thin-walled lymphatics and vasculature, allowing access to systemic circulation.[12,13]

Once inside the vascular system, cells or cell clumps (emboli) are circulated, and must survive hemodynamic filtering as well as immune surveillance. They must then arrest in a distant organ. There is likely a complex inter-action between the malignant cell and the endothelium or exposed basement membrane, allowing cell arrest. Once arrested in a tissue bed, the cells extravasate into the tissue, enabling formation of a metastatic focus. These metastatic cells can become dormant or proliferate; what determines this fate is not fully understood. Growth in the distant organ after deposition is a major limiting factor in the formation of metastasis. Some metastatic cells can remain dormant while others proliferate, and must again go through tumori-genesis, angiogenesis, and evasion of the immune system. This complex multistep process of metastasis formation is related to multiple genetic changes among malignant cells. Recent studies have shown differences in the genetic fin-gerprints of matched primary tumors and their lymph node metastasis suggesting that tumors may undergo continual mutagenesis. The metastatic tumor cells may genetically look very different from its parent primary tumor cells.[14] This finding appears to confirm that there are genes specific to tumorigenesis, invasion, angiogenesis and other steps. A number of genes have been identified that suppress meta-static potential and, by their down-regulation, affect a cell's ability to metastasize without affecting tumorigenicity.[14]

These discoveries provide a sense of the future challenge in elucidating the multiple, step-wise and specific changes that regulate a cell's ability to metastasize. Advances in this field will have obvious and profound implications for the treatment of cancer.

Diagnosis/Staging

Initial staging evaluation should include colonoscopy with biopsy, and imaging of the primary tumor, liver, and lungs. When feasible, endorectal ultrasound or MRI is recommended for rectal cancers to document the initial T and N stage. Spiral CT scanning of the chest/abdomen/pelvis is a highly accurate and efficient method of detecting metastases. PET scanning detects occult disease not seen on CT scan in 20% of stage IV patients and should be considered if such findings might affect patient management.[15] Increasingly, more patients are undergoing combination CT/PET scans to evaluate both the primary and metastatic lesions as this combined modality allows for better localization of tumor deposits and can assist with operative planning as well as radiation-based therapy.[16]

Once the extent of disease workup is complete and distant metastases have been documented, the surgeon must make three important judgments. First is whether the patient is fit for aggressive treatment. Patients with poor performance status or serious co-morbidities may not tolerate chemotherapy or major surgery. Second is whether the primary tumor presents a clinically significant risk of bowel obstruction. Symptoms, radiographic findings, and endoscopic findings are important considerations. If the proximal colon is not dilated on radiographic studies and a colonoscope can traverse the tumor, it is generally safe to begin treatment with chemotherapy. The third determination is whether the patient's metastases are surgically resectable, and the patient can be treated with curative intent. If complete resection of all disease can be expected, then surgical intervention should be attempted.

Multidisciplinary Evaluation

Management of patients with advanced disease is complex, and multidisciplinary evaluation can be helpful in determining initial therapy. The multidisciplinary team or "tumor board" ideally involves a surgeon, medical oncologist, radiation oncologist, pathologist, radiologist, and gastroenterologist. As treatment plans become increasingly complex and we enter an era of targeted therapies for specific gene mutations, patients are best served in a center where the goals, priorities, and expected course of treatment, as well as opportunities for enrollment into clinical trials are reviewed and vetted through a multidisciplinary group of experts.

Palliative Management of the Primary Cancer: Laser, Fulguration, and Stents

Incidence and Presentation

Approximately 8–29% of patients with colorectal cancer initially present with symptoms of partial or complete bowel obstruction.[17] In a review of 713 obstructing carcinomas, 77% were left-sided and 23% were right-sided cases.[18] The majority of patients with obstructing colorectal carcinomas have either stage III or stage IV disease.[19] Acute malignant colon or rectal obstruction is an indication for emergent surgical intervention. However, these emergency operations are associated with a mortality rate of 15–34% and a morbidity rate of 32–64% despite advances in perioperative care.[19,20] Therefore, alternative palliative endoluminal strategies aimed at relieving obstruction have gained increasing popularity over the past decades.

The initial symptoms of bowel obstruction include mild discomfort and a change in bowel habits. With disease progression and luminal narrowing, the symptoms may worsen ranging from crampy abdominal pain, abdominal distension, nausea, abdominal tenderness, and obstipation. Vomiting is a late symptom unless there is an associated small bowel obstruction. Leukocytosis is a concerning finding and may indicate a near or complete obstruction. Without treatment, the process can progress to complete obstruction, ischemia, and perforation. The risk of cecal perforation is greatest in patients who have a competent ileocecal valve which does not allow decompression of the large intestine into the proximal small intestine.

In the setting of metastatic cancer, the clinician must first answer the following critical question, "is the colon or rectal obstruction a contraindication for systemic chemotherapy or radiotherapy?" The degree of obstructive symptoms, endoscopic, and radiographic findings are key elements to consider when answering this question. If the patient has minimal symptoms, the cancer can be traversed endoscopically, and there is no radiographic evidence of high grade obstruction, many patients with partially obstructing colon and rectal cancers will tolerate aggressive chemotherapy. In those patients with partially obstructing rectal cancers, the addition of radiation therapy is also well tolerated and can be highly effective. Patients must be instructed to monitor their symptoms closely, and to report any signs of worsening obstruction immediately. A liquid diet or pureed diet with adequate protein and calorie intake taken in small portions may help reduce obstructive symptoms. For patients with advanced obstruction, nonsurgical palliative options include laser therapy, fulguration, and colonic self-expanding metal stents. If less invasive endoluminal strategies are not successful in patients with nonresectable malignant obstruction of the colon and rectum, surgical creation of a palliative proximal diverting stoma or intestinal bypass should be performed.

Laser Therapy and Fulguration

Laser therapy has been utilized for palliation of obstructing rectal cancers.[21–24] In a large series of 272 patients who underwent palliative laser therapy for rectosigmoid cancers, the immediate success rate in treating obstructive symptoms was 85%.[25] Other studies have shown similar success rates, in the range of 80–90%.[23,24] However, laser therapy is practical only for treating cancers of the distal colon and rectum and is rarely used to treat proximal lesions. In addition, multiple sessions are often required in order to achieve lasting relief of symptoms. Serious complications like bleeding, perforation, and severe pain have been reported in 5–15% of patients, especially those undergoing multiple treatment sessions.[22,24–26]

Surgical fulguration of rectal cancers is another method of opening the rectal lumen and relieving obstruction.[27,28] Fulguration, in combination with endoluminal debulking, can remove a large volume of tumor. However, unlike laser therapy, fulguration and debulking requires hospital admission and regional or general anesthesia.

Self-Expanding Metal Stents

Since their introduction in 1991, colonic stents have become an effective method of palliation for obstruction in colorectal cancer patients, especially those with unresectable metastatic disease. These self-expanding metallic stents can potentially dilate the lumen to a near-normal diameter, providing quick relief of symptoms. Stents can be placed in patients using minimal sedation and allow endoscopic assessment of the proximal colon. Moreover, these stents can be placed across relatively long lesions by overlapping stents in a "stent-within-stent" fashion. Laser therapy has also been used in certain situations, in conjunction with colonic stents, to recanalize and decompress large bowel.

A systematic review from 1990 to 2000 of the published data on stenting of colorectal obstruction included 29 case series in the analysis.[29] The review evaluated technical and clinical success, complications, and reobstruction. Cases involving stent placement for palliation and stent placement as a "bridge to surgery" were both assessed. Stent insertion was attempted in 598 cases. Stent deployment was technically feasible in 551 (92%) cases and clinically successful in relieving obstruction in 525 (88%) cases. Palliation of obstruction was achieved in 302 (90%) of 336 cases. Stent placement as a "bridge to surgery" was successful in 223 (88%) of 262 insertions of which 95% had a one-stage surgical procedure. There were three deaths (1%). Perforation occurred in 22 cases (4%). Stent migration was reported in 54 (1%) of the 551 technically successful cases. Stent reobstruction occurred in 52 (10%) of 525 clinically successful cases and trended toward a higher incidence of reobstruction in the palliative treatment group.

The reviewers concluded that "stent usage can avoid the need for a stoma and is associated with low rates of mortality and morbidity."[29] A series of 52 patients with malignant obstruction secondary to either primary or recurrent colon or rectal carcinoma, who underwent stent placement by colorectal surgeons reported that 50 out of 52 were successfully palliated.[30] One patient had a perforation, and in another patient obstruction was not relieved because of multiple sites of obstruction. The overall complication rate in this series was 25%. Stent migration was the most common complication (15%), followed by reobstruction secondary to tumor ingrowth (4%), perforation (2%), colovesical fistula (2%), and severe tenesmus (2%). Surgical intervention was required in 17% of cases due primarily to one of the above complications or recurrent obstruction.

A large series of 102 colorectal stents placed over a 5-year period predominantly for palliative intent reported success in 87 patients (85%).[31] The procedure was performed as a palliative procedure in 90 of these patients. Stent placement location was primarily in the rectum, rectosigmoid, and sigmoid colon ($n = 75$). The location of the remaining stents were descending colon ($n = 15$), splenic flexure ($n = 3$), and transverse colon ($n = 3$). Perforation occurred in four patients. Late complications occurred in 9%, and included five stent migrations, two blocked stents, and one colovesical fistula. Ninety percent ($n = 76$) of the successful cases needed no further radiological or surgical intervention.[31]

There is limited data evaluating stent placement proximal to the splenic flexure. In a recent publication, colonic stenting was attempted in 97 patients with malignant large-bowel obstruction.[32] Sixteen (17%) patients had lesions proximal to the splenic flexure (eight ascending, eight transverse colon). Stenting was successful in relieving obstruction in 14 (88%) of these patients. Stenting was performed for definitive palliation in nine of these patients, and as a bridge to elective surgery in the other seven patients. One patient developed gastrointestinal bleeding that was managed conservatively. No perforations or stent migrations were reported.[32]

Complications reported in the literature for colonic and rectal stents include stent malpositioning, stent migration, tumor ingrowth (through the stent interstices), tumor overgrowth (beyond the ends of a stent), perforation, stool impaction, bleeding, tenesmus, and postprocedure pain. Stenting of cancers in the mid to low rectum may result in urgency, pain, and incontinence. While the complications associated with stents and other less invasive endoluminal strategies should not be taken lightly, one must keep in mind that emergency operations for malignant colon and rectal obstruction have a mortality rate of 15–34% and a morbidity rate of 32–64%. As more experience is gained, these endoluminal palliative strategies provide increasingly effective and durable relief for patients with malignant obstruction.

Surgical Management of the Primary Cancer: To Resect or Not to Resect?

The role of surgical resection of the primary colon or rectal cancer in patients with unresectable metastases is controversial. It is important to recognize that there are no randomized controlled trials demonstrating a survival benefit for bowel resection in stage IV patients. However, palliative resection of the primary tumor does provide durable local control, is generally well tolerated, and can benefit select stage IV patients.[33] Randomized trials of 5FU-based chemotherapy vs. best supportive care, conducted in the 1990s, have shown that stage IV patients receiving systemic chemotherapy have increased length and quality of life.[34] Moreover, with modern multidrug regimens and monoclonal antibody therapy options, the beneficial impact of chemotherapy continues to increase. At this time, standard management for patients with unresectable metastatic colorectal cancer is systemic chemotherapy.

The proper use of elective colon and rectal resections in nonobstructed patients is a source of continuing debate. Loss of performance status, risk of surgical complications, and delay in chemotherapy are potential downsides to palliative surgical resection. On the other hand, elective operations have a far lower morbidity than emergency surgery. In addition, there are increased risks and potential complications associated with operations performed on patients who develop large-bowel obstruction while receiving chemotherapy or who present with more advanced disease after multiple cycles of ineffective chemotherapy.

Table 47-1 lists six retrospective studies comparing operative and nonoperative management of the primary cancer in patients with stage IV colon and rectal cancer.[34–38] The data is predominantly from the 1990s, when 5-flourouracil-based chemotherapy was the standard systemic therapy. In all of these studies, the majority of patients were treated by initial resection of the primary cancer. Patients who did not undergo surgical resection were more likely to have rectal cancers, to have more extensive metastatic disease, and to be older. The operative mortality for patients undergoing initial bowel resection ranged from 1.6 to 11%. Patients who did not undergo bowel resection underwent a subsequent colorectal operation in 9.3–32% of cases, although the indications for subsequent operation were often not specified and "colorectal operation" included palliative stoma creation and intestinal bypass. From these limited data, it is clear that initial colon resection is frequently practiced, particularly for patients with colon primaries and with less extensive metastatic disease. However, it is difficult to assess the impact of colon and rectal resection on symptom control, tolerance to subsequent chemotherapy, quality of life, or survival from these studies.

A recent meta-analysis evaluating patients with stage IV colorectal cancer treated with chemotherapy combined with and without surgical resection revealed prolonged survival in patients undergoing palliative surgical resection and chemotherapy when compared to chemotherapy alone.[39] Chemotherapy regimens included 5-flourouracil, oxaliplatin, and irinotecan. Eight retrospective studies with a sum total of 1,062 patients met the inclusion criteria for this study. The median survival for palliative surgical resection

[b] Significant difference in median survival ($p < 0.0001$).

combined with chemotherapy ranged from 14 to 22 months (data extracted from studies with 100% patient participation in systemic chemotherapy). The median survival for chemotherapy alone was 6–15 months. The estimated standardized median difference in survival was 6.0 months in favor of palliative surgical resection (standardized difference 0.55; 95% CI 0.29, 0.82; $p<0.001$). In addition, patients managed with chemotherapy alone were more likely to experience a complication related to the primary tumor (95% CI 1.7, 34.4; $p=0.008$). There was no difference in the incidence of metastatic disease tumor burden becoming more favorable and amenable to curative resection after systemic chemotherapy in either group (0.85; 95% CI 0.40, 1.8; $p=0.662$). There are obvious limitations of this meta-analysis given the retrospective nature of the studies available for review as well as the chemotherapy regimens utilized in these studies not being equivalent to current regimens. The group acknowledged these limitations and concluded that palliative resection of the primary tumor in asymptomatic or minimally symptomatic patients with stage

IV colorectal cancer is associated with prolonged survival. In addition, palliative resection of the primary tumor is associated with a reduced incidence of complications from the primary tumor and the need for emergency procedures.[39]

There is little published data evaluating the effectiveness of radiotherapy in palliative management of stage IV rectal cancer. Crane and colleagues reported 55 patients who received chemoradiotherapy and 25 patients who received chemoradiotherapy followed by surgery. The majority of both groups received systemic therapy (78% of patients).[40] Pelvic symptom control was high (81%) in the chemoradiotherapy group but not as high as in the chemoradiotherapy combined with surgical resection group (91%). There was limited data on the durability of symptom control over time.

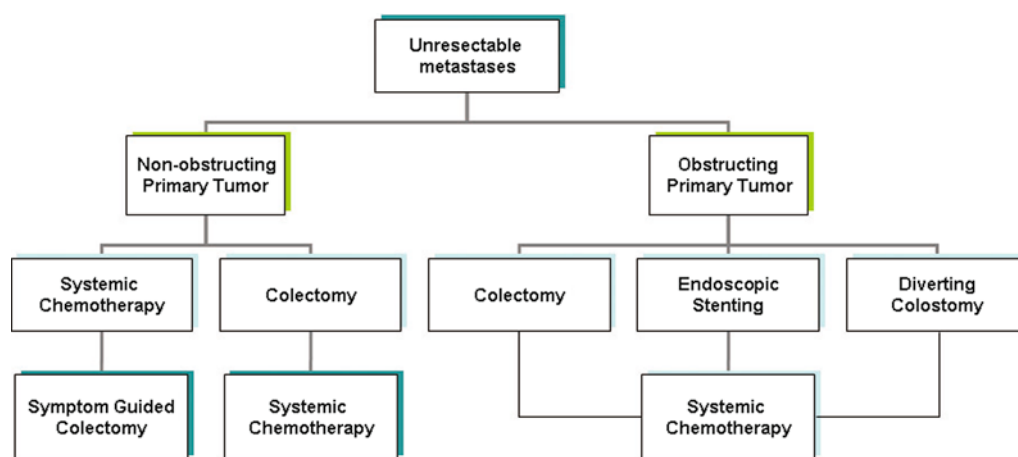
To summarize the treatment options for stage IV patients with unresectable metastases, treatment algorithms are shown for patients with stage IV colon cancer (Figure 47-2) and stage IV rectal cancer (Figure 47-3). The algorithms show multiple treatment options, reflecting the heterogeneity


FIGURE 47-2. Treatment algorithm for patients with stage IV colon cancer: use of palliative colon resection.
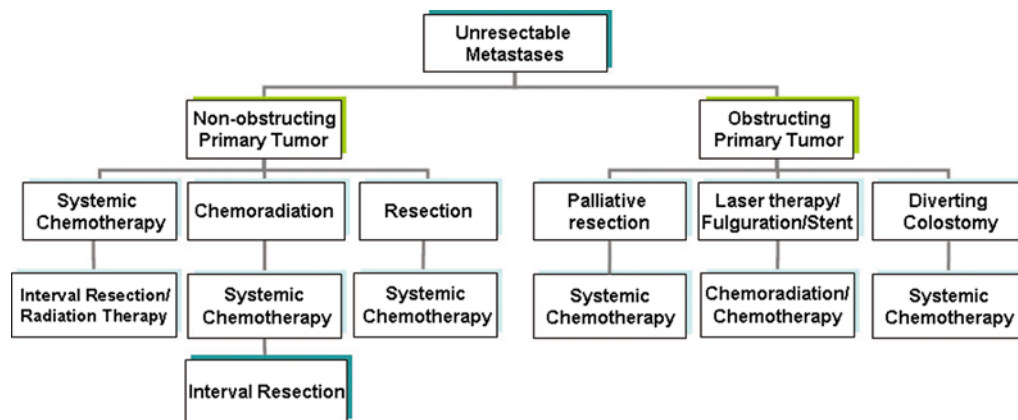

FIGURE 47-3. Treatment algorithm for patients with stage IV rectal cancer: use of palliative rectal resection.

of disease presentation. The major variables to consider are location of the primary tumor, degree of colon and/or rectal obstruction, extent of metastatic disease, and fitness of the patient for surgery. For patients with nonobstructing primary tumors, initial treatment with systemic chemotherapy is favored because, in this era of increasingly effective chemotherapy, it is important that patients be given the full benefit of aggressive systemic therapy. However, it should be remembered that the goal of therapy is effective palliation, and surgical resection remains the most effective and durable local treatment option.

Liver Metastasis

Of the 150,000 new cases of primary colorectal cancer diagnosed in the USA each year, approximately 60% of these patients will develop liver metastases and about one-third will have disease limited to the liver.[1] Liver resection and tumor ablation are currently the only available curative treatments for metastatic colorectal cancer with 5-year survival ranging from 28 to 45%.[41] Overall, it is been estimated that about 10% of all patients with colorectal liver metastases are candidates for potentially curative hepatic surgery.[42] Of those able to undergo complete hepatic resection, 25–35% achieve long-term survival.[43] The remaining majority of patients receive palliative therapy. This underscores the importance of patient selection in determining optimal treatment. These statistics also highlight the fact that the majority of patients with liver metastases have unresectable disease and require evaluation for chemotherapy or supportive care. It should be noted, however, that with improvements in chemotherapy, surgical technique, and ablative techniques, the number of patients eligible for hepatic surgery is on the rise.[44,45]

Natural History of Untreated Liver Metastases

In order to understand the impact of any therapy on outcome for patients with hepatic colorectal metastases, the natural history of untreated disease must be reviewed. This is especially relevant in understanding the impact of surgery for hepatic metastases, as there has never been a randomized trial comparing any therapy to surgery (nor is there ever likely to be). Prior to the 1980s, most hepatic metastases were left untreated. Several investigators have retrospectively studied untreated patients, documenting median survivals of 5–10 months; long-term survival was rarely seen.[46] The majority of these patients, however, had extensive disease, and most had their primary tumor in place, making comparison to modern surgical series irrelevant. Nonetheless, some investigators retrospectively identified patients with isolated, potentially resectable hepatic metastases who were left untreated. In these patients with limited metastases isolated to the liver, who would otherwise be potential candidates for surgery, 3-year survival was 14–23% and 5-year survival was 2–8%.[46–48] While these studies were instrumental in demonstrating the relationship between bulk of disease and survival, they also clearly showed that, even in the best of circumstances, 5-year survival of patients with untreated liver metastases is distinctly uncommon.

Diagnosis

Once a diagnosis of colorectal cancer is made a careful evaluation is made to accurately stage the patient with appropriate imaging. Complete cross-sectional imaging of the abdomen and pelvis with triple phase CT and or MRI is essential to rule out extrahepatic disease. The additional advantage of routine chest CT is low compared to that of a plain chest X-ray but should be considered in high-risk cases.[49,18] F-FDG positron emission tomography (PET) scanning is routinely performed because of early prospective data documenting its utility. The information obtained from PET scanning changes management decisions in patients with recurrent colorectal carcinoma 20–50% of the time. The major strength of PET scanning appears to be the detection of occult extrahepatic disease.[18] In many centers, the combination of PET/CT imaging allows for operative planning and accurate tumor localization. Once the issue of extrahepatic disease has been addressed, high-quality imaging of the liver is essential in determining bulk of disease and resectability. CT scans are the most common modality used to address liver disease and, with modern dynamic helical scanning techniques, this remains the mainstay of hepatic imaging. Routine CT scans can now evaluate the liver in combination with CT angiography or triphasic imaging of the parenchyma through various phases of intravenous contrast circulation.

Ultrasound and magnetic resonance imaging (MRI) are additional imaging techniques that can be useful in specific circumstances. Ultrasound is not an accurate method for addressing extrahepatic disease and, indeed, often cannot visualize the entire liver. However, in experienced hands ultrasound is excellent at distinguishing neoplastic tumors from benign lesions such as cysts, focal nodular hyperplasia or hemangiomata. Additionally, ultrasound can specifically evaluate the relationship of specific lesions to major vascular structures and the biliary tree. It can be of particular utility when performing intraoperative ablative procedures. MRI is an excellent method for characterizing liver lesions. Particularly if there are multiple hepatic lesions, not all of which are suspected to be metastatic tumors, MRI can help distinguish malignant lesions from cysts, hemangiomata, and other benign lesions. MRI is also an excellent modality for evaluating relationships of tumor to the biliary tree (via magnetic resonance cholangiopancreatography – MRCP) and to hepatic vasculature. High-quality MRI and triple phase CT are probably equivalent for evaluating extent of liver disease, and as aids in surgical planning.[50–52] In any patient being considered for hepatic resection, a complete medical workup should be performed to assess the patient's fitness for undergoing a major abdominal operation.

Any potential for liver dysfunction, such as alcohol abuse or chronic hepatitis, must be carefully evaluated.

Treatment Options

In the patient who presents with liver metastases, the first consideration must be whether the liver disease is curable. The second consideration is whether the patient's disease if initially unresectable can be made amenable to surgery or ablative procedures with the addition of systemic chemotherapy.

Chemotherapy

Until recently, chemotherapy was considered largely ineffective as treatment of unresectable metastatic colorectal cancer. However, with the development of irinotecan, oxaliplatin, hepatic arterial infusional chemotherapy with FUDR, and newer molecular-based therapies, there are now more effective chemotherapeutic options for these patients. For nearly 50 years, 5-fluoruracil (5FU) was the only effective chemotherapeutic regimen for metastatic colorectal cancer. Despite many attempts to modify 5FU with other agents, response rates generally ranged from 15 to 20%, and survival beyond 1 year was uncommon. The addition of leucovorin (5FU/LV) and the use of infusional dosing techniques are associated with an increased response rate, and are commonly utilized despite no improvement in survival.[53,54]

Irinotecan (CPT-11) in conjunction with 5FU/LV has been recently shown to be more effective than 5FU/LV alone for treatment of metastatic colorectal cancer. Two randomized trials established the superiority of single-agent irinotecan over 5FU/LV alone or best supportive care as second-line therapy.[55,56] Additionally, two randomized trials utilizing combined irinotecan/5FU/LV (FOLFIRI) as first-line chemotherapy have shown response rates of 40%, with modestly improved survival (median 15–17 months vs. 12–14 months).[57,58] The addition of oxaliplatin has been particularly exciting because of the in vitro sensitivity seen in cisplatin-resistant cell lines, as well as its synergy with 5FU.[58,59] In a trial comparing oxaliplatin/5FU/LV (FOLFOX) to 5FU/LV, response rates for FOLFOX were in excess of 50% (compared to 22% for 5FU/LV). There was no difference in survival, but this is likely due to a 37% crossover from 5FU/LV to FOLFOX during the trial.[60] Early analyses of comparisons of irinotecan/5FU/LV to FOLFOX have so far shown FOLFOX to yield superior response rates.[61] Ongoing trials continue to define optimal timing, dosing, and sequence of various combination regimens.

Biomarker Targeted Therapy

Monoclonal antibodies that target epidermal growth factor receptor (EGFR) have increased the treatment options for patients with metastatic colorectal cancer. The detection of positive EGFR immunostaining of the primary tumor is not a reliable predictor of response to therapy and as a result biomarker assays for *Kras* mutation are used to determine potential response to treatment.[62] Epidermal growth factor receptor is a member of the tyrosine kinase family and its activation stimulates many cancer-related processes such as proliferation, angiogenesis, invasion, and metastasis.[62] Overexpression of EGFR is found in a number of tumor types and in most cases is associated with poorer outcomes.[63] Several studies have found an association between a *Kras* mutation and a lack of response to EGFR-directed therapy. The importance of defining the KRAS status of the primary tumor has provided oncologists with important information about response to treatment. Early results from studies on patients with metastatic colorectal cancer show that the addition of cetuximab to FOLFIRI, improved overall survival (OS) by 3.5 months in *KRAS* wild-type patients. The response rate was 57.3% for the addition of cetuximab compared with 39.7%. As these trials mature, and modern systemic chemotherapy regimens are refined, we are now seeing median survivals in excess of 20 months.[59,62] More recent data from the CAIRO (capecitabine, irinotecan, and oxaliplatin)-2 study found the addition of an EGFR inhibitor had no effect on progression-free interval among those with wild-type *Kras* expression but was deleterious to those patients whose had *Kras* mutations in the tumor.[64] Similar data has been shown with the BRAF mutation as well.[65] Interestingly, it has been shown that the multikinase inhibitor sorafenib may restore sensitivity to EGFR inhibitors in BRAF-mutated colorectal cancer cell line.[65,66] As a result, studies are underway to determine the significance of this in human trials. As the understanding of molecular pathways in colorectal cancer continue to be elucidated, parallel developments are occurring in the fields of drug discovery and biomarker assay.

Hepatic Arterial Infusion

Regional hepatic therapy via hepatic artery infusional chemotherapy (HAI) has been studied since the 1970s. Hepatic metastases derive their blood supply largely from the hepatic arterial branches compared with mixed arterial and portal blood supply of the surrounding parenchyma.[41,67] This has an advantage over systemically delivered chemotherapy as the drugs used in HAI have a higher therapeutic index due to high first-pass hepatic extraction and high systemic clearance. Conversely, when regional therapy is given in the form of HAI, less is delivered to the systemic blood supply and therefore fewer systemic side effects are experienced. The most commonly used agent for HAI is fluorodeoxyuridine (FUDR), which has a 90% hepatic extraction ratio, while this is beneficial for isolated hepatic disease it limits treatment of occult extrahepatic disease. This can be addressed by giving additional systemic agents, or by using 5FU via the hepatic artery with a higher "spill-over" effect into the systemic circulation.

Early phase II trials of HAI FUDR or 5FU for unresectable colorectal hepatic metastases demonstrated remarkable

response rates ranging from 29 to 88%.[68–71] Subsequently 10 randomized phase III trials comparing HAI chemotherapy to systemic chemotherapy have been completed (Table 47-2). From 1987 through 1990, five trials were done comparing HAI FUDR to intravenous FUDR or intravenous 5FU/LV. All of these trials showed significantly increased response rates, but only trials comparing HAI chemotherapy to best supportive care showed improved survival. Most of these trials were underpowered and most allowed crossover, making conclusions about survival difficult. Two meta-analyses of the first seven trials have been performed on the assumption that each was underpowered, in an attempt to detect significant survival differences.[72,73] Both clearly confirmed the increased response rates, and both showed a modest survival benefit. A CALGB trial comparing HAI FUDR to systemic 5FU/LV without crossover found response rates to be significantly higher with HAI FUDR (48% vs. 25%), as was overall survival (22.7 months vs. 19.8 months).[74] Finally, a meta-analysis of FUDR-HAI vs. systemic chemotherapy for unresectable liver metastases from colorectal cancer that included results from ten RCT has shown a greater tumor response rate with FUDR-HAI when compared with systemic therapy; however, this did not translate to a survival advantage over 5FU-based systemic therapy.[75]

One explanation for the lack of survival advantage is while control of hepatic disease was excellent with HAI, there was significant extrahepatic failure. FUDR while an effective agent for treating liver metastases can have liver-related complications including biliary sclerosis (18–29%).[41] Finally, the placement of the HAI catheter is an invasive procedure and technical complications including primary catheter failure, catheter-related thrombosis, and infection.[41]

Currently, with the explosion of new active systemic agents, a new paradigm has developed in the treatment of hepatic colorectal metastases. Many phase I and II trials are now evaluating combinations of HAI FUDR or oxaliplatin with systemically administrated 5FU/LV with irinotecan and/or oxaliplatin. Even in pre-treated patients, impressive response rates in excess of 80% are being seen.[72] The combination of HAI and systemic 5FU/LV has further improved transformation rates of previously isolated unresectable colorectal liver mets into resectable lesions in as many as 26% of cases.[41] While recent advances in cytotoxic chemotherapy for colorectal cancer over the last decade have been very exciting, the development of targeted molecular-based therapy provides even greater hope for more effective systemic treatments. Results of current clinical trials are anxiously awaited to see where these molecular-based targeted therapies will ultimately fit in among the armamentarium of systemic therapy for colorectal cancer.

Resection

As described above, it is clear that patients with untreated hepatic colorectal metastases have poor survival. Although response rates to chemotherapeutic regimens are improving, the only therapy ever shown to be potentially curative for hepatic colorectal metastases is complete resection. Traditional principles that govern surgical intervention reserved hepatic resection of colorectal metastases for those would had unilobar disease, less than four lesions, lesions that were less than 5 cm in greatest dimension and those without extrahepatic disease.[66] However, in modern times with the addition of more effective systemic therapies, ablative techniques and treatment modalities aimed at "downstaging" the liver disease, more patients can be made amenable to resection. Mortality rates for hepatectomy for metastatic colorectal cancer are uniformly 5% or less (Table 47-3). Nonetheless, morbidity for these operations remains substantial and is usually reported between 20 and 50%. Fortunately, this morbidity does not generally translate into long hospital stays, intensive care unit stays, long-term disability, or early mortality. The most ominous complications, such as liver failure and significant hemorrhage, are now distinctly uncommon, thanks to better surgical technique and postoperative care. A recent review of more than 1,800 liver resections (57% of a lobe or greater) over the last decade, the median hospital stay was 8 days, morbidity was 45% and mortality was 3%. Furthermore, of the 1,245 hepatectomies performed for metastatic disease, mortality was 2.4%.[76]

Major institutional and multi-institutional reviews have now clearly documented the 5-year survival of patients undergoing hepatectomy for metastatic colorectal cancer ranges from 25 to 40%, 10-year survival ranges from 20 to 26%, and median survivals range from 24 to 46 months

TABLE 47-3. Outcome of patients undergoing pulmonary metastasectomy for colorectal cancer

(Table 47-3). These results obviously compare favorably to the results of no treatment (median survival 5–10 months) and to those of chemotherapy (median survival 10–14 months). Despite recent improvements in chemotherapy resulting in median survivals as high as 20 months, complete resection still provides the best outcomes. True long-term cure from chemotherapy is extraordinarily rare, while at least half of the long-term survivors after liver resection are disease-free and presumably cured.[77] For these reasons, no trial has ever compared hepatectomy to no treatment or chemotherapy alone. Liver resection for resectable hepatic colorectal metastases is the treatment of choice.

Patient Selection

Many studies of patients undergoing liver resection for isolated hepatic metastases have evaluated prognostic factors to help select those patients most likely to benefit from hepatectomy and, conversely, to identify those unlikely to benefit. The two most consistent negative prognostic factors are the presence of extrahepatic disease and the inability to resect all tumor; these two factors remain contraindications to hepatectomy. The exception to this rule is the patient with limited pulmonary metastases or colonic anastomotic recurrence, who may undergo combined resections with some success.[42] Although there are many inconsistencies in the major reported series, a list of other poor prognostic factors exist; these include lymph nodes involved by the primary colorectal tumor, synchronous presentation (or shorter disease-free interval), larger number of tumors, bilobar involvement, CEA elevation greater than 200 ng/ml, and involved histologic margins.[78–82] While it appears to be true that the stage of the primary tumor, the interval in which metastatic disease has developed, and the bulk of tumor in the liver (measured by size, number, and/or CEA level) can provide prognostic information on outcome after hepatectomy, none of these findings in and of themselves preclude the potential for long-term survival. Fong et al. conducted a multivariate analysis of 1,001 patients who underwent potentially curative hepatectomy, and identified five factors as having the most influence on outcome.[83,84] These included size greater than 5 cm, disease-free interval of less than 1 year, more than one tumor, lymph node-positive primary, and CEA greater than 200 ng/ml (Table 47-3). A clinical risk score (CRS) was created using regression analysis may be used preoperatively as a prognostic indicator of long-term outcome and hence aid in patient selection.

Margin Status

The importance of obtaining negative margins with hepatectomy has been demonstrated in multiple studies showing improved disease-free and overall survival. By comparison a recent study demonstrated a survival benefit of 46 months for those patients who underwent resection with negative

margins vs. 24 months for those with positive margins.[85] Wide resection margins with >1 cm clearance is desirable; however, a consensus statement from the Society of Surgical Oncology concluded that while wide margins of >1 cm are desirable and should be sought, anticipation of a close margin should not preclude a resection.[86] As a result, a more recent study examined the difference in outcomes between those patients with R0 resections vs. R1 resections. When coupled with SCT, the R1 resection group has similar 5-year overall survival rates to the R0 resection group (57% vs. 60%, $p = 0.12$). Intrahepatic recurrence demonstrated a higher recurrence of 28% for the R1 resection group vs. 17% for the R0 resection ($p = 0.004$) group.[87] One can surmise again from this study that an R1 resection.

Recurrence

Recurrence following hepatectomy for colorectal metastases is common, occurring in more than two-thirds of patients. In fact, long-term survival does not necessarily imply that there has been no recurrence. In a study of 96 actual 5-year survivors, nearly half had experienced a recurrence at some point and received further therapy.[87] In patients who do recur, the liver is the most common site of recurrence and is involved approximately 45% of the time. Most of these recurrences are isolated to the liver. Other common sites are lung, bone, and various intra-abdominal sites.[88] Since many recurrences are isolated to the liver, repeat liver resection has been attempted by several surgeons with some success. Unfortunately, only 5–10% of patients are candidates for a second liver resection, underscoring the importance of patient selection. Currently, at least 14 series reporting on more than 700 patients have documented that repeat hepatectomy for metastatic colorectal cancer is safe and effective in well-selected patients. Mortality is less than 5%, median survival from the time of the second liver resection ranges from 23 to 46 months, and 5-year survival ranges from 30 to 41%.[88] The factors most commonly associated with a poor outcome following repeat hepatectomy are size and number of tumors, as well as short disease-free interval. Because of the potential for further effective therapeutic interventions after primary liver resection, patients eligible for such treatment should be followed with serial CEA and imaging studies to detect recurrences at an early and potentially treatable phase.

Since recurrence after hepatectomy for metastatic colorectal cancer is common, there is a sound rationale for use of adjuvant therapy. Indeed, adjuvant 5FU-based systemic chemotherapy after liver resection was often given, but its use was not supported by prospective trials. A number of retrospective comparisons have been performed, but no definitive published data support the routine use of adjuvant postoperative 5FU-based systemic chemotherapy. The effect of newer, more effective chemotherapeutic regimens on long-term survival following hepatectomy is not known but is promising.

Since hepatic metastases derive their blood supply from the hepatic artery and the most common site of recurrence after hepatectomy is within the remnant liver, there is a strong argument for the use of HAI chemotherapy. Three randomized trials have addressed the efficacy of adjuvant HAI chemotherapy. In the German Cooperative multicenter study, HAI 5FU/LV was compared to no treatment after hepatectomy. No significant differences in outcome were found; however, many patients in the HAI arm did not receive therapy, and 5FU is not considered the optimal therapeutic for HAI chemotherapy.[89]

In the recently published Intergroup study, adjuvant HAI FUDR combined with systemic 5FU was compared to no treatment. A significant improvement in survival (46% vs. 25% 4-year survival, $p = 0.04$) was demonstrated only when analyzed by actual treatment received. There was no significant difference in outcome when analyzed in an intent-to-treat manner.[90] The third trial, performed at MSKCC, compared systemic 5FU/LV to systemic 5FU/LV combined with HAI FUDR. Ninety-two percent of patients received therapy as assigned, and there was a significant improvement in 2-year survival (the primary endpoint) favoring the addition of HAI FUDR (86% vs. 72%).[91]

Given the growing number of chemotherapeutic options for patients with metastatic colorectal cancer, there are many options for the patient who has had all of his or her liver metastases resected. Since HAI FUDR combined with systemic 5FU/LV is the only therapy ever shown to improve survival in this setting, there is a strong argument for the use of this modality; however, the surgeon and medical oncologist need to have experience with pump implantation and management. With the advent of more effective systemic chemotherapy such as irinotecan and oxaliplatin, as well as molecular targeted agents, new trials are needed to assess optimal adjuvant therapy.

Because the large majority of patients with hepatic colorectal metastases are technically unresectable, the development of more effective chemotherapy has inspired many oncologists to employ a "neoadjuvant" chemotherapy strategy in an attempt to render patients resectable. In a series from France, 701 patients with unresectable liver metastases received chronomodulated 5FU/LV and oxaliplatin. Ninety-five (14%) of these patients became resectable, secondary to chemotherapeutic response, and underwent staged resection. The resections employed techniques such as portal vein embolization and intraoperative ablation to extirpate all tumor, and achieved an actuarial 5-year survival rate of 35%.[44] Another study analyzed 23 previously treated patients with unresectable liver metastases. HAI FUDR was administered, and six patients (26%) were ultimately able to undergo an R0 resection.[45] These early studies suggest that patients with unresectable liver metastases should be treated aggressively with chemotherapy and reevaluated at intervals for the possibility of resection.

Ablative Procedures

While resection has become the gold standard for treatment of liver metastases it is curative in a minority of patients, therefore other methods of tumor destruction utilizing thermal ablation techniques have also been developed to treat and palliate those tumors that are not amenable to resection.

Cryotherapy has been used for decades and employs the use of probes to freeze tumors and surrounding normal hepatic parenchyma. Cryotherapy generally requires a laparotomy, and complications such as bleeding, liver cracking, and a cryoshock phenomena characterized by thrombocytopenia and disseminated intravascular coagulation can occur.

Radiofrequency ablation (RFA) and microwave ablation (MWA) probes have been developed that can heat liver tumors and a surrounding margin of tissue to create coagulation necrosis. RFA and MWA can be employed percutaneously, laparoscopically, and at laparotomy under ultrasound, CT, or MRI guidance. Furthermore, RFA has low morbidity that generally ranges around 10% and is rarely serious.[91–93] While RFA can be used near blood vessels, as the heat-sink effect of blood flow protects the endothelium, major bile ducts can be seriously injured, limiting the use of RFA in central tumors situated near major bile ducts. Local recurrence following RFA is a significant problem, and appears to be strongly correlated with tumor size. Generally, recurrence is more common in tumors greater than 4 or 5 cm in diameter and in tumors abutting major blood vessels. With improvements in localization and monitoring of thermal application, however, these therapies are very promising alternatives to surgery. Perhaps the greatest application of ablative techniques will be in their use as additions to resection in patients with multiple bilobar tumors.

Yttrium-90 microspheres is a way of delivering a pure beta emitting form of radiation to an unresectable liver lesion without suffering the locoregional side effects of external beam radiation. The microspheres are most often administered via a angiographic guided catheter placement. The procedure first requires accessible feeding vessels that allows for treatment of the lesions, but it is imperative that healthy liver and lungs are excluded and therefore appropriate treatment dosing is critical. The first study to combine radioembolization (REB) with systemic chemotherapy (SCT) randomly assigned patients to either treatment arm with REB plus The overall median survival was 29.4 months in the study arm vs. 12.8 months in the SCT alone arm.[94] This trial and others show promising results in patients with metastatic colorectal cancer. Currently, radioembolization is undergoing multicenter trials that include simultaneous and sandwiched systemic chemotherapy as for both treatment and radiosenstization. The results from these trials will ultimately determine whether REB has a role in the management of unresectable metastatsis from colorectal cancer.

Lung Metastasis

Approximately 10% of patients with colorectal cancer develop pulmonary metastasis. The vast majority of patients with metastatic colorectal cancer to the lung have advanced disease, and are therefore treated with systemic chemotherapy or best supportive care. Approximately 11% of these individuals will have isolated pulmonary metastases.[95] Patients with isolated or limited pulmonary may be considered candidates for pulmonary metastasectomy.[96]

Due to the retrospective nature of the reported information in the literature, clinical outcome data after metastasectomy for colorectal lung metastases must be interpreted with caution. Improved clinical outcome and survival data is more likely due to ideal patient selection and tumor biology rather than the surgical intervention in and of itself. In addition, there are no adequate control groups in these reports; therefore, survival statistics are difficult to interpret. However, there are patients who undergo pulmonary metastasectomy with no evidence of disease after long-term follow-up.[95] In addition, long-term survival without complete resection is very rare, suggesting that select patients do occasionally benefit from pulmonary metastasectomy.

Modern series of lung resection for metastatic colorectal cancer report operative mortalities of less than 2% (Table 47-3). Five-year survival rates range from 16 to 64%, but generally cluster around 30% to 40%. Most studies evaluate factors associated with outcome; however, given the limited number of cases, the statistical power of these studies to detect significant factors is limited. In general, the pathology of the primary tumor (grade, location, stage) has not been shown to impact clinical outcome. The most commonly cited significant factors associated with adverse outcomes include the number and size of pulmonary metastasis, short disease-free interval (DFI), elevated CEA, and incomplete resection.

While the majority of series evaluate metastatic disease limited to the lungs, several series have evaluated patients with both liver and lung metastases. Some authors advocate resection of synchronous limited extrapulmonary disease[97]; however, the majority of studies that have analyzed synchronous liver and lung metastases report a uniformly poor outcome following combined resections. Long-term survival is very uncommon in this situation.[98,99] In the setting of isolated pulmonary recurrence after partial hepatectomy, pulmonary metastasectomy appears to have more favorable outcomes similar to those for the initial hepatectomy.[98–100]

The surgical approach to patients who are potential candidates for pulmonary metastasectomy has been somewhat controversial. Based on older studies reported in the 1980s citing a 38% yield of contralateral thoracotomy in finding radiographically occult disease, routine bilateral thoracotomy had been advocated.[101] With modern day imaging, routine bilateral thoracotomy is no longer justified. The use of video-assisted thoracoscopic surgery (VATS) has increased significantly and is often used in metastasectomy when a

minimal parenchymal resection is necessary. Initially, VATS was deemed substandard to thoracotomy due to the inability to palpate the lung parenchyma; a prospective study evaluating confirmatory thoracotomy after VATS showed that 22% of lesions were missed.[101,102] However, with improvements in modern imaging and VATS technique, a minimally invasive approach can be justified.

Radiation therapy for colorectal cancer pulmonary metastasis has been of limited utility in the past due to radiation-induced pneumonitis, rib and spinal fractures, and skin toxicities. However, these toxicities can be minimized with the advent of robotic assisted Gamma Knife radiotherapy or "cyberknife."[103] Initial reports appear to have minimal toxicity associated with single-session lung radiotherapy using robotic image-guided real-time respiratory and tumor tracking. This is an exciting field of research and may become an additional therapeutic modality in the future. However, the outcome and efficacy data is limited at this time and the associated cost of robotic image-guided radiotherapy will be a limiting factor in widespread availability.

Peritoneal Metastasis

Peritoneal carcinomatosis represents one of the most challenging aspects of metastatic colorectal cancer. The peritoneal surface is involved in approximately 10–15% of colorectal cancer patients at time of initial presentation (synchronous metastases) and in 20–50% of patients who develop recurrence (metachronous metastases).[104–106] As a site of colorectal cancer metastasis, the peritoneal surface ranks second only to the liver. It is characterized by intraperitoneal spread of metastatic nodules. Peritoneal metastasis occurs by direct implantation of cancer cells via one of four mechanisms (1) spontaneous intraperitoneal seeding from a T4 colorectal cancer that has penetrated the serosal surface of the colon; (2) extravasation of tumor cells at the time of colon perforation from an obstructing cancer; (3) iatrogenic tumor perforation through an area of serosal injury or enterotomy at the time of colon resection; and (4) leakage of tumor cells from transected lymphatics or veins at the time of colon resection.[105] The risk of peritoneal metastasis is therefore highest in the setting of locally advanced cancers.

Peritoneal metastases are clinically important because of their frequent progression to malignant ascites and/or malignant bowel obstruction.[106–110] Synchronous peritoneal carcinomatosis was found in 58.5% of the patients with colorectal cancer. The most frequent symptoms were ascites (29.7%) and bowel obstruction (19.5%).

Preoperative detection of peritoneal metastases is not reliable. Noninvasive imaging frequently misses small peritoneal lesions, even when these are widely disseminated. The sensitivity of CT scanning for lesions smaller than 5 mm is only 28%, as compared to 70% for lesions 2 cm or greater.[111] Thus, indirect signs such as bulky primary tumor, ascites, or bowel obstruction are important clues. The utility of MRI in diagnosis of peritoneal carcinomatosis beyond that of CT is largely unknown and PET scans are of limited value. Unfortunately, in the majority of cases, diagnosis is made at the time of primary resection.[112]

The extent of carcinomatosis is a major prognostic factor and is best assessed by either laparoscopic or open exploration. Two different peritoneal carcinomatosis staging systems (Gilly's classification and Peritoneal Cancer Index of Sugarbaker) can be used to assess the extent of carcinomatosis.[113,114] These staging systems have both shown utility in determining the prognosis and treatment of patients with peritoneal carcinomatosis. By Gilly's classification, carcinomatosis is classified principally by the dimensions of the peritoneal tumor implants: stage I, tumor nodules less than 5 mm in diameter localized in one part of the abdomen; stage II, tumor nodules less than 5 mm disseminated widely through the abdomen; stage III, tumor nodules 5–2 cm in diameter; and stage IV, tumor nodules greater than 2 cm. The Peritoneal Cancer Index scores the extent of carcinomatosis on the basis of tumor size and location within 13 regions of the abdomen and pelvis. The lesion with the largest size in each abdominopelvic region is scored on a scale of 0–3 (0, no tumor; 1, tumor up to 0.5 cm; 2, tumor up to 5.0 cm; 3, >5 cm or confluence). The total score of the Peritoneal Cancer Index can vary from 0 to 39. The Peritoneal Cancer Index is shown to correlate with survival. Median survival and 5-year survival after surgical debulking and intraperitoneal chemotherapy were 48 months and 50% for peritoneal index <10, compared to 12 months and 0% for index >20.

Standard management of patients known to have peritoneal metastases at initial presentation is systemic chemotherapy. Colon resection plays an important role for patients with obstructing primary cancers, and also for patients with occult metastases that are first detected in the operating room. Historically, the median survival for patients with unresected peritoneal metastasis treated with 5-fluorouracil-based systemic chemotherapy was very poor (6–8 months).[115,117] However, patient survival is highly variable, depending on the extent of metastatic disease and response to chemotherapy.[116,117] Contemporary combination chemotherapy regimens have significantly greater efficacy and can produce long periods of disease control in certain patients.

Despite the grim prognosis for patients with peritoneal carcinomatosis from colorectal cancer, a subset of patients once thought unsalvageable are now being considered for surgery with curative intent. Pioneered by Sugarbaker, the goal of cytoreductive surgery and intraperitoneal (IP) chemotherapy is to remove all macroscopic disease with peritonectomy procedures and visceral resections followed by perioperative IP chemotherapy to destroy residual microscopic disease. IP delivery offers a pharmacokinetic advantage over standard intravenous delivery by producing high regional concentrations of drug while simultaneously minimizing systemic toxicities.[118–120] The most widely reported

method of IP chemotherapy is intraoperative delivery of mitomycin in a hyperthermic (41C) circuit for 90 min. An alternative approach is postoperative infusion of 5-fluoro-2′-deoxyuridine (FUDR) via an implanted intraperitoneal catheter.[120]

Despite early skepticism, in carefully selected cases there appears to be a survival benefit. Multiple phase II and one phase III study establish superiority over conventional palliative surgery or systemic chemotherapy[121] Several phase II studies show 5-year survival rates ranging between 19 and 28%.[122] The most consistent and important prognostic factor in these studies is the ability to achieve complete resection of all gross disease. Five-year survival rates reported for patients with completely resected disease range from 27 to 54%.[122–124]

A phase III study conducted by the Netherlands Cancer Institute randomized 105 colorectal cancer patients with peritoneal carcinomatosis to either standard treatment (systemic 5-fluorouracil/leucovorin with or without palliative colectomy) or experimental therapy (aggressive cytoreductive surgery, hyperthermic IP mitomycin, and systemic 5-fluorouracil/leucovorin).[123–125] In the experimental arm, median operation time was 585 min, treatment toxicity was high, and treatment-related mortality was 8%. After a median follow-up of 22 months, median survival was 12.6 months in the standard therapy arm and 22.3 months in the experimental therapy arm. It is not known if the survival benefit observed in the experimental therapy arm is due to surgical debulking, IP chemotherapy, or both.

In summary, the standard therapy for patients with peritoneal metastases is systemic chemotherapy. However, there is evidence that aggressive surgical cytoreduction and IP chemotherapy will benefit patients with limited peritoneal tumor burden. Additional clinical trials are needed to define optimal use of this aggressive treatment approach.

Ovarian Metastasis

Approximately 4–30% of ovarian neoplasms are metastatic cancers, the most common being colorectal and breast cancer.[126] Between 6 and 14% of all women dying with colorectal cancer are found to have ovarian metastases at the time of autopsy.[127] The risk of developing ovarian metastasis is substantially higher in woman with stage IV disease and approaches 90% in women with established peritoneal metastases. In addition, women with adenocarcinoma of the vermiform appendix have a very high risk of ovarian metastasis. Thus, in a woman with recent diagnosis of advanced colorectal cancer, any ovarian mass should be considered a metastasis from colorectal cancer until proven otherwise.

The pathogenesis of colorectal cancer ovarian metastasis is variable. Metastatic spread occurs primarily through the peritoneum but can also occur via the blood stream, through lymphatic vessels, or by direct extension. Careful intraopera-

tive assessment of the ovaries at the time of colon cancer surgery is essential. Synchronous metastases occur in 0–8.6% of patients in various clinical studies,[128–132] while metachronous metastases develop in 1.4–6.8% of colorectal cancer cases,[126,127,133,134] usually within 2 years after the primary resection.[129–136] Most often these metastatic lesions are large, and at least half of the cases have bilateral ovarian involvement.[137,138] Approximately 40% of these patients also have associated extraovarian pelvic metastasis.[137] Distinguishing a metastatic colorectal cancer from primary ovarian tumor is difficult by gross assessment alone, but a correct diagnosis can generally be determined through integration of clinicopathologic, immunohistochemical, and cytogenetic features. Most metastatic colorectal lesions are $CK20^+/CEA^+/CK7^-$ on staining, while primary ovarian neoplasms are $CK20^-/CEA^-/CK7^+$.[138–141]

Primary en bloc resection of CRC with direct extension to the ovary (T4) or resection of macroscopic metastatic disease to the ovary with prophylactic bilateral resection has been suggested to offer survival benefit and should be performed with curative intent in the absence of other significant metastatic disease. However, the removal of macroscopically normal ovaries, prophylactic oophorectomy, in women with colorectal cancer is the subject of much debate. Proponents of resection argue that removal improves the cure rate by removing potential microscopic "undetectable" synchronous disease, eliminates the risk of ovarian cancer and removes the risk of future metachronous ovarian metastatic disease.[127] Others argue that the low incidence of ovarian metastasis, paucity of supportive data and few clinical correlations with predictive value make this additional intervention unnecessary.[127] Clinical studies attempting to document the benefit of ovarian metastasectomy in patients with colorectal cancer are small and retrospective.[128,142,143] The majority of studies to date, however, fail to show any survival benefit for prophylactic oophorectomy and most studies demonstrate that when ovarian metastatsis is present it is a poor prognostic sign.[127] Based on the available data, it is reasonable to offer prophylactic oophorectomy to all postmenopausal patients, in particular to those women who have undergone pelvic radiation as part of their treatment for rectal cancer. For premenopausal patients, only those with established peritoneal metastases, those with a clearly increased risk of developing ovarian carcinoma [strong family history, known carriers of breast cancer (BRCA) or hereditary nonpolyposis colorectal cancer (HNPCC) mutation], or those who have already completed their families should be considered for prophylactic oophorectomy.

Most ovarian metastases are asymptomatic and are only detected at the time of surgery; however, large metastatic ovarian lesions can compress or invade adjacent organs (ureter, bladder, bowel), rupture, and on rare occasions bleed. Survival of women with synchronous ovarian colorectal metastases is significantly worse than that of patients without such metastases.[126,144] Ovarian metastases are frequently

resistant to systemic chemotherapy even when other sites of metastatic disease are responding, and therefore, resection of synchronous ovarian metastases should be performed when noted intraoperatively.[145–148] Bilateral oophorectomy and complete resection of gross disease is recommended. Reoperation for metachronous metastases should be considered in selected patients with good performance status and limited tumor burden elsewhere. To prevent local tumor progression, an aggressive surgical approach should be undertaken to achieve complete resection. The survival benefit of removing ovarian metastases has never been well documented, although complete metastasectomy is associated with significantly better outcome when compared to palliative debulking, especially in the setting of metastatic disease confined to the pelvis.[149,150] It should be noted that complete resection is only possible in 50% of these cases. The median postresection survival for women with isolated ovarian metastases is 18 months.[145] Women with other sites of disease have shorter survival, however, and 5-year survival after resection of established ovarian metastases is rare.[146,147] In these cases, systemic chemotherapy should be strongly considered, particularly when residual disease is present. With the availability of stronger chemotherapeutic regimens containing oxaliplatin, irinotecan, and/or bevacizumab, better survival can be expected.[151–154]

Bone and Brain Metastases

Bone metastases from colorectal cancer reportedly occur in 7–9% of cases, and most often present in the context of widespread metastatic disease.[155–158] Routine diagnostic bone imaging is not indicated in colorectal cancer patients, however, unless there are specific bone-related symptoms. There are no curative modalities, but palliation of pain, fractures, or spinal cord involvement are important issues for these patients. Symptomatic relief from bony metastases can usually be accomplished with radiation and medical therapy. However, pathologic fractures are best treated by operative internal fixation. The systemic issues related to bone metastases are serious and include debilitation, immobility, hypercalcemia, and thromboembolic disease.

Cerebral metastases from colorectal cancer are uncommon, occurring in 1–4% of colorectal cancer cases.[155–157] Colorectal tumors account for approximately 3% of all metastatic brain tumors.[158] These are generally found in the context of widespread metastases to multiple organ sites, but on rare occasion can present as an isolated brain metastasis. There is no role for routine brain imaging at primary presentation or at presentation with metastases elsewhere, unless there are specific neurologic symptoms. Once brain metastases occur, symptoms are common; palliative therapies include steroids to decrease swelling and anticonvulsants to control seizures. Definitive therapy of colorectal brain metastases usually involves surgery, radiation, or a combination of the two. For isolated, single brain metastases, resection can result in survival beyond 1–2 years.[157–160] As with pulmonary metastasis, there is increasing interest and data in the literature regarding Gamma Knife and Cyber Knife radiotherapy for bone and brain metastasis.[161] The outcome and efficacy data is limited at this time and the associated cost of robotic real-time image-guided radiotherapy may be a limiting factor in widespread applicability.

Colorectal Cancer: Surveillance

Nadav Dujovny and Jon S. Hourigan

Introduction

The majority of patients with colon and rectal cancer undergo curative resection and become candidates for continuing surveillance. It is well understood that the risk of colorectal cancer recurrence is largely dependent on the stage of disease at initial presentation and the appropriate level of postoperative surveillance should reflect this degree of risk stratification. Therefore, considerable effort has been devoted to the follow-up and surveillance of patients who have undergone curative-intent surgery. Continued surveillance is imperative to detect both metachronous neoplasms and prevent the development of subsequent cancers. In theory, proper surveillance allows subsequent polyps to be removed before malignant transformation occurs and improve survival by early identification of treatable recurrent cancer. Furthermore, surveillance directs family members of patients with hereditary cancers to receive proper screening and genetic counseling.

A dilemma, however, is the lack of agreement on the most effective surveillance program. Although the majority of colorectal surgeons report some degree of patient surveillance after curative resection, frequency of follow-up and surveillance techniques are largely inconsistent. A survey of American Society of Colon and Rectal Surgeons (ASCRS) members indicates that only 50% of practicing colorectal surgeons follow general surveillance guidelines.[1,2] The importance of disease stage is noted, but the risk of recurrence is also influenced by a variety of other factors, including surgical technique (local vs. radical resection, total mesorectal excision, etc.), primary tumor location, disease clearance, and histologic grade. Patient age and comorbidities, in addition to patterns of recurrence, also influence the intensity of surveillance.

In regards to advances in the detection and treatment of cancer recurrence, select patients will be candidates for resection of locoregional and metastatic recurrence. Many patients benefit from the removal of metachronous benign colorectal neoplasms and follow-up is critical for early identification of the subset of patients who benefit from selective treatment of recurrent malignant disease. Recent improvements in chemotherapy, radiation therapy, and surgery have allowed a relative survival advantage for people diagnosed with stages II and III disease. Furthermore, similar advances have extended median survival from 6 to 16 months for patients with stage IV cancer.[3] In addition to improvements in survival, a population-based study by Guyot et al.[4] demonstrated improvements in resectability and management of recurrent disease. The authors of this study showed that the proportion of patients with recurrent disease resected for cure increased from 6.7% (1976–1984) to 23.7%(1994–2003; $p < 0.001$) for distant metastases and from 15.9 to 58.1% ($p < 0.001$) for local recurrence. Improvements in outcome for metastatic colorectal cancer were demonstrated by Kopetz et al.[5] through the increased use of hepatic resection and advancements in medical therapy. In this study, 5-year survival improved from 9.1 to 19.2% and the median survival improved from 18 to 29.2 months in selected patients with Stage IV disease.

Risk and Timing of Recurrence

In 2009, approximately 147,000 cases of colon and rectal cancer were diagnosed in the USA. Among these newly diagnosed cases, most patients presented with locoregional disease (Stage I–III) and underwent curative intent surgery. The 5-year survival rate in this collective group ranged from 64 to 90% depending primarily on the stage at presentation.[6] Overall, 30–38% of patients who were treated with curative resection for locoregional disease developed a recurrence.[7,8] Patients with Stage IIb and Stage III disease were at the highest risk of recurrence. The risk of recurrence in those high-risk patients with primary colon or rectal cancer was 40 and 52%, respectively.[9] Approximately 20% of patients presented with Stage IV, or metastatic, disease. Most patients with Stage IV colorectal cancer were not candidates for curative

resection and underwent palliative treatment. Surveillance was not applicable for the patients unless their metastatic disease was limited and resected for cure. The majority of recurrences occur within 2 years of a curative resection, and more than 95% of recurrences are evident within 5 years of surgery. Late recurrence, defined as recurrence after 5 years from initial resection, is certainly unusual and typically represents less than 2% of recurrent cancer diagnoses. The longer interval to recurrence in these patients often reflects the use of adjuvant therapy.[9–12]

Hereditary Colorectal Cancer

Hereditary factors play a role in 10–25% of colorectal cancers, and identification of these patients often influences surgical management and surveillance intensity. Patients who are less than 50 years of age, have multiple polyps or synchronous cancers, or have a personal/family history of a malignancy should be recognized and considered for genetic counseling. The important noncolorectal malignancies to consider are those associated with hereditary nonpolyposis colorectal cancer (HNPCC), such as endometrial, ovarian, ureteral, gastric, and others. Obviously, family history plays a substantial role in identifying these patients and needs to be reviewed thoroughly at the initial consultation. Both HNPCC and familial adenomatous polyposis (FAP) are examples of genetic colorectal cancer syndromes that may affect patients and their families. Recognition of affected individuals alters screening and surveillance strategies for both themselves and their family members. This information may also modify surgical management to include a more extensive or prophylactic surgery, and direct surveillance of other potential sites of malignancy.

Surveillance Measures

Intensity of Follow-Up

The first question that must be answered is whether or not routine follow-up should be offered at all to patients based on a proven survival, recurrence, or quality-of-life benefit. At one extreme of comparison, Ohlsson et al.[13] randomized patients to either no follow-up or an intense follow-up program at frequent intervals after curative surgery for colorectal cancer. Of interest, this study demonstrated no significant difference in overall survival (67% vs. 75%), cancer-specific survival (71% vs. 78%), or tumor recurrence (33% vs. 32%) between the control and follow-up groups despite a rigorous surveillance program. This study alone would suggest that there is no benefit to patient follow-up, although it may have been underpowered. A subsequent study with randomization to either risk-adapted follow-up or minimal follow-up by Secco et al.[14] again validated that follow-up, regardless of intensity,

had no impact on tumor recurrence. However, in comparison to Ohlsson et al.,[13] improved survival was statistically significant among patients in risk-adapted follow-up programs versus patients with minimal follow-up. The lack of influence on tumor recurrence from these two studies should not be unexpected considering recurrence is primarily determined by the inherent characteristics of the tumor and its stage at presentation. However, the lack of influence on survival by Ohlsson et al.[13] raises the question as to whether the primary goal of improved survival is achieved by surveillance. In a 2007 collaborative review from the Cochrane Database, Jeffery et al.[15] analyzed eight randomized controlled trials to conclude an overall survival benefit in patients followed by a "more intensive" surveillance program after curative colorectal resection. Furthermore, the utilization of more tests in and of itself was significantly associated with improved overall survival. The variation among program strategies did not allow a standardized recommendation regarding timing, frequency, and components of follow-up.[13,16–21]

History and Physical Examination

Various practice guidelines, including those of the ASCRS, American Society of Clinical Oncology (ASCO), and National Cancer Care Network (NCCN), recommend patient history and clinical examination be performed every 3–6 months for the first 2–3 years after curative resection. Subsequent follow-up then occurs for a total of 5 years of surveillance. Additional follow-up after that time may be warranted based on perceived risk of recurrence and is at the physician's discretion.[22–24] Concerning symptoms include coughing, abdominal or pelvic pain, change in bowel habits, rectal bleeding, and fatigue. The physical exam should include wound examination, lymph node palpation, digital rectal exam, and a pelvic examination for female patients. Unfortunately, patients who present with symptomatic recurrences are less likely to be resected for cure. However, posttreatment surveillance also allows for the evaluation of psychosocial distress after colorectal cancer treatment and potential to offer help for other treatment-related sequelae, such as diarrhea, incontinence, and/or stoma care. It also helps to serve as a reminder for patients to check carcinoembryonic antigen (CEA) levels and schedule subsequent colonoscopies. Moreover, it provides patients a teachable moment in regards to genetics/family risk, and for healthy lifestyle choices. Smoking cessation, a healthy body mass index, exercise, and healthy diet have all been associated with improved outcomes in colorectal cancer.[25–27]

Laboratory Evaluation

The only laboratory test recommended for colorectal cancer surveillance is the serum CEA level. CEA is an oncofetal protein, which is elevated in colorectal cancers along with other gastrointestinal malignancies.[28] Preoperative CEA

level does have prognostic value in terms of risk of recurrence. A study by Wiratkapun et al.,[29] prospectively followed 261 patients after potentially curative resection and found that those patients with a preoperative CEA level > 5ng/ml had a worse disease free survival (DFS). At 5 years, recurrence was 7.5% compared to 37.2% in patients with normal versus elevated preoperative CEA levels. In addition, failure of elevated preoperative CEA levels to return to normal after potentially curative resection is a poor prognostic indicator[30] and may represent incomplete surgical resection or occult metastases.

After colorectal cancer resection, post-operative CEA levels should be monitored in patients who are medically fit for further treatment if a recurrence were found. The recommended interval of testing varies between societies; however, most recommend checking CEA levels every 3 months for the first 2–3 years and then biannually up to 5 years after resection. Elevated CEA is often the first sign of recurrent disease. CEA often predates other testing modalities in terms of identifying recurrence with a median lead time of 4.5–8 months.[31–34] Of note, sensitivity is much higher in detecting distant metastatic disease than locoregional disease (92% vs. 62%).[35] CEA sensitivity also varies with the site of recurrence, being 78% sensitive for hepatic metastasis, but only 42 and 45% sensitive for pulmonary and local recurrences, respectively.[34] Furthermore, an elevated CEA level should be rechecked prior to searching for recurrent disease because it may be falsely elevated. The false positive rate for CEA levels range from 7 to 16%.[33,34] CEA levels should not be evaluated while the patient is receiving 5-fluorouracil-based chemotherapy because this may falsely elevate the CEA level.[34]

Serum hemoglobin, liver function tests, and fecal occult blood test should not be used as part of a surveillance regimen. In regards to these tests, the ASCRS, ASCO, and NCCN guidelines are in agreement.[22–24]

Chest Surveillance

The incidence of isolated pulmonary metastases is approximately 5–10% and over 20% of patients who develop recurrent disease after curative resection have pulmonary lesions in addition to other areas of metastases. This pattern of recurrence is variable depending on the initial stage and location of the primary malignancy.[36,37] Even though pulmonary recurrence tends to occur more commonly with rectal cancer rather than colon cancer, both groups are followed collectively according to current surveillance recommendations. Plain chest radiograph (CXR) and chest CT scan are the two available options for chest surveillance and their utilization is not mutually exclusive. As with other surveillance measures, the utilization of chest surveillance requires that a patient is medically fit for pulmonary metastasectomy to justify its use. The ability of surveillance CXR to first detect evidence of cancer recurrence is reportedly under 20%, and more realistically less than 10%.[38,39] Graham et al.[40] identified recurrence

in 421 of 1,356 (32%) patients who underwent curative resection of a primary colorectal malignancy. Follow-up CXR was the first indication of recurrence in less than 1% of patients. In contrast, routine chest CT has shown an improved ability to primarily detect occult colorectal cancer recurrence within the chest in asymptomatic individuals and is more sensitive than CXR in identifying resectable pulmonary disease.[41,42] Clear evidence indicating which option is superior is not available and various surveillance programs preferentially use routine CXR or chest CT. ASCRS practice parameters neither support nor refute the use of routine chest radiography for surveillance, yet both ASCO and NCCN recommend annual chest CT for the first 3 years following curative resection.[22–24] ASCO and NCCN guidelines seem to be the most reasonable as abnormal findings on surveillance CXR require further imaging with chest CT prior to metastasectomy. Regardless of which method of surveillance is chosen, initial and repeated pulmonary resection for isolated metastatic disease offers an excellent long-term survival advantage with 2- and 5-year survival rates greater than 60 and 40%, respectively.[43–46] Although the majority of patients have multiple pulmonary lesions and may not be candidates for metastasectomy, routine chest imaging for colorectal follow-up is warranted to identify the subset population of patients who benefit from pulmonary resection.[37]

Abdomen/Pelvis Surveillance

There has been continued improvement in both the identification and treatment of metastatic colorectal cancer, and patients now have more options for the treatment of recurrent and advanced stage disease. The detection of abdominal and pelvic recurrence has primarily focused on hepatic imaging because the liver is the most common site of recurrence. Over 30% of patients ultimately develop hepatic metastasis after curative resection.[36] This typically occurs within the first 3 years after surgery. Recommendations regarding the use of routine liver imaging are influenced by the ability of abdominal CT and/or liver ultrasound to identify liver metastasis before clinical symptoms develop or other modalities of surveillance are positive for recurrence. In general, the accuracy of abdominal CT is superior to liver ultrasound for hepatic metastasis. The sensitivity of liver ultrasound is under 60% for the detection of colorectal metastasis, and the ability of ultrasound to identify liver lesions less than 1 cm is truly inadequate.[47] Abdominal CT, on the other hand, is more accurate and able to detect liver metastasis with sensitivity greater than 75%. Some studies suggest that routine liver imaging with both CT and ultrasound should be included in surveillance programs because of improved ability to identify treatable recurrence. For example, Bleeker et al.[48] reported on 42 of 213 patients with recurrence that underwent resection with curative intent and concluded that combined liver imaging was critical in over 30% of patients for identifying curable recurrence before any other method of surveillance.

The most recent Cochrane review suggested an overall survival benefit when routine liver imaging was included as part of intensive surveillance programs.[15] The utilization of routine liver imaging, however, remains controversial because the identification of liver metastases has not historically translated into subsequent resectability or improved survival in either asymptomatic or symptomatic patients.[21] Other topics of debate include the cost-effectiveness of liver imaging and its ability to complement routine surveillance when other measures are normal. Deveney and Way[49] found similar specificity and sensitivity between a less expensive CEA and more costly abdominal CT for routine follow-up. The ability of hepatic imaging to act as the first indicator of recurrence is low and very rarely does it identify recurrence prior to CEA elevation.[17,20] As a result of these concerns, published guidelines for the use of routine hepatic imaging after curative resection are inconsistent.

The most recent ASCRS published guidelines (2004) do not recommend the routine use of hepatic imaging. This is based on the lack of evidence that identification of hepatic recurrence leads to subsequent resection, the overlap of results between elevated CEA measurement and hepatic imaging, and the cost of routine CT imaging.[23] In contrast, both ASCO and NCCN guidelines recommend annual abdominal CT for 3 years after curative resection in patients who are considered to be both high-risk and candidates for subsequent resection if recurrence is found.[22,24] The recommendations for annual imaging focus on a reduction in mortality when imaging strategies are compared to nonimaging strategies for surveillance. Earlier identification of asymptomatic recurrence allows for curative reoperation and improved survival.[22,36]

In conclusion, there is no clear consensus among published guidelines in regards to routine abdominal imaging after curative resection. There is strong evidence that early identification of hepatic recurrence by CT imaging, particularly in asymptomatic patients, improves survival through subsequent curative resection.[41] Otherwise, liver recurrence left untreated carries a very poor prognosis. The survival benefit demonstrated in patients who undergo curative resection, therefore, should prompt serious consideration to imaging strategies in patients at high-risk for recurrence.[50] Clearly, the benefit of liver imaging is best realized when it is used as an adjunct to other modes of surveillance (in-office visit, CEA), and not as a single strategy.

Endoscopic Surveillance

The options for endoscopic evaluation after curative resection include colonoscopy, flexible sigmoidoscopy, and rigid proctoscopy with or without endorectal ultrasound (ERUS). The full benefit of endoscopic surveillance is clearly dependent on clearing the colon and rectum of synchronous neoplasms in the perioperative period. Synchronous colorectal polyps and cancers occur in 30 and 5% of patients, respectively,

and their identification at index colonoscopy may change the operative management of a patient.[51,52] Preoperative colonoscopy, or post-operative colonoscopy within 6 months of surgery, is therefore fundamental in the management of patients with a newly diagnosed colorectal cancer. After curative resection, endoscopic surveillance is designed to detect metachronous colorectal neoplasms and early disease recurrence. The timing and frequency of this surveillance is variable among published consensus guidelines and a source of debate.

Metachronous Colon and Rectal Neoplasms

A prior diagnosis of colorectal cancer is a significant risk factor for the subsequent development of polyps and/or cancer. Unlike colorectal cancer recurrence, which typically occurs within 2–3 years after treatment, the risk of developing metachronous colorectal neoplasms is collective over the life of a patient. Metachronous polyps occur in up to 50% of patients and metachronous cancers develop in 2–9% of individuals with a prior colorectal cancer diagnosis.[53,54] A recent systematic review of post-cancer resection surveillance by the US Multi-Society Task Force on Colorectal Cancer described 137 metachronous colorectal cancers among 9,029 patients (approximately 1.5%). Fifty-seven of the 137 malignancies reportedly occurred within 24 months of initial resection. Although some lesions likely may have been missed synchronous lesions, a high incidence of early metachronous cancers were identified. The majority of metachronous lesions were asymptomatic, discovered at an early stage by endoscopic surveillance, and resected for cure. This prompted a joint update by the US Multi-Society Task Force and American Cancer Society to recommend intraluminal surveillance with post-resection colonoscopy 1 year after surgery.[55] Although metachronous cancers were reported within 2 years of surgery, it is understood that they can develop over an extended period of time from the initial diagnosis and patients generally require long-term endoscopic follow-up.[56]

According to their most recent update for colon and rectal cancer surveillance in 2004, the ASCRS Standards Practice Task Force has not endorsed the utility of early (1-year) post-resection colonoscopy. ASCRS practice guidelines indicate that the initial posttreatment colonoscopy should occur 3 years after resection and at subsequent 3-year intervals.[23] Obviously, clinical judgment recognizes that certain risk factors place some patients at greater risk for developing metachronous lesions. This influences the need for endoscopic evaluation with different timing and frequency. Patients who are at risk for hereditary colorectal cancer syndromes should undergo more frequent surveillance endoscopy. The absence of synchronous neoplasms at the initial diagnosis of colorectal cancer confers a lower risk of metachronous lesions.[57] The physician responsible for index colonoscopy should be considered in determining the timing of post-resection colonoscopy, as well. Hyman et al.[58] suggest a lower incidence of

high-risk metachronous lesions at 1-year post-resection colonoscopy if the operating surgeon was responsible for the index colonoscopy. Overall, most authors recommend 1-year colonoscopy based on the reported higher risk and incidence of metachronous neoplasms within 2 years and the reality of missed synchronous lesions.[42,59] In consideration of the risk associated with metachronous lesions, colonoscopy is the only option for continued endoscopic surveillance after curative resection. All other options are insufficient.

Locally Recurrent Colon Cancer

In addition to the identification of metachronous lesions, endoscopic surveillance is also utilized to discover local and anastomotic recurrence of colorectal cancer. Unlike metachronous colorectal neoplasms, recurrent colorectal cancer typically occurs within 2–3 years after initial treatment. There is a distinct difference, however, between local recurrence rates of colon cancer and rectal cancer, and their respective patterns of recurrence require different approaches to surveillance. Endoscopic surveillance for recurrent colon cancer has limited utility because of local and anastomotic recurrence is unusual. Distal recurrence is much more typical and not identifiable by endoscopic surveillance. Intraluminal recurrence of colon cancer typically occurs in only 2–4% of patients after resection and the time to recurrence is generally 13–16 months.[60] The low incidence of local recurrence is recognized by ASCRS practice parameters, and periodic evaluation of the colonic anastomosis is not endorsed.[23] Surveillance of metachronous lesions allows for concurrent anastomotic evaluation by the visualization of prior surgery sites and mucosal biopsy as indicated. The incidence of local recurrence is quite low even with poor-risk factors. Harris et al.[61] defined factors predictive of local recurrence to include advanced stage of disease, poor differentiation, perforation, and fistula formation. Nevertheless, routine anastomotic biopsy is not indicated in the absence of mucosal abnormality. Unfortunately, local anastomotic recurrence is frequently associated with unresectable widespread colon cancer recurrence.

Locally Recurrent Rectal Cancer

Locally recurrent rectal cancer is more common than locally recurrent colon cancer; yet, endoscopic visualization remains limited because of the tendency for local rectal cancer recurrence to begin extraluminally. Total mesorectal excision (TME) and chemoradiation therapy have both contributed to improved tumor clearance and locoregional control of rectal cancer. Studies have reported that 5-year local and systemic recurrence rates are 4 and 18%, respectively, with TME.[62] Such improvements translate into patterns of recurrence that make endoscopic follow-up beneficial in only a small percentage of patients because primary anastomotic, or intraluminal, recurrence is low assuming proper surgical technique is employed. ASCO recommends 6-month endoscopic evalu-

ation by flexible sigmoidoscopy or rigid proctoscopy for rectal cancer recurrence in patients who have not received pelvic radiation.[22] Although the exact schedule for surveillance is not defined, periodic anastomotic evaluation is recommended by the most recent ASCRS guidelines. This is despite the fact that intraluminal recurrence is relatively low in comparison to other patterns of recurrence.[26] Local extraluminal recurrence, on the other hand, remains a problem for patients after rectal cancer resection and typically reflects advanced stage disease or incomplete tumor clearance. Circumferential resection margins have been validated as an important prognostic indicator for both local and distant failure.[63,64] Other factors that increase local recurrence and affirm the need for continued endoscopic surveillance include lymphovascular or perineural invasion and lymph node positive disease.[65] As a consequence of extraluminal recurrence, post-resection surveillance not only requires the ability to evaluate the anastomosis, but the ability to look outside the lumen, as well. Visualization of low anastomoses by flexible sigmoidoscopy or rigid proctoscopy is therefore enhanced with other modalities of endoscopic surveillance, such as ERUS.

Practice guidelines for post-resection ERUS have not been firmly established in part because operator dependence and questions regarding the ability of ERUS to differentiate between benign and malignant changes raise concern. Lower sensitivity (65%) is reflective of its inability to differentiate between benign and malignant changes after surgery and/or radiation.[66] Of 44 patients with locally recurrent rectal cancer following local or radical excision, 80% of recurrences were detected on ERUS. Fourteen asymptomatic patients (approximately 30%) were solely diagnosed by ERUS after normal digital examination and endoscopic surveillance.[67] Further studies suggest that ERUS is a useful adjunct to rectal cancer surveillance, however, its position in current guidelines is lacking until further prospective data confirms its impact on survival and changes in patient management.[39]

Positron Emission Tomography

Positron emission tomography (PET) technology uses radiotracers to detect and quantify cellular and biochemical processes noninvasively. ^{18}F-2-fluoro-2-deoxy-D-glucose (FDG) is the most common radiotracer used in oncology. FDG concentrates in malignant tissue because of an increase in glycolysis compared to normal tissue. This modality is frequently combined with CT scans to improve anatomical and functional detail. NCCN guidelines do not recommend routine surveillance with PET scans in detecting recurrences without other evidence of recurrent or metastatic disease.[24]

However, FDG-PET scanning has developed a role in the evaluation of recurrent disease and in the setting of suspected recurrence. For those patients who are asymptomatic with an elevated CEA level, the diagnostic sensitivity and positive predictive value of PET for recurrence is 95.3%.[68] A meta-analysis by Huebner et al., found an overall

sensitivity and specificity of 97 and 76%, respectively, for FDG-PET detecting recurrent colorectal cancer. PET imaging changed management in 29% of the patients.[69] Moreover, FDG-PET helps to predict resectability of recurrence and improves the selection of appropriate surgical candidates. A randomized study by Sobhani et al.[70] added PET scan to the surveillance of colorectal cancer patients with a high risk of recurrence. These patients had Stage III or IV disease who had undergone an R0 resection and completed adjuvant chemotherapy. PET scan was performed at 9 and 15 months compared to the conventional group which had a CT scan at those time points. The PET group had a significantly shorter time to recurrence (12.1 vs. 15.4 months, $p = 0.01$) and recurrences were more frequently removed for curative intent (R0, $p < 0.01$).[70]

Abnormal Results

Abnormal results from surveillance prompt further investigations to detect, confirm, or exclude recurrence. If the CEA level rises after resection, management should include physical exam, colonoscopy and CT of the chest, abdomen, and pelvis. If the work-up is negative, consideration should be given to PET scanning as well. Repeat CT scans should be done every 3 months until recurrent disease is identified or the CEA stabilizes or declines.[24] Abnormalities may require further evaluation, such as biopsies or serial imaging, to confirm lesion stability. If recurrence is identified, PET scan should be performed and consideration given to further resection if possible.

Quality of Life

Surveillance after colorectal cancer resection can be stressful for patients and have a significant impact upon their quality of life. Patients undergo many tests that may lead to further investigations or treatments. Moreover, these tests have a false positive rate and examinations, such as colonoscopy have associated risks. Various studies have looked at the impact of surveillance on the quality of life. A study by Kjeldsen et al.[71] only found marginal benefit to surveillance for health-related quality of life, which did not justify the expense of follow-up. In comparison, Stiggelbout et al.[72] reported a positive attitude toward surveillance in that it reassured the patients. Patients experienced slight nervous anticipation, but expressed a strong preference for follow-up even if it would not lead to earlier detection of a recurrence.

Cost-Effectiveness

When considering an intensive surveillance regimen, expense needs to be considered. Since different societies have disparity among their follow-up regimens, there is a variable cost to the insurers. Using 5-year Medicare allowed charges, the cost between follow-up regimens varied between $910 and $26,717 per patient.[73] Another study performed in the UK, found that the adjusted extra cost for each patient was $4,288 and for each life year gained was $5,885.[74] Another study performed in France, divided the cost-effectiveness of surveillance between Stage I and II disease compared to Stage III. Only Stage III patients had a favorable cost-effective analysis of 1,058 Euro per quality-adjusted life-years.[75]

Surveillance Effectiveness and Meta-analyses

The effectiveness of surveillance after curative resection is based on its ability to detect recurrent and/or metachronous disease at a point in time when subsequent curative treatment is successful. Of equal importance is a willing patient who is healthy enough to undergo potential therapy. Most surgeons would agree that patients should receive some degree of follow-up after curative resection of colon and rectal cancer. Some studies have shown that intensive follow-up has demonstrated a small but significant survival advantage over minimal or no follow-up after curative resection.[15,36,76] Improved detection of resectable recurrence has been demonstrated with intense surveillance, as well.[13,77] When compared with minimal follow-up, intense surveillance delivers a 5-year improvement in overall survival of 7–10%. The process is most likely multifactorial and is thought to be secondary to earlier detection of both locoregional disease and curable liver metastasis. Earlier palliative chemotherapy and downstaging of pelvic tumors after radiation therapy also play a role.[15,76,78]

Surveillance strategies, however, are limited because the benefits from the independent components of a surveillance program are difficult to validate. Strategies are often classified as "less-intensive" or "more-" or "highly-intensive" and there is considerable variability among intensive-surveillance groups. The literature does not really define what is meant by "more intense follow-up" and this lack of standardization affects the ability to identify which methods of surveillance are truly critical to survival and patient care.[78,79] Although a number of measures are available, the primary components of follow-up include history and physical examination, serial tumor marker measurement, radiographic imaging, and endoscopic evaluation. Still, physicians have multiple options that can be employed at different frequency and intensity.[47]

Different meta-analyses of the available randomized-controlled trials[15,36,76,80] show a significant survival benefit with intensive surveillance compared to nonintensive surveillance. The meta-analysis by Tjandra et al.[76] demonstrated a significant reduction in overall mortality in patients receiving intensive follow-up compared to nonintensive follow-up (21.8 vs. 25.7%; $p = 0.01$). CEA surveillance and

TABLE 48-1. Summary of recommended surveillance protocols

Test/procedure	ASCRS [23]	ASCO [22]	NCCN [24]
History and physical	Minimum of 3 times per year for the first 2 years	Every 3–6 months for 3 years, then every 6 months during years 4 and 5, then per physician discretion	Every 3–6 months for 2 years, then every 6 months for 5 years
CEA	Minimum of 3 times per year for the first 2 years	Every 3 months for 3 years or longer, for patients with Stage II or III disease	Every 3–6 months for 2 years, then every 6 months for 5 years for T2 or greater
Flexible sigmoidoscopy or proctoscopy for rectal cancer patients	Periodic anastomotic evaluation is recommended for patients who have undergone resection/anastomosis or local excision of rectal cancer	Every 6 months for 5 years for patients who have not received pelvic irradiation	Consider proctoscopy every 6 months for 5 years
Colonoscopy	Every 3 years	At 3 years then every 5 years if normal	At 1 year, if advanced adenoma repeat in 1 year, if none repeat in 3 years, then every 5 years
Computed tomography of the chest–abdomen–pelvis	Not recommended	CT chest/abdomen every 1 year for 3 years, consider CT pelvis for rectal cancer patients especially if they have not received radiation therapy	Annually for 3 years, for patients at high risk for recurrence
Fecal occult blood test	Not recommended	Not addressed	Not addressed
Complete blood count	Not recommended	Not recommended	Not addressed
Liver function tests	Not recommended	Not recommended	Not addressed
Chest radiography	Not recommended	Not recommended	Not recommended
Abdominal ultrasound	Not recommended	Not addressed	Not addressed

These are the recommended surveillance protocols for those patients who are candidates for further intervention.

colonoscopy significantly influenced overall mortality, while intensive surveillance detected asymptomatic recurrence earlier and more frequently. Recurrences that were more amenable to curable resection were found more commonly during intensive follow-up. In this study, the cancer-related mortality was not improved and the survival benefit was not related to earlier detection and treatment of recurrent disease. Due to the disparities between the different meta-analyses, it is not possible to say specifically what frequency or combination of surveillance modalities yields the improved survival benefit. Table 48-1 summarizes the recommended surveillance protocols.

Conclusions

Colon and rectal cancer surveillance after curative resection is recommended for patients who can tolerate further surgery or therapy if needed. The optimal surveillance protocol has not been established, however, general agreement supports the use of routine office visits, serum tumor marker measurement, and endoscopic surveillance for post-resection follow-up. Although the timing and frequency of surveillance measures is variable, continued follow-up is recommended based on improved overall survival with intensive surveillance programs.

Miscellaneous Neoplasms

Robin P. Boushey and Husein Moloo

While adenomas and adenocarcinoma account for the majority of colorectal neoplasms, several other less frequent types of malignancy can occur, which can often present as diagnostic and therapeutic challenges to the clinician. These tumors can be classified based on their tissue of origin and include epithelial, mesenchymal, neural, vascular, or lymphoid tumors.

Carcinoid Tumors

The clinical presentation of carcinoid tumors was first described in 1888 by Lubarsch. In 1907, Oberndorfer coined the term carcinoid ("karzinoid") as these tumors were noted to behave differently from adenocarcinoma, acting in a more indolent fashion. Carcinoid tumors are neuroendocrine in origin and originate from Kulchitsky cells in the crypts of Lieberkuhn which represent a type of enterochromaffin cell.[1] They belong to the amine precursor uptake and decarboxylation (APUD) system. These cells are argentaffin positive (silver staining) and usually argyrophilic meaning they are capable of silver staining with the addition of an external reducing agent. These cells use various amine precursors to synthesize various biologically active compounds that exert their biological actions locally and systemically. This includes several hormones, neuropeptides, and neurotransmitters such as serotonin, adrenocorticotrophic hormone, bradykinin, histamine, dopamine, substance P, neurotensin, kallikrein, and prostaglandins E and F.[2] As such, in 1969 Pearse used the term "APUDomas" to describe carcinoid tumors. While neuroendocrine tumors of the gastrointestinal tract are rare, carcinoid tumors are the most common.

Incidence and Classification

Carcinoid tumors can develop in a wide range of organs including the lungs, bronchi, and gastrointestinal tract. Approximately 67% arise within the gastrointestinal tract and about 25% arise within the bronchopulmonary system. The incidence is slightly higher in African Americans and there appears to be a higher incidence in females (as high as 2:1 in some reports). Tumors most commonly occur between the fifth and seventh decade of life.

Several classification schemes have been proposed to categorize carcinoid tumors; however, the most commonly utilized scheme involved classification based on embryological origin. (1) Foregut tumors originating from the lung, bronchus, thymus, stomach, pancreas, and duodenum. (2) Midgut tumors arising from the small intestine, appendix, and right colon. (3) Hidgut tumors arising from the distal colon and rectum.[1]

Within the intestinal tract, midgut carcinoids are most common and account for 62% of all carcinoids, while foregut and hindgut carcinoids account for 7 and 30%, respectively. The greatest density of APUD cells are within the distal small intestine, and as such the most common site for a carcinoid tumor to develop is within the appendix (35%) and small intestine (23%), usually within two feet of the ileocecal valve. Rectal carcinoid tumors account for approximately 20% of all gastrointestinal carcinoids and account for 1% of all rectal tumors. Synchronous carcinoid tumors occur in approximately 25% of patients with foregut and midgut carcinoids while synchronous carcinoid tumors are rare with hind gut tumors. Irrespective of the site of origin, carcinoid tumors are associated with an increased incidence of other malignant tumors that includes gastric, esophageal, colorectal, lung, prostate, and urinary tract tumors. In some series, that estimated incidence to be as high as 50% and is thought to be a result of the trophic effects of the various hormones and peptides secreted by the carcinoid primary including bombesin, gastrin, and cholecystokinin.[1]

Pathology

Grossly, these tumors have a very typical appearance that includes a rounded, well-circumscribed submucosal lesion that are yellow in color on sectioning because of the high lipid content of the tumor. They are often multicentric and <2 cm in size.

Microscopically, carcinoid tumors are composed of small round uniform cells that contain very dense neurosecretory granules that are packed with various secretory peptides. They generally have benign cytoplasmic features and only rare mitotic figures are seen. They have five histologic patterns that include insular, trabecular, glandular, undifferentiated, and mixed. Pathologic analysis alone is rarely able to distinguish a benign from a malignant carcinoid tumor, although increased cellular atypia, high mitotic activity, or necrosis are suggestive of more aggressive tumors and are termed atypical/anaplastic carcinoid tumors.

Traditionally, silver staining has been used to confirm the diagnosis of carcinoid tumors as serotonin is capable of reducing silver salts to metallic silver following carcinoid cell uptake – so-called argentaffin positivity. Tumors capable of uptaking silver salts but not capable of reducing silver unless an external reducing agent is added are termed argyrophilic. Two distinct type of neurosecretory granules have been observed by electron microscopy (EM), a smaller granule associated with argyrophil carcinoids and a larger one with argentaffin tumors although EM is not routinely needed to confirm the diagnosis. Midgut carcinoids are mostly argentaffin positive while hindgut carcinoids are usually mixed with 60–70% being argyrophil and 8–16% being argentaffin positive.

Currently, immunohistochemistry techniques are utilized to diagnose carcinoid tumors and involve antibodies that target various cytoplasmic proteins including chromogranin, synaptophysin, and neuron-specific enolase.[3]

Clinical Presentation

Carcinoid tumors were initially considered indolent tumors with limited metastatic potential when initially described over 100 years ago. However, it is clear that these tumors can lead to significant morbidity and mortality due to local tumor growth, distant metastatic spread or through the production of various bioactive substances acting both locally and distally. Although the carcinoid syndrome is classically described as the hallmark of carcinoid tumors, it occurs in only 10–18% of all patients with carcinoid tumors and in only 50% of individuals with advanced disease. Most patients will be symptomatic for a median duration of 2 years prior to diagnosis. Up to 90% of symptomatic patients will have an advanced tumor often with metastasis.[2]

Approximately 50% of all gastrointestinal carcinoid tumors will be diagnosed following appendectomy. Less than 1% will have the carcinoid syndrome as the initial clinical manifestation. The commonest presentation in patients with midgut carcinoid tumors is abdominal pain and occurs in up to 40% of individuals while hindgut carcinoids are nonsecretory and almost always asymptomatic and discovered incidentally by the pathologist following polypectomy during routine colonic surveillance. Occasionally, larger tumors will present with bleeding, obstructive symptoms, and tenesmus.

The clinical manifestations of the carcinoid syndrome include episodic flushing, wheezing, nonbloody watery diarrhea, abdominal pain, and right-sided heart failure. This can be precipitated by several factors including stress and particular foods including caffeine and alcohol. Serotonin appears to be responsible for many of the gastrointestinal symptoms including abdominal cramping and intestinal hypermotility manifesting as diarrhea and occurs in 80% of patients with the carcinoid syndrome. Kallikrein secretion is thought to account for wheezing and flushing, the latter occurring in 85% of affected patients.[4] Intestinal obstruction leading to possible arterial insufficiency often results from mesenteric fibrosis, although the exact mechanism leading to mesenteric and retroperitoneal fibrosis has yet to be elucidated. Other retroperitoneal structures can be involved including the ureters and Peyronie's disease has been reported (inflammation and scarring of the tunical albuginea). Right-sided heart failure due to severe damage to the tricuspid and pulmonary valves accounts for 50% of the deaths from the carcinoid syndrome. Serotonin and other vasoactive substances have been suspected to be responsible as patients with higher 5-hydroxyindolacetic acid (5-HIAA) levels, a by-product of serotonin metabolism, which correlates with increased valvular damage.[2] The right side of the heart is most commonly affected as the lung will inactivate the humoral substances prior to exposure to the left side of the heart. Attempts at surgical valvular replacement have been associated with high perioperative morbidity and mortality.

Most of the peptide hormones produced and secreted by the carcinoid tumor are metabolized by the liver. Therefore, a patient with the classic carcinoid syndrome must have a tumor with venous drainage into the systemic rather than the portal circulation. Patients often have diarrhea or unexplained abdominal pain with or without the other classic signs of the carcinoid tumor. They are often diagnosed with tumors located in the bronchus (with or without metastasis), primary gastrointestinal tumor with metastasis to the lymph nodes or invasion into the retroperitoneum.[5–7] In contrast, the diagnosis of asymptomatic carcinoid tumors is usually established after the excision of a gastric or colonic polyp that is diagnosed pathologically as a carcinoid tumor, or incidentally at the time of appendectomy or laparotomy.

Midgut tumors are most commonly associated with the carcinoid syndrome as these tumors produce high levels of serotonin.[8] Almost 90% of individuals with the carcinoid syndrome will have a midgut carcinoid tumor. Foregut tumors typically lack the enzyme needed to convert the precursor compound 5-hydroxytryptophan into serotonin. Hindgut tumors rarely produce 5-hydroxytryptophan or serotonin. Therefore, tumors arising from these regions cannot produce the classic carcinoid syndrome even if metastatic lesions are present.

Atypical or variant carcinoid syndrome can occur in patients with gastric carcinoid tumors. Patience will experience patchy cutaneous flushing and pruritis. Diarrhea, bronchospasm, and cardiac lesions are rare. It is thought

that the syndrome results from histamine rather than serotonin release.[2]

A life-threatening carcinoid crisis characterized by flushing, severe abdominal pain, diarrhea, hypotension, or hypertension can be precipitated by severe stress including surgery, anesthesia, and adrenergic agents. It is recommended that all patients with carcinoid tumor wear a medical alert bracelet indicating their diagnosis in the event of an accident or the need for emergency surgery. This crisis can often be managed with short-acting octreotide agents.[1]

Diagnostic Tests

Biochemical Tests

The most useful and widely used biochemical test for diagnosing carcinoid tumors in the symptomatic patient is the 24-h urine 5-HIAA measurement with a sensitivity and specificity of 73 and 100%, respectively.[2] 5-HIAA is excreted in the urine after serotonin metabolism and is measured more reliably than serotonin levels, which can vary between persons. Urinary 5-HIAA levels can be falsely elevated if a patient has consumed certain serotonin-rich foods such as bananas, pineapples, nuts, and kiwi fruits or following the ingestion of various medicines affecting urinary 5-HIAA levels. Chromogranin A is a sensitive serum marker but is nonspecific for carcinoid tumors and can be elevated in other types of neuroendocrine tumors. Platelet serotonin levels may be more sensitive than urine or blood tests but is not readily available at many institutions.

Imaging Tests

Computerized tomography (CT) scan of the thorax and abdomen/pelvis should be performed in symptomatic patients to identify the primary tumor and extent of disease. Somatostatin receptor scintigraphy (SRS) scan should be considered in most patients to identify occult metastasis in patients being considered for curative resection and to determine if the patient is likely to respond to octreotide. Approximately 88% of carcinoid tumors express receptors (SSTR 1–3) that possess moderate-to-high affinity for somatostatin and its analogs.[5] The ability of SRS to obtain whole body images, along with its high sensitivity, makes it the imaging modality of choice in patients with carcinoid tumors. However, SRS can fail to detect tumor in approximately 10% of patients who do not express the somatostatin receptor. Whole body positron emission tomography (PET) relies on differential metabolic uptake and is used increasingly but no studies have directly compared SRS and PET scans. 18F-Dopa-PET imaging is more sensitive in identifying the primary tumor and local lymph node involvement, while CT and MRI are more sensitive for identifying distant metastasis. Esophagogastroscopy and colonoscopy should be considered in patients with metastatic disease with an unknown primary. Electrocardiography and echocardiography should be performed in symptomatic

and asymptomatic patients to rule out right-sided valvular disease and should be performed prior to elective surgical resection.

Treatment

Small intestinal carcinoids are often multicentric and located in the distal ileum, and associated with the carcinoid syndrome.[9] Most patients will have metastasized to the regional lymph nodes or liver. Size of the tumor correlates poorly with predicting distant metastatic disease as tumors less than 0.5 cm in diameter has been shown to metastasize to the liver. Carcinoid tumors greater than 2 cm diameter and are usually malignant in most locations except in the ileum where nearly all tumors will have metastasized. Small bowel resection including a resection of the mesenteric lymph nodes is indicated even in patients with known metastatic disease to reduce the likelihood of developing small bowel obstruction or mesenteric fibrosis and ischemia. The entire small intestine should be carefully examined at the time of laparotomy to exclude the possibility of a synchronous tumor.

Appendiceal carcinoid tumors represent the most common tumor of the appendix. Approximately 95% of these tumors are less than 2 cm in diameter; nearly 75% of these tumors are located in the distal third of the appendix.[10] These tumors are rarely multicentric and tumor size is the best prognostic indicator, with most tumors less than 2 cm rarely metastasizing to regional lymph nodes or distally. Patients with tumors under 1 cm are usually treated by simple appendectomy, as long as there is no evidence of local tumor spread. In contrast, 30–60% of lesions greater than 2 cm in diameter are associated with nodal or distant metastases and will require formal right hemicolectomy. The treatment of patients with tumor diameter between 1 and 1.9 cm must be individualized based on the risk of recurrence vs. the risk of surgery. The presence of lymphovascular invasion, involvement of the mesoappendix (lymph node involvement or by direct extension), or a positive margin are poor prognostic indicators and usually warrant right hemicolectomy.[11]

Approximately two-thirds of colonic tumors arise in the ascending colon (most in the cecum), and remain asymptomatic until they develop into large tumors with nodal spread or distant metastasis. Most of these patients will require colonic resection and the extent is usually determined by the location of the disease.[12]

Rectal carcinoids are usually asymptomatic and identified at the time of routine endoscopy in approximately 50% of patients. Symptomatic patients usually have rectal bleeding, tenesmus, pain, constipation, and rarely the carcinoid syndrome. Tumor size correlates well with the likelihood of metastasis – tumors less than 1 cm in diameter metastasize in fewer than 5% of patients. Most tumors greater than 2 cm will have metastasized at the time of diagnosis.[13] The majority of rectal carcinoid tumors are smaller than 1 cm and can usually be treated with local endoscopic excision. The management

of tumors 1–2 cm in diameter remains controversial. Some authors advocate for more extensive resection in the presence of muscular invasion, symptoms at diagnosis, or ulceration. Tumors with a diameter greater than 2 cm have traditionally been treated by proctectomy.[14,15] This approach has recently been challenged by several retrospective studies that did not demonstrate improved survival beyond that observed with local excision. The correct surgical approach to large rectal carcinoids must be individualized and must consider factors such as patient age and morbid illnesses.

Metastatic Disease

Treatment of liver metastasis is effective in providing long-term palliation of the hormone-related symptoms in patients who do not respond to or tolerate the somatostatin analogs. Tumor debulking can involve hepatic resection, cryotherapy, radiofrequency ablation, hepatic artery embolization, or chemoembolization. Hepatic artery occlusion or chemoembolization can be considered in select patients who are not surgical candidates for hepatic resection. Carcinoid tumors that have metastasized to the liver are extremely vascular and obtain a large proportion of its blood supply from the hepatic artery. Occlusion of the hepatic artery results in less compromise to the hepatocyte which will continue to receive its blood supply from the portal vein. Patients with large tumors or tumors refractory to somatostatin usually experience marked transient symptom improvement. This procedure can be repeated up to four times every 2–3 months in selected patients. Attempts at liver transplantation in patients with metastatic carcinoid tumor have been associated with high perioperative mortality rates and local recurrences, although more recent reports suggest improved survival rates. Carcinoid tumors are slow growing and patients exhibit favorable 5- and 10-year survival rates despite extensive metastasis.

Systemic Therapy

One of the most important advances in the treatment of carcinoid syndrome has been the development of various somatostatin analogs for the diagnosis and treatment of metastatic disease.[16] More than 80% of carcinoid tumors express one of the five subtypes of somatostatin receptors. Although five somatostatin receptors have been identified, the beneficial effects of these somatostatin analogs seems to be mediated by the somatostatin receptor subtype 2.[17] Activation of this receptor results in reduced hormone synthesis and secretion. The 14 amino acid peptide somatostatin has a half-life in the order of minutes, making pharmacological dosing difficult. The somatostatin analog octreotide is an eight-amino acid peptide with a longer half-life and retained specificity for the somatostatin receptor. Octreotide is effective at controlling the hormonal manifestations of the carcinoid syndrome and may halt progression of some of the fibrosing effects, namely cardiac and mesenteric fibrosis. Initial studies using octreotide administered at a dose of 150 μg three times daily improved symptoms in 88% of patients and reduced 5 HIAA

urinary excretion in 72%. Some reports in the literature have described a temporary stabilization of tumor growth in as many as 85% of patients, suggesting a role of these analogs in decreasing tumor progression, but no overall improvement in survival rate has been demonstrated.

Long-acting somatostatin analogs, octreotide long-acting repeatable (LAR) and lanreotide prolonged release (PR) are currently available and can be administered as a depot injection.[18] Octreotide LAR can be administered at a dose of 20 mg intramuscularly (IM) monthly and lanreotide PR at a dose of 30 mg IM every 10 days. The most commonly reported adverse effects of these analogs include cholelithiasis in approximately 50% of patients and tachyphylaxis. The effects of these various somatostatin analogs on survival rates in patients with metastatic carcinoid syndrome have not been reported in a large patient series.[19]

Cytotoxic chemotherapy has been ineffective in the treatment of metastatic carcinoid tumors.[20–24] In a trial by the Eastern Cooperative Oncology Group, 118 patients with metastatic carcinoid tumor received streptozocin and cyclophosphamide or streptozocin and 5-fluorouracil (%-FU).[22] Response rates, based on reduced urinary 5-HIAA levels and tumor regression were 26 and 33%, respectively, but were associated with considerable toxicity. The best response to chemotherapy have been in patients with aggressive carcinoid tumors that have been treated in a similar way to small cell lung cancer with cisplatin-based chemotherapeutic regimens. Combined cisplatin and etoposide therapy led to 67% response rate in patients with neuroendocrine tumors but was less effective in the setting of the less aggressive variants of carcinoid tumors.[25] Interferon-alpha has been shown to provide symptom relief in one-third of patients refractory to octreotide treatment. A trial examining the use of interferon-alpha in 111 patients with the carcinoid syndrome demonstrated reduced urinary 5-HIAA levels in 42% and tumor regression in 15% of patients.[25] The routine use of interferon has been limited by the side effect profile which includes fever, weight loss, fatigue, and anorexia.

External beam radiation therapy has not been used extensively in patients with carcinoid tumor, although it has proven to be effective in palliative treatment of bone and central nervous system metastasis.[26,27] However, targeted therapy with radiolabeled somatostatin analogs remains a very exciting development in the treatment of patients with metastatic or inoperable carcinoid tumors. This involves the use of radiolabeled somatostatin analogs for SRS scan positive tumors. Initial results are very encouraging and in the phase IIa MAURITIUS study, 90-yttrium-DOTA-lanreotide in 70 patients with SRS scan positive tumors resulted in stable disease in 35% and regression in 10%.[28]

Neuroendocrine Carcinoma

The neuroendocrine (NE) system is comprised of endocrine cells found throughout the body including the pancreas, thyroid, lung, adrenal gland, as well as the gastrointestinal

system amongst other areas. NE tumors occur most commonly in the lung in the form of small cell carcinoma but have been reported less commonly in the colon and rectum. In comparison with carcinoid tumors that are usually slow growing and indolent neuroendocrine tumors, NE tumors of the colon and rectum tend to be poorly differentiated high grade tumors, highly aggressive, and associated with a poor prognosis. In fact, many poorly differentiated adenocarcinomas are probably NE tumors when stained appropriately for the various enteroendocrine cell markers such as chromogranin and synaptophysin. It is important to differentiate these tumors from other small cell cancers such as lymphoma. An extensive metastatic workup is critical to determine an appropriate treatment plan as up to two-third of patients will have metastasis at the time of diagnosis. Multimodality treatment is indicated and involves surgical resection when possible for curative intent, with adjuvant chemotherapy and radiation treatment being utilized. Chemotherapeutic agents used to treat small cell cancer of the lung are often effective in treating these tumors.[29]

Melanoma

Melanomas of the gastrointestinal tract can be divided into (1) metastatic melanoma usually from a cutaneous neoplasm or more rarely (2) a primary GI melanoma.

Metastatic Melanoma

Melanoma is one of the most common cancers to metastasize to the GI tract and studies have documented that the majority of these are to the small intestine (up to 67%), followed by the colon (up to 15%) and stomach (5–7%).[30–34] Although there is a high rate of metastases, less than 5% of patients with melanoma are diagnosed with a GI metastasis, but based on autopsy studies the GI system may be second only to lung in terms of site of spread.[35] Once a melanoma metastasizes, it carries a poor prognosis with usually less than 6 months survival; however, gastrointestinal metastases may be symptomatic and present with bleeding, obstruction, or most commonly pain.[33–35]

Evaluation of a patient with a history of melanoma who presents with obstructive symptoms or anemia may include colonoscopy, upper endoscopy, upper GI series with a small bowel follow through. CT scanning can be useful but sensitivity has been estimated at around 60% – one study identified four patterns of small bowel involvement based on CT including (1) intraluminal mass, (2) mesenteric implants causing compression of the lumen, (3) ulcerating lesions, and (4) diffuse infiltration.[36] PET scanning can also be used to help identify metastatic disease.[37] One study found that only 6% of patients had evidence of GI metastases when CT scanning for staging was routinely used and all of these were thought to be liver metastases.[38] In patients who have already developed metastatic disease, if a patient is not symptomatic, looking for these lesions in the GI tract is likely not going to alter management and therefore probably should not routinely be done.

When patients present with symptoms, intervention in selected patients is likely beneficial even though it will be done for palliative purposes. Studies from various institutions have found that the majority of patients selected for an operation benefit from a surgical intervention with an acceptable morbidity and mortality rate.[33,39–41] Symptom improvement varies between 79 and 97% in published studies. The most common procedure is usually a small bowel resection. The mortality rates in these studies ranged from 1.5 to 3%.[33,39–41] In a multivariate analysis in one study complete resection of all disease as well as a low preoperative serum LDH was predictive of long-term survival – 38% of patients survived to 5 years.[41]

In summary, in terms of lesions metastatic to the GI tract, melanoma is common. However, it is not common to operate on patients with metastatic melanoma to the GI tract. If a patient is symptomatic, even though the resection may be considered palliative, there is improvement in symptoms in the majority of patients who are selected to go to the operating room.

Primary Melanoma

A primary melanoma of the gastrointestinal tract is rare but can occur in the esophagus, small intestine, rectum, and anus.[35,42] Of these, the anus is the most common location. There are very few case reports of primary colonic melanoma.[43,44] Compared to cutaneous melanomas, gastrointestinal lesions carry a worse prognosis – this may be related to the fact that they are discovered at a more advanced stage when they become symptomatic.[45]

The diagnosis of a primary gastrointestinal melanoma is made if after a thorough search there is no cutaneous melanoma identified. In addition, a solitary lesion in the gastrointestinal tract should be present without any metastatic disease to be confident in calling it a primary.

Melanoma affecting the rectum or anus is rare with an estimated incidence of 1–2 cases/million per year.[35,46] Although the rate is low, it ranks third in terms of site of primary melanoma (skin and ocular melanoma being first and second).[46] Cumulatively these represent less than 1% of malignancies discovered in the anus and rectum. In contrast to cutaneous melanomas, there does not appear to be a relationship to sun exposure; women may be at higher risk compared to males and individuals are usually in their seventh decade.[45]

The diagnosis of anorectal melanoma can be difficult – many patients have bleeding which is usually thought to be secondary to hemorrhoids. Other symptoms include pain, tenesmus, and change in bowel habit. Weight loss, decreased energy, and other systemic signs may suggest metastatic disease. Most of these lesions are pigmented; however, up to a third may be a amelanotic.[35] Morphologically, these can present as ulcerated or polypoid lesions and can be mistaken for thrombosed external hemorrhoids. Incidental diagnosis is sometimes made after a routine hemorrhoidectomy is done underscoring the importance of a careful anorectal exam on

every patient who presents with issues in this area. Biopsy can be done of any suspicious lesion or ulceration present. The only chance for cure in these patients is early diagnosis and excision.[47] Unfortunately, the prognosis for these patients is poor. Five-year survival is estimated to be 6% and median survival after diagnosis is 12–18 months.[35] Approximately half of these patients will present with metastatic disease and 20% will have gross inguinal lymphadenopathy.[48]

The surgical approach to this disease is made difficult because of the poor prognosis and it does not seem to be based on recent case series that radical excision (APR) results in better survival compared to local excision.[49–51] If a patient has a tumor that is invading into the sphincters and causing intractable pain, then a patient like this may benefit from an APR. In patients who are having only local symptoms, a local excision is a reasonable approach. Again, based on retrospective reviews there does not seem to be a survival advantage with a radical approach.

Chemotherapy thus far has been disappointing. Most of the information regarding the use of chemotherapy is based on the experience with cutaneous melanomas. Dacarbazine, levamisole, and BCG have not yielded survival advantages and two meta-analyses examining the use of interferon-alpha have not demonstrated a consistent advantage with its use.[52,53] Combined use of dacarbazine, nimustine, cisplatin, and tamoxifen plus interferon-beta has been described but not surprisingly can result in significant toxicity to the patient.[54] Molecular-based therapy targeting tyrosine kinase receptors may lead to better survival in the future, but at the present time there is not enough data to support its routine use.[55]

Overall, anorectal melanoma is a "bad actor." It is associated with a poor prognosis and at the present time there is not a good treatment that provides long-term survival. Careful examination of all patients who present to the clinic with any type of anorectal complaint is important and biopsy of suspicious lesions should be done early. In the case of anorectal melanoma, the only chance for cure is an early diagnosis.

Gastrointestinal Stromal Tumor

The concept of "GIST" (gastrointestinal stromal tumor) was first introduced by Mazur and Clark in 1983.[56] They used immunostaining and electron microscopy to show that tumors that had previously been described as leiomyomas or leiomyosarcomas (using light microscopy) actually did not have smooth muscle or Schwann cells. The cell of origin is thought to be the interstitial cell of Cajal. An important article regarding mutations in the protooncogene c-kit in GISTs was written by Hirota et al.[57] This author along with Heinrich et al. described mutations in platelet-derived growth factor receptor a (PDGFRa another tyrosine kinase).[58] Mutations of c-kit and PDGFRa are thought to be two different pathways to the formation of GISTs. Over 90% of GISTs have a mutation in c-kit and up to 10% have a mutation in PDGFRa.[59]

Microscopically, spindle cells are usually seen. CD117 (immunohistochemical marker for KIT) is a very sensitive and specific marker for GISTs. CD34 is seen in approximately 70% of GISTs. If CD117 is negative but the appearance microscopically is consistent with a GIST, the diagnosis can be made if staining for S100, SMA, and desmin are negative.[60]

GISTs represent the most common mesenchymal tumor of the GI tract. They tend to occur in the middle aged and elderly (mean age of 60) with men affected more often.[61] It should be noted that pediatric cases have been reported.[62] The stomach is the most common site followed by the small intestine. GISTs can also be seen in the rectum but rarely in the colon. When considering small intestinal GISTs the jejunum is the most common location followed by the ileum. Duodenal lesions are usually in the second part. Tumors in the stomach have a lower rate of malignancy (20%) compared to lesions in the small and large bowel (40%). It is rare to find a GIST of the esophagus and these are usually leiomyomas.[59,60,63]

Most GISTs occur sporadically but there are some hereditary entities to consider. Carney's triad consists of (1) synchronous or metachronous GISTs, (2) extra-adrenal paragangliomas, and (3) pulmonary chondromas.[60,63] It is usually seen in women before age 30 and interestingly no mutation in KIT or PDGFRa have been identified.[64,65] Patients affected with neurofibromatosis type I more commonly are affected with GISTs and also present at a younger age than the sporadic cases. These usually present as multiple small intestinal tumors.[66,67] In these patients as well there has been no KIT/PDGFR mutation identified.[60,63]

A recent autopsy series found that one in four patients over the age of 50 had small GISTS located near the gastroesophageal junction. These have been termed "GIST tumorlets" and are thought to be clinically insignificant lesions that would need some additional stimulus to evolve into something that would be clinically significant.[68]

Clinical presentation will depend on the location and size of the tumor.[63,69,70] Symptoms are usually nonspecific and can include dyspepsia, bleeding, and pain. Advanced lesions can present as a palpable mass. Not surprisingly, increased symptoms are associated with increased size. In a study from Sweden, the median size was 8.9 cm in symptomatic patients compared to 2.7 cm in asymptomatic individuals.[63]

Lesions are usually submucosal – as a result imaging is the most important tool in making the presumptive diagnosis. Final diagnosis is usually made once the pathologist has the specimen. Imaging modalities that can be used include CT, MRI, PET, and endoscopic ultrasound. CT and MRI (low intensity on T1, high intensity on T2) scanning are often used.[71] GISTs usually involve the muscularis propria and an intramural mass that is well circumscribed is the characteristic appearance. In tumors that are larger, there can be areas of central necrosis. Percutaneous biopsy with fine or core needle aspiration is not recommended since neovascularisation

is associated with these tumors and hemorrhage can occur if they are biopsied. In addition, there is the possibility of tumor rupture and spread.[63] If the tumor is large and extending into the mesentery or other adjacent structures it can be difficult to discern if it is a lymphoma or sarcoma that is the underlying problem. Metastases are most commonly seen in the liver and peritoneum. Lymphatic spread is not common and therefore lymphadenopathy is not usually seen.[72] Lung and bone metastases have seen in advanced cases. CT scan is usually best for staging and for determining if there is potential for surgical resection.[73] PET is not normally required for diagnosis or determining resectability but can be used to see if there has been a response to treatment.[73] Endoscopy as well as endoscopic ultrasound for lesions that are within reach of a scope is likely a good idea to visualize the mass for operative planning as well as biopsy the tumor if possible – this can potentially change treatment if biopsies return with lymphoma. Endoscopic ultrasound-guided fine needle aspirations have a higher rate of diagnosis compared to endoscopy alone but fine needle aspiration with endoscopic ultrasound is controversial because it still carries similar risks to percutaneous biopsy described earlier.[74,75]

The treatment of GIST can be divided into (1) surgical resection and (2) imatinib and sunitinib. Ideal surgical management involves resection of the tumor en bloc with any other associated contiguous involvement with microscopically negative margins.[76,77] In order to attain a microscopically negative margin a gross margin of at least 1 cm is suggested. Even after a complete resection there is a high recurrence rate,[78] and therefore adjuvant therapy with imatinib should be considered.

When rectal GISTs specifically are considered, the symptoms associated are bleeding, pain (abdominal or rectal), or mass found on DRE or with endoscopy. Consistent with other GISTs at other sites, the larger the size, the more symptomatic a patient is. Complete excision is the best treatment including any pseudocapsule that is present. High local recurrence rates exist and are higher with wide local excision when compared to abdominoperineal resection or anterior resection.[79] Another modality that could be used is transanal endoscopic microsurgery as long as the surgeon is confident in being able to perform a complete excision. GISTs do not typically spread lymphatically and therefore a wide excision of the mesentery is not necessary; however, an en bloc resection of the tumor with microscopically negative margins is important.

If a complete resection is not possible due to the size of the tumor there are multiple reports involving the neoadjuvant use of imatinib which have decreased the size of the tumor to a point where surgical resection becomes feasible – at least 50% of patients will have tumor shrinkage.[80–82] CT scan can be used to follow these patients and judge the response to treatment. A trial being done by the RTOG (Radiation Therapy Oncology Group) is looking at this question and patients are given neoadjuvant imatinib therapy for 2–6 months in patients who present with large tumors that would likely require additional organ resection.[82] One additional benefit that is being considered with this neoadjuvant therapy is whether it will decrease the vascularity of the tumor and make the operation safer. It should be remembered that up to 15% of GISTs will be resistant to imatinib, and therefore the lesion could theoretically grow bigger and become unresectable while neoadjuvant therapy is being done. Also, a tissue biopsy in the form of fine needle aspiration usually needs to be done prior to an oncologist agreeing to give neoadjuvant treatment and this can lead to some of the issues that were mentioned earlier in this section.

With respect to prognosis, tumor size and mitotic rate are the most important parameters. A tumor with less than 5 mitoses per 50 high-powered fields is usually benign acting although there are a small number that may metastasize. Lesions with a diameter of less than 2 cm are almost always benign.[60]

When GISTs recur or are metastatic the treatment algorithm is similar. Usually, Imatinib will be used first and then the response to this treatment evaluated radiologically. If patients respond, then lifelong treatment can be used. In patients presenting with metastases, 45% will have a partial response and 30% will have stable disease. Imatinib has had a big impact with respect to survival as median survival with metastatic disease is 5 years; it used to be 15 months after resection of recurrent GIST when imatinib was not available. Imatinib does not offer a cure, and therefore surgery can be attempted. In addition, by utilizing surgery there may be a delay in resistance of the tumor to Imatinib.[59,60,63]

In patients that do not respond to Imatinib one option can be to increase the dose from 400 to 800 mg per day if the patient is only receiving the 400 mg dose. Sunitinib can be used as a second line treatment. In a prospective randomized trial that compared sunitinib to a placebo in patients with imatinib resistance, there was a longer time to tumor progression in the Sunitinib group.[63] These patients also had longer overall survival. With respect to other options, GISTs are considered to be resistant to radiation. Palliative treatment could be considered for rectal GIST. Radiofrequency ablation for lesions in the liver can be attempted. Hepatic artery embolization can also be done for unresectable liver metastases. Other chemotherapy regimens have not been as successful as Imatinib and Sunitinib. Vatalanib and Dasatanib are other tyrosine kinase inhibitors that are being studied.[63]

Leukemia and Neutropenic Enterocolitis

All forms of leukemia can lead to infiltration of the gastrointestinal tract. Most commonly, the ileum, appendix, and colon are affected due to their higher concentrations of lymphatic tissue.[83,84] Involvement can result in diarrhea, pain, obstruction, colitis, or watermelon colon.[83,85] The infiltration can lead to lesions ranging from ulcers to polypoid lesions which can cause obstruction not only from the mass itself but also from intussusception.[86] Anorectal complications include

plaques, fistulas, ulcers, fissures, and abscesses.[87] Since there is a high risk of creating infectious complications in patients with leukemia and receiving chemotherapy, instrumentation of the rectum should be avoided if possible.[87]

Neutropenic enterocolitis is a complication that is most frequently seen after the chemotherapy for leukemia. It has been seen in a variety of malignancies – solid and hematologic – secondary to the chemotherapy regimens.[88–93] Numerous agents have been implicated although cytotoxic agents are mainly involved. The small bowel, appendix, and colon can be involved,[94,95] and the organisms involved include Staphylococcus Aureus, Acinetobacter, Enterobacter, Aspergillus, Pseudomonas, Candida, Klebsiella, and Morganella.[96,97] The overall pathogenesis involves a combination of mucosal injury, neutropenia, and decreased defense against gastrointestinal bacteria.[96,97] There has been one systematic review which reported a 5.3% pooled incidence rate in patients who were hospitalized for the treatment of hematologic/solid malignancies or aplastic anemia.[98]

Fever and abdominal pain in the setting of neutropenia (absolute neutrophil count less than 1,500/mm^3) is the triad of findings associated with this diagnosis.[96,97] Other findings can include nausea and vomiting, diarrhea, and distention. Abdominal pain and tenderness can be diffuse but is often localized to the right lower quadrant. CT scanning can show bowel wall thickening, edema/hemorrhage, pneumatosis, free fluid, and free air. Imaging can help decrease the use of nontherapeutic laparotomies and help identify other etiologies for the pain.[96,97] Ultrasound can be used and there are characteristic patterns associated with neutropenic enterocolitis such as "doughnut like hypoechoic, fluid-filled intestinal lumen separated from a thickened bowel wall by a thin mucosal layer."[98] One study demonstrated that using high resolution ultrasonography systematically decreased the time between fever and the diagnosis of neutropenic enterocolitis (3 days vs. 9 days, $p = 0.01$).[99] Further, with the use of systematic ultrasound, mortality appeared to be reduced. Ultrasound studies have also shown that bowel wall thickening appears to be related to a longer duration of symptoms and a higher mortality rate compared to patients without this sonographic finding.[99]

There is no high level evidence to guide the treatment of neutropenic enterocolitis.[98] In patients that do not have peritonitis or perforation can likely be managed medically initially. Conservative management consists of hydration, bowel rest, a nasogastric tube if there is a significant ileus, TPN, and broad spectrum antibiotics. Granulocyte colony stimulating factor may be a consideration.[97,98]

If a patient requires exploration, treatment usually consists of a bowel resection and an ostomy since complications have been reported if primary anastomosis is performed on leucopenic patients.[100, 101] In addition, there may be mucosal necrosis even though the serosa may only appear edematous. Based on the systematic review, there is no good evidence to determine the optimal surgical approach.[98]

Overall, there is not good evidence to guide management as a systematic review has shown. In patients who present with fever, abdominal pain, and neutropenia a CT scan or ultrasound should be done as soon as possible. Further treatment depends on the clinical scenario, but broad spectrum antibiotics should be initiated.

Lymphoma

The gastrointestinal tract is the most common site of extra-nodal lymphoma.[102] Primary colorectal lymphoma is rare accounting for 15–20% of GI lymphomas (stomach 50–60%, small bowel 20–30%).[103] Diffuse large B-cell lymphoma is the most common histologic type seen in the colon with the second most common type being MALT-associated low-grade B-cell lymphoma.[103,104] It should be noted that colorectal lymphomas do not have the association with H. Pylori like their gastric counterpart. As a result, they cannot be treated with H. Pylori eradication therapy.[102] In terms of staging, the modified Ann Arbor staging system is usually used. HIV, EBV, prolonged steroid therapy, and inflammatory bowel disease have been suggested as possible risk factors.[105] Dawson's criteria has been used for the diagnosis of primary colorectal lymphoma.[106]

Patients are usually between the ages of 50 and 70 with a slight male predominance (1.5:1). Weight loss and abdominal pain are the most common symptoms at presentation and many patients present with a palpable mass as these tumors often progress without symptoms until reaching a large size. Interestingly, although reaching a large size, they rarely cause obstruction or perforate. Gastrointestinal bleeding can also be seen in 20–30% of cases.[102,107,108]

Most colonic lesions are found in the cecum and ascending colon with 70% of colorectal lymphomas occurring proximal to the hepatic flexure likely because of the increased lymphoid tissue in this area of the bowel.[104, 109–111] Treatment involves a multidisciplinary approach using surgery and chemotherapy. Surgical excision still appears to the main treatment for this disease as it provides staging information as well as the chance for cure (with or without chemotherapy). It also helps avoid possible complications such as bleeding or obstruction.[104,112,113]

The role of chemotherapy as the initial treatment has not been studied except for some series in which there have been patients included in whom surgery was contraindicated.[104,112,113] In these patients, there was no benefit shown compared to the patients in groups receiving surgical therapy or combined therapy. Radiation therapy is used in selected cases. Five-year survival rates range between 27 and 55%.[100–102,104] While one study suggested that patients with tumors larger than 5 cm or are lymph node positive have the worst prognosis.[114]

Hirschsprung's Disease

Hirschsprung's disease (congenital megacolon) is an anomaly characterized by functional partial colonic obstruction due to the absence of ganglion cells. It occurs in approximately 1 in 5,000 births. Boys are more frequently affected than girls and it is more common in caucasians.[1] The functional disturbances in this condition are attributed to the absence of ganglion cells from the Auerbach's myenteric plexus (located between the circular and longitudinal layers of smooth muscle of the intestine), the Henle's plexus (located in the submucosa), and the Meissner's plexus (in the superficial submucosa). The absence of these cells most probably produces uncoordinated contractions of the affected colon, which translates into a lack of relaxation of the colon that result in partial colonic obstruction.

The length of the aganglionic colonic segment varies. In the most common type, it includes the rectum and most of the sigmoid colon. Nearly 80% of all patients suffer from this type. In approximately 10% of the patients, the aganglionosis extends to the area of the splenic flexure or the upper descending colon. Total colonic aganglionosis occurs in another 8–10% of the patients. In those cases, the absent ganglion cells sometimes extend to the distal terminal ileum. In the rather controversial condition of "ultrashort" aganglionosis, the ganglion cells supposedly are lacking for only a few centimeters above the pectinate line. Very rarely, one can see patients who suffer from universal aganglionosis, meaning that ganglion cells are absent in the entire gastrointestinal tract, which is a lethal condition, unless the patient undergoes intestinal transplantation.

The clinical manifestations are those of a partial colonic obstruction. In addition, these patients suffer from a poorly characterized immunologic mucosal defect that may explain why they can get an inflammatory process called enterocolitis, which is the main cause of death. In addition, fecal stasis seems to promote the proliferation of abnormal colonic flora as well as production of endotoxins that contribute to the aggravation of the clinical condition.

Usually the patient becomes symptomatic during the first 24–48 h of life. Delayed passage of meconium (more than 24 h), abdominal distention, and vomiting are the most common symptoms. A rectal examination may produce explosive passage of liquid bowel movements and gas, which dramatically improves the baby's condition. This clinical improvement only lasts for a few hours, following which, the symptoms recur. If the colon is not decompressed, the infant usually suffers from sepsis, hypovolemia, and endotoxic shock. Cecal perforation may occur. About 25–30% of these babies die when unrecognized or not treated. Patients that do survive unrecognized and without treatment, ultimately develop the classic clinical picture initially described for this condition. They suffer from severe constipation, a huge megacolon, and an enormously distended abdomen, a clinical situation that is extremely rare nowadays in developed countries. Occasionally, these patients are misdiagnosed as suffering from idiopathic chronic constipation. In the latter condition, the patients are not seriously ill, and it is very common for them to suffer from overflow pseudoincontinence (encopresis). A rectal examination discloses a rectum full of fecal matter. Patients with Hirschsprung's disease on the other hand usually suffer from malnutrition, and a lack of normal development. They usually have an empty, aganglionic, and narrow rectum, and they do not suffer from soiling.

The presence of distention, vomiting, and delayed passage of meconium in a newborn must alert the clinician to the diagnosis of Hirschsprung's disease. An abdominal film shows massive dilatation of small bowel and colon. A contrast enema is used to clarify the diagnosis. The catheter for the study should be introduced only a few centimeters into the rectum in order to be able to visualize the nondilated aganglionic segment of the rectosigmoid, followed by a transitional zone and then a proximal dilatation. These typical changes are often not obvious during the neonatal period. The older the patient, the more obvious the size difference between normal and aganglionic segment. In patients with total colonic aganglionosis, the entire colon is not distended; the dilatation affects the small bowel only.

The definitive diagnosis by a rectal biopsy is based on both the histological absence of ganglion cells, and the presence of hypertrophic nerves. Acetylcholinesterase staining used by some centers is also abnormal. The biopsy can be taken full-thickness under direct vision, or a suction biopsy can be performed. The specimen, however, must include mucosa and submucosa.

Medical Management

Colonic decompression and irrigation with saline solution is the most valuable tool for the emergency management of newborns. This maneuver may dramatically improve a very ill neonate. Irrigations should not be confused with enemas. An enema is a procedure in which an amount of fluid is instilled into the colon. In a normal patient, it is expected that this fluid will be spontaneously expelled. However, patients with Hirschsprung's disease are incapable of expelling this fluid and, therefore, enemas are contraindicated. A colonic irrigation, on the other hand, promotes the expelling of the rectocolonic contents through the lumen of a large rubber tube, which is cleared with small amounts of saline solution. Rectocolonic irrigations may save the baby's life but of course are not the ideal long-term form of treatment. Once the histologic diagnosis has been established, the irrigations must continue in preparation for the surgical treatment.

Surgical Treatment

The basis of the surgical treatment consists in the resection of the aganglionic segment and pull-through of a normoganglionic segment to be anastomosed just above the anal canal, immediately above the pectinate line. This should guarantee the preservation of bowel control as the anal canal and sphincters are preserved. There are several ways to achieve these basic goals. The surgical treatment has evolved significantly since 1948 when the first surgical technique was described.[1]

Originally, these patients were subjected to a staged approach. The first stage consisted in the opening of a diverting colostomy, usually in the transverse colon. The second stage included the resection of the aganglionic segment and pull-through of the normoganglionic bowel, and the third stage was the colostomy closure. Subsequently, surgeons adopted a two-stage modality that included the opening of the colostomy during the newborn period at the level of the ganglion cells. The second stage consisted in the pull-through, leaving the patient without a colostomy.

More recently, the treatment most commonly used consists in a neonatal primary procedure without a protective colostomy.[2,3] This approach is less invasive and avoids the morbidity of a stoma and multiple surgeries. This can be done with a transanal approach alone (Figure 50-1).[4,5] or with the addition of laparoscopy to the transanal approach.[6] However, approaches may vary from country-to-country and with the surgeon's experience. In addition, a primary procedure, without a protective colostomy requires the presence of an experienced clinical pathologist, familiar with the interpretation of frozen sections. Also, in the case of a very ill, low-birth weight newborn, or a very sick baby, with enterocolitis unresponsive to the irrigations, a colostomy is still the optimal way to protect the patient. If a two-stage approach is chosen, in the presence of an experienced pathologist, the colostomy must be opened in a normoganglionic portion of the colon. In the absence of an experienced pathologist, the surgeon must open the colostomy, proximal to the transition zone in the right transverse colon or with an ileostomy. In the event of a colon that is not dilated, the patient should receive an ileostomy.

The definitive procedure (resection of the aganglionic segment and pull-through of the normal ganglionic colon) can be done in different ways. Swenson and Bill[1] described their operation consisting in an intra-abdominal resection of the aganglionic segment including a part of the normoganglionic dilated colon, and pull-through of a normoganglionic bowel, with a coloanal anastomosis of the normoganglionic bowel to the rectum, above the pectinate line. Nowadays, this can be done transanally.

FIGURE 50-1. Transanal procedure.

Duhamel[7] described an operation designed to avoid pelvic dissection and potential nerve damage. He proposed to preserve the aganglionic rectum, dividing the colon at the peritoneal reflection. The normoganglionic colon is then pulled through a presacral space, created by blunt dissection and anastomosed to the rectal wall above the pectinate line.

Soave[8] designed a procedure consisting in an endorectal (submucosal) dissection of the aganglionic colon, leaving a seromuscular cuff. He carried this dissection down to the rectum above the pectinate line. The normally innervated colon is passed through the muscular cuff and anastomosed to the rectum. The purpose of this operation, again, was to avoid the perirectal dissection and its potential negative effects due to denervation of pelvic organs. This is now done transanally[4,5] sometimes with laparoscopy[6] and is the most commonly chosen technique worldwide.

The original Soave procedure was performed in two stages. During the first stage, the colon was pulled down but was not anastomosed to the rectum. It was left protruding outside the rectum. In the second stage, a week later, the protruded bowel was resected and the anastomosis was performed. Subsequently, Boley[9] proposed a primary anastomosis.

The abdominal portion of all of these operations can be done laparoscopically.[6,10,11] The technique of a seromuscular biopsy done laparoscopically has an important limitation in that it may avoid sampling the submucosa. We advocate for a full-thickness biopsy which includes submucosa.[12] It is possible to have ganglion cells in the muscularis but have hypertrophic nerves in the submucosa. Thus the wrong position for the pull-through could be selected.

In 1998, de la Torre and Ortega[4] and subsequently in 1999 Langer et al.[5] reported the novel transanal approach for the management of this condition. They demonstrated that the whole procedure can be done transanally provided the transition zone is in the sigmoid. If not, laparoscopy can be added for splenic flexure mobilization. A special retractor (Lone Star Retractor, Lone Star Medical Products®, Stafford, TX, USA) is very helpful to expose the dentate line and anal canal.

We recommend the use of multiple fine sutures taking the rectal mucosa 1 cm above the pectinate line, taking great care to preserve it. These allow the surgeon to exert a uniform traction on the rectal mucosa (Figure 50-2). Peripheral to this series of silk stitches, an incision is performed with cautery and a circumferential dissection of the rectum is performed applying uniform traction (Figure 50-3). The dissection can be performed submucosally (Soave-like) or full-thickness (Swenson-like) and is carried up through the peritoneal reflection. As the surgeon progresses in the dissection, full-thickness biopsies are taken to determine the place where the normoganglionic portion of the colon is reached. If laparoscopy was used to start the case, the ganglionic level is already known. The peritoneal reflection is soon found. The normoganglionic bowel is transanally anastomosed to the anal canal, 1 cm above the pectinate line.

FIGURE 50-2. Multiple fine sutures taking the rectal mucosa 1 cm above the pectinate line, allowing the surgeon to apply uniform traction on the rectal mucosa.

Since the majority of patients have a transition zone in the sigmoid colon, it is possible to repair the entire defect using this technique, without a laparotomy or laparoscopy.[4,5] When the transition zone is located higher, the surgeon determines when he or she needs a laparoscopic-assisted procedure or a laparotomy. We specifically recommend resecting not only the aganglionic segment of the colon but also the very dilated part of the colon since a very dilated colon also has very poor peristalsis.

Complications and postoperative sequelae can be divided into two categories: preventable and nonpreventable. An algorithm to the approach to post pull-through Hirschsprung's patients with problems is shown in Figure 50-4. Preventable complication should not occur since they are due to technical errors. A feared preventable sequela is fecal incontinence. This is most likely related to injury to the continence mechanism.[13] All these procedures were originally designed to prevent this from happening, providing they are performed correctly. The key factors are preservation of the dentate line and not overstretching the sphincters. Dehiscence, retraction, stricture, abscess, and fistula are all considered preventable since they are usually due to technical errors (Table 50-1).[14] During the pull-through, the surgeon must be familiar with the manipulation of the blood supply and the arcades of the colon in order to guarantee a good blood supply in the
FIGURE 50-3. Peripheral to this series of silk stitches, an incision is performed with cautery and a circumferential dissection of the rectum is performed applying uniform traction.

pulled-through colon. The anastomosis should be done without tension.

A relatively nonpreventable complication is enterocolitis unless there is an anatomic explanation, such as a stricture causing stasis. This is also an unpredictable, and a rather mysterious condition. Despite receiving a technically adequate operation, patients may suffer from enterocolitis. The frequency of this condition varies[15] and its etiology is unknown. Fecal stasis is the most important predisposing factor. If this occurs in the colon in a normal individual it produces constipation; in patients with Hirschsprung's disease, stasis frequently results in proliferation of abnormal bacteria, ulcerations of the colon, absorption of endotoxins, shock, and sometimes perforation. These patients respond to colonic irrigations, and on rare occasion require a colostomy. In a patient with recurrent episodes of enterocolitis there may be an anatomic cause and a secondary pull-through may be curative.[12]

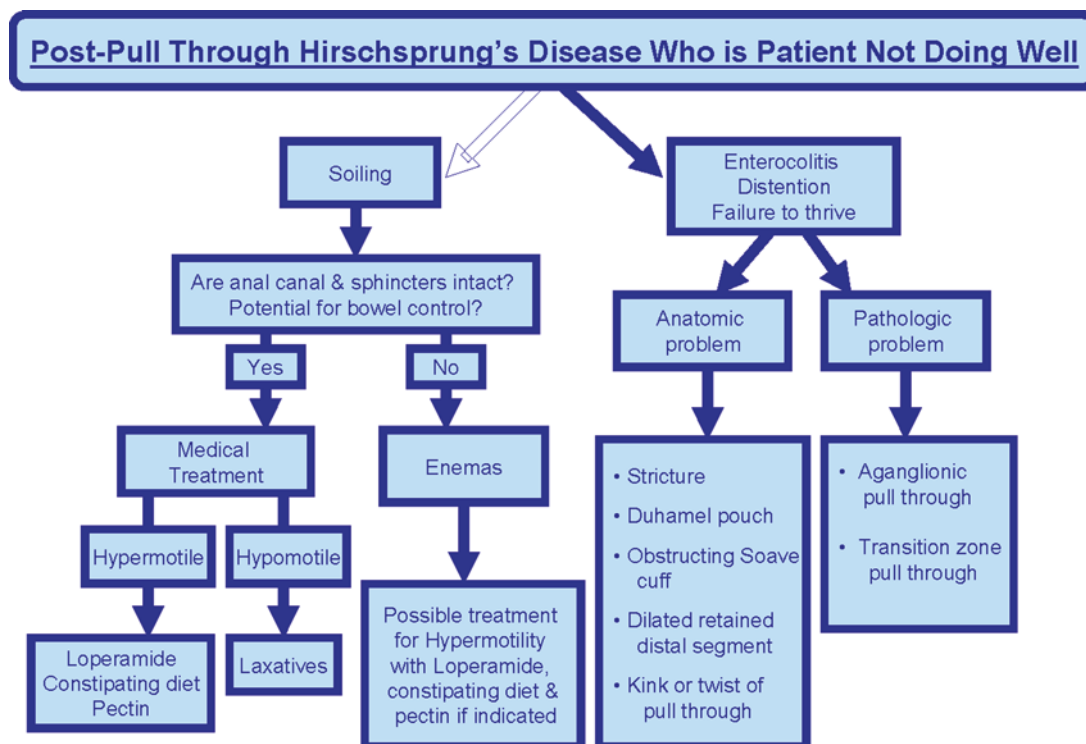
Constipation may also occur after these procedures. It is more common in patients in whom the aganglionic segment was resected, but a dilated portion of the colon was pulled down.[12] This is a partially preventable condition. Most cases of constipation can be avoided by resecting not only the aganglionic segment but also the dilated portion of the colon. In addition, a Duhamel pouch that is too large can compress the ganglionic pull-through causing obstructive symptoms. Many of the issues can present years after the pull-through, even in adulthood, and the adult surgeon caring for a Hirschsprung's patient must understand these anatomic issues.


FIGURE 50-4. Algorithm for post-pull-through Hirschpsrung's disease who is not doing well.

TABLE 50-1. Indications for Hirschsprung's disease reoperations

Reoperations for Hirschsprung's disease (75 patients[a,b])	
Mechanical indications	
Stricture	29
Megarectal pouch (post-Duhamel)	22
Obstructing Soave cuff	11
Dilated segment	5
Pathological indications	
Aganglionosis	15
Transition zone	8
Other indications	
Fistulae (rectocutaneous, rectourethral, rectovaginal)	12
Recurrent pelvic abscess	7

[a] Several patients may have more than one indication for surgery.

[b] The first 51 patients have been reported in Peña, Elicevik, Levitt.[14]

Each one of the techniques described has its own advocates. The analysis of different series shows that the most important factor that affects the clinical results is the experience and familiarity of the surgeon with their chosen procedure. Some surgeons claim that the Swenson operation exposes the patient to nerve damage that may provoke urinary and sexual disturbances. We as well as Dr. Swenson have not found this to be true. The Duhamel procedure is commonly followed by severe problems of constipation and dilatation of the aganglionic piece of colon left in place.[16] In the Soave operation, patients may suffer from fecal incontinence,[13] as well as perianal fistulas and abscesses due to the presence of islets of mucosa left behind during the endorectal dissection, much like the known complication of this sort following a mucosectomy for ulcerative colitis.

Advocates of a transanal approach site the decreased morbidity and enhanced recovery as a consequence of a procedure without the intra-abdominal dissection.[17–19] In addition, this approach permits early postoperative feeding, shorter length of stay, faster recovery, and possibly less chance for postoperative adhesions.

Surgical Management of Total Colonic Aganglionosis

The current treatment of this condition consists in a newborn ileostomy and then at age 1–3 years resection of the entire aganglionic colon and pull-through of the normal ganglionic terminal ileum that is anastomosed just above the anal canal. In order to avoid fluid losses and in an attempt to decrease the number of bowel movements per day, as well as to promote water absorption, Martin[20] proposed to leave a part of the rectosigmoid and descending aganglionic segment in place, and anastomose the normoganglionic terminal ileum to this colon and connect it to the posterior aspect of the rectum like in the Duhamel procedure. Kimura et al.[21] proposed the use of a right colon patch with the hope of creating a reservoir for water absorption. The use of a pouch can cause stasis of stool in the small bowel which is why many surgeons choose an ileo-Duhamel[22]; however, this stasis can produce bacterial proliferation and enterocolitis. Rather than absorbing water, very often the intestine secretes fluid into the lumen, producing a secretory diarrhea. It is therefore our opinion, as well as others,[23] that a straight ileorectal anastomosis is the preferred option.

They, as all patients with a surgically resected colon, suffer from multiple stools. Treatment of this with loperamide, pectin, and a constipating diet helps. We also like to wait until the child can sit on a potty and is toilet trained for urine as the avoidance of stool in a diaper dramatically reduces the problem of a perineal rash.

Surgical Treatment of Ultrashort Hirschsprung's

The surgical treatment of the ultrashort-segment aganglionosis is as controversial as the existence of this condition. Normal individuals have an area of aganglionosis above the pectinate line, but the length of this aganglionic area has not been accurately or scientifically determined. This is the reason why the diagnosis of ultrashort Hirschsprung is so controversial. Some surgeons propose an operation called a myectomy, consisting in the resection of a strip of smooth muscle from the anal verge up to the area where ganglion cells are found. The results of this procedure, again, are highly controversial and there is no scientific basis to explain why this may improve the condition. More scientifically conducted studies are required to clarify this issue.

Most cases of Hirschsprung's disease are diagnosed early in life, but a few patients reach their late teens and even adulthood before a diagnosis is made. Hirschsprung's disease in adults must be distinguished from other causes of mega colon such as Chagas disease, sigmoid volvulus, colonic inertia, Oglvie's syndrome, and other disorders of the central nervous system. Typically, Hirschsprung's in adults is of the short segment variety. Many such patients are confused with Hirschsprung's and in fact have idiopathic constipation which responds to laxative therapy.

Neuronal Intestinal Dysplasia

Neuronal intestinal dysplasia (NID) refers to a histologic condition that includes hypertrophy of ganglion cells, immature ganglia, hypoganglionosis, hyperplasia of the submucosal and myenteric plexus, giant ganglion cells as well as hypoplasia or aplasia of the sympathetic innervations of the myenteric plexus. These histologic abnormalities have been described as occurring in a localized or disseminated manner,[24] but even the existence of this condition can be questioned.[25] We suspect that most cases described as NID are in fact a sampled areas of colon that is actually transition zone bowel in a Hirschsprung's patient.

Anorectal Malformations (Imperforate Anus)

Anorectal malformations represent a spectrum of defects characterized by the absence of an external anal orifice. The overwhelming majority of the patients have an abnormal communication between the rectum and the perineum (perineal fistula), the vestibule (vestibular fistula), or the vagina (vaginal fistula), in the female. In some female patients, rectum, vagina, and urethra are fused together forming a common channel (cloacal malformation) and open into a single external orifice. In the male, the communication is with the urethra (rectourethral fistula), or the bladder (rectobladder neck fistula). Only 5% of the entire spectrum of patients are born with no fistula and the rectum is blind-ending. Anorectal malformations occur in about one in every 5,000 newborns. Males seem to suffer from this condition slightly more frequently than females. The most common type of defects seen in boys is a rectourethral fistula and the most common type in girls is vestibular fistula. Table 50-2 shows the anatomic classification.

Associated Anomalies

Urogenital abnormalities occur in about 50% of all patients with anorectal malformations. The higher and more complex the anorectal malformation, the higher the incidence of associated urologic defects. Urologic malformations are a common source of morbidity in these patients. About 90% of patients with a rectobladder neck fistula in males as well as in cases of cloacas with a common channel longer than 3 cm, have an associated urological problem. Unilateral renal agenesis is the most common urologic anomaly, followed by vesicoureteral reflux. Other important abnormalities include cryptorchidism, hypospadias, renal ectopia, and hydronephrosis.

TABLE 50-2. Current classification of anorectal malformations

Male
  Perineal fistula
  Rectourethral fistula
    Bulbar
    Prostatic
  Rectobladder neck fistula

  Rectal atresia and stenosis
Female
  Perineal fistula
  Vestibular fistula
  Imperforate anus without fistula
  Rectal atresia and stenosis
  Cloaca
Complex malformations

Sacral and spinal abnormalities are also very common in patients with anorectal malformations. The sacrum is frequently abnormal. The sacral abnormalities also represent a spectrum that varies from a completely absent sacrum to a completely normal one, including different degrees of hypo development. There seems to be a direct relationship between the degree of sacral abnormality and the final functional prognosis. These patients also suffer from hemivertebrae and as a consequence different degrees of scoliosis. The presence of hemivertebrae also seems to be related to a poorer functional prognosis.

Twenty-five percent of patients with anorectal malformations suffer from a defect called tethered cord.[26] In this condition, the cord is abnormally attached (tethered) to the spine. During the baby's natural growth, it is believed that the spine grows faster than the cord, producing traction on the nerve fibers that may produce functional disturbances in the motion of the lower extremities and may contribute to sphincter problems particularly impacting bladder emptying.

Hemi sacrum is sometimes associated with an anorectal malformation and there can be a mass located in the area of the sacral defect. An anorectal malformation with hemisacrum and a presacral mass is known as the Currarino triad. The most common sacral masses in these patients are a dermoid, teratoma, lipoma, anterior meningocele, or a combination of all these. These patients also have a poor functional prognosis.

Approximately 8% of all patients with anorectal malformations suffer from esophageal atresia. About 30% have some sort of cardiovascular congenital anomaly. Most commonly seen are patent ductus arteriosus, atrial septal defect, ventricular septal defect, tetralogy of Fallot, as well as other more complex malformations. Only 10% of patients have a cardiovascular malformation with significant hemodynamic repercussions that requires surgical treatment.

The main concern in a patient with anorectal malformation is whether or not the child will have bowel control, urinary control, and sexual function in the future. The higher the malformation, the worse the functional prognosis will be. The higher the anorectal defect, the more likely the child will suffer from fecal incontinence, but the less the chance of suffering from constipation. Conversely, the lower the malformation, the higher the incidence of constipation but the lower the incidence of fecal incontinence.

Description of Specific Defects

Males

Perineal Fistula

This is the simplest of all defects. The rectum opens anterior to the center of the sphincter mechanism in the perineum. The rectal orifice is usually too narrow to allow normal passage of stool. Sometimes, the end of the rectum lies immediately

below a very thin layer of epithelium with an external opening located at the base of the scrotum or sometimes at the base of the penis. The meconium or mucous sometimes can be seen below that very thin layer of epithelium giving an impression of a black or white ribbon. The overwhelming majority of these patients have a normal sacrum, less than 10% of them have associated defects. The final functional prognosis is excellent,[27] provided these patients receive adequate treatment. These patients can be operated on during the newborn period, with an operation that consists in moving the anal orifice back to the center of the sphincter creating a normal-sized anus.

Rectouretheral Fistula

In this group of malformations, the rectum connects to the urethra. In the most common subtype, the rectum opens into the lower part of the posterior urethra known as the bulbar urethra, and, therefore, the defect is called rectourethral bulbar fistula (Figure 50-5A). The rectum passes through a funnel-like striated sphincter mechanism to reach the lowest part of the posterior urethra. Eighty-five percent of these patients achieve bowel control when treated properly.[27] Approximately 30% of them have other associated defects.[27]

In the second subtype, the rectum opens into the upper part of the posterior urethra (prostatic), and, therefore, it is called rectoprostatic fistula (Figure 50-5B). Only 60% of these patients achieve bowel control later in life. Sixty percent of them have significant associated defects.[27] Most of these patients (rectourethral fistula) require a colostomy at birth and subsequently (usually 1–2 months later) they receive the definitive repair of the malformation.

The perineum of patients with anorectal malformations, have characteristic features that must be recognized. The higher the malformation, the more likely the patient will have a flat bottom, meaning that the natural midline groove is absent and there is no distinguishable anal dimple. The lower the malformation, the more prominent the midline groove and the anal dimple. In patients with rectourethral bulbar fistula, there is a recognizable midline groove as well as an anal dimple and in patients with rectoprostatic fistula, there is a tendency for the perineum to be flat. Also, the anal dimple tends to be closer to the scrotum the higher the malformation. One can also frequently see a bifid scrotum in cases of prostatic fistula.

Rectobladder Neck Fistula

This is the highest of all defects in male patients (Figure 50-5C). The rectum is connected to the bladder neck. Ninety percent of these patients have significant associated defects. The perineum is frequently flat. These patients are the only ones that require a laparotomy or laparoscopy in addition to the posterior sagittal approach to be repaired. Only 15% of these patients achieve bowel control later in life.[27]
FIGURE 50-5. **A** Bulbar fistula, **B** Prostatic fistula, **C** Bladderneck fistula. (Reprinted with permission from Pena A. Atlas of surgical management of anorectal malformations. New York: Springer Verlag; 1989).

Imperforate Anus Without Fistula

This is a rather unusual anomaly that occurs in 5% of all children with anorectal malformations. Half of them also suffer from Down's syndrome. More than 90% of all patients with Down's syndrome who suffer from an anorectal malformation have this specific type of defect, clearly pointing to a genetic influence.[28] Eighty percent of the babies with Down's syndrome and this malformation will eventually have bowel control when they receive an adequate operation. Approximately 90% of patients with this defect and without Down's syndrome have bowel control,[29] and patients usually have a good sphincter mechanism and a good sacrum.

Rectal Atresia or Stenosis

This malformation occurs in only 1% of all cases. It consists of a complete or partial interruption of the rectal lumen located between the anal canal and the rectum. The external appearance of the perineum is normal and the anal canal is normal or appears like a funnel with a long skin lined canal. The malformation is usually discovered when a nurse tries to take the newborn's rectal temperature. The sacrum is normal as is the sphincter mechanism. Some patients have a hemisacrum and a presacral mass which must be screened for. All of these patients (100%) will have bowel control after a correctly performed operation.[27]

Female Defects

Perineal Fistula

In these female newborns, the rectum opens in what is called the perineal body between the normal location of the anus and the female genitalia. All that was described about this defect in males is true for females. These patients can be repaired at birth without a colostomy. The prognosis is excellent.[27]

Vestibular Fistula

This is by far the most common defect seen in female patients (Figure 50-6). The rectum opens in the vestibule of the female genitalia just outside the hymen. The rectum and vagina share a very thin common wall. About 30% of these babies have associated defects; 95% of these babies will have bowel control when properly treated.[27] The sacrum is usually normal. Vestibular fistula is frequently misdiagnosed as a rectovaginal fistula.[30] Vaginal fistula is an extremely unusual defect, representing less than 1% of all the female defects. In those unusual cases of vaginal fistula, the rectum opens into the posterior vaginal wall deeper to the hymen.

Most of the vestibular fistula cases are successfully operated on at birth without a colostomy. However, those undiverted patients can suffer from dehiscence and retraction, when the surgical technique employed is not adequate so diversion is a safe approach. A secondary operation in these cases does
FIGURE 50-6. Vestibular fistula. (Reprinted with permission from Pena A. Atlas of surgical management of anorectal malformations. New York: Springer Verlag; 1989).

not render the same good result as in cases of a well-done primary procedure.

Imperforate Anus Without Fistula

It is uncommon to see this type of defect in females. All that was mentioned about this defect in males is true about this defect in females, except of course that the distal rectum is adjacent to the posterior vagina rather than to the urethra.

Rectal Atresia or Stenosis

This condition does not differ from the defect described in males. Again, the patient must be screened for a presacral mass.

Cloaca

A cloaca is defined as a malformation in which the rectum, vagina, and urinary tract are fused together forming a common channel (Figure 50-7). This single channel opens where the normal urethra is located in females. Externally, these babies have rather small-looking genitalia. Separation of the small labia allows the observer to see a single orifice, which confirms the clinical diagnosis of a cloaca. Cloacas represents another spectrum of defects. The length of the common channel varies from 1 to 7 or even 10 cm, and is directly related to the final functional prognosis for bowel and urinary control. Patients with a common channel shorter than 3 cm can be repaired posterior sagittally without opening the abdomen and the prognosis for bowel and urinary control is good.
FIGURE 50-7. Cloaca. (Reprinted with permission from Pena A. Atlas of surgical management of anorectal malformations. New York: Springer Verlag; 1989).

FIGURE 50-8. Hydrocolpos in cloaca. (Reprinted with permission from Pena A. Atlas of surgical management of anorectal malformations. New York: Springer Verlag; 1989).

On the other hand, cloacas with a common channel longer than 3 cm represent a serious technical challenge, whereby the operation frequently requires not only a posterior sagittal approach but also a laparotomy and a creative vaginoplasty or a vaginal replacement. The repair of these complex defects requires experience with pediatric urology. The final functional prognosis is not very good in cases with a long common channel.[27] Associated defects occur in about 90% of all patients with a common channel longer than 3 cm.

About 40% of patient with cloaca suffer from hydrocolpos (a very dilated vagina full of fluid). The dilated vagina compresses the trigone and may produce ureterovesical obstruction, megaureters, and hydronephrosis (Figure 50-8).

FIGURE 50-9. Cloaca with double uterus and double vagina. (Reprinted with permission from Pena A. Atlas of surgical management of anorectal malformations. New York: Springer Verlag; 1989).

Approximately 40% of the patients with cloaca also have different degrees of septation of the vagina and the uterus (Figure 50-9) which have important future implications, impacting menses as well as obstetric potential.[31]

Initial Management

Male Newborns

Perineal inspection and urinalysis allows the clinician to determine the type of malformation that the baby has in about 90% of cases.

The presence of a perineal orifice, by definition makes the diagnosis of a perineal fistula. This is also true when the baby has an external defect called a "bucket-handle" malformation that is a skin bridge in the midline in the area of the anal dimple. If a patient has a good midline groove, an anal dimple, and meconium in the urine, that is consistent with a prostatic or rectourethral fistula. A flat bottom and bifid scrotum are signs of a very high malformation, high prostatic or bladderneck fistula.

Diagnostic studies should be done after 24 h of life, but not later than 36 h. The reason for this is that is necessary to wait until the most distal part of the rectum is distended in order for it to be seen by any diagnostic modalities. An MRI, ultrasound, CAT scan, or simple X-ray film done prior to 24 h will not show the most distal part of the rectum, because it is collapsed by compression of the sphincteric funnel. In order for meconium to be forced through a tiny distal fistula, it is necessary to wait until the intraluminal pressure is high enough to overcome the tone of the striated muscle

FIGURE 50-10. Cross-table lateral X-ray. (Reprinted with permission from Levitt MA, Peña A. Imperforate anus and claocal malformations. In: Ashcraft's pediatric surgery. 5th ed.; 2010 with permission from Elsevier).

that surrounds the distal rectum, which usually happens after 24 h. During the first 24 h, the clinician must try to answer two very important questions:

1. Does the baby have an associated defect that threatens his/her life?
2. Does the baby need a primary repair or a colostomy?

The baby should be examined to rule out the presence of cardiovascular defects. The patient will remain with nothing by mouth, and insertion of a nasogastric tube is recommended to avoid vomiting and potential risk of aspiration. Passage of this tube also rules out an associated esophageal atresia. An ultrasound of the abdomen is indicated to rule out the presence of hydronephrosis. An ultrasound of the spine is also useful to evaluate for the presence of tethered cord. An X-ray film of the lumbar spine and the sacrum will assess for the presence of hemi vertebrae and sacral abnormalities. A very abnormal sacrum is usually associated with a very high defect. If after 24 h, the surgeon is still not sure as to the type of defect that the baby has, a cross-table lateral film with the baby in prone position and the pelvis elevated should be performed. This will show the location of gas inside a distended rectum (Figure 50-10). If the rectum is visualized below the coccyx and the surgeons have experience with the neonatal repair of this malformation, the patient can be approached primarily. Conversely, if the rectum is located higher than the coccyx, or the surgeons have no experience with these neonatal operations, it is better to perform a diverting colostomy and to postpone the main repair for a later date.

Female Newborns

It is also true in females that simple inspection of the perineum will allow for a correct diagnosis during the neonatal period in most cases. The presence of a small opening in the perineum anterior to the sphincter mechanism makes the diagnosis of perineal fistula. Sometimes, it is difficult to see the opening

of the rectum in the vestibule because the female genitalia are swollen at birth due to the effect of the maternal hormones. The presence of a fistula in the vestibule establishes the diagnosis of a rectovestibular fistula (Figure 50-6). In order to make the diagnosis of a rectovaginal fistula (extremely unusual defect) one would have to see meconium coming from inside the vagina, deeper than the hymen. The presence of a single perineal orifice makes the diagnosis of a cloaca (Figure 50-7).

If none of these signs are present after 24 h, the baby should have a cross-table lateral film in prone position (Figure 50-10). Most likely the baby has an imperforated anus with no fistula – which represent 5% of all cases.

During the first 24 h of life, the baby should be subjected to the same tests described for the male patient. If the baby has a cloaca, an ultrasound of the abdomen should be performed not only in the upper abdomen to rule out hydronephrosis but also in the lower abdomen to rule out the presence of hydrocolpos (Figure 50-8). Most babies with a cloaca need a diverting colostomy. These babies should not be taken to the operating room unless the surgeon has already ruled out the presence of hydrocolpos. The hydrocolpos must be drained at birth, usually with a tube at the time of colostomy opening, particularly when the baby suffers from hydronephrosis. Prior to trying other procedures for the treatment of a hydronephrosis and megaureter, the hydrocolpos must be drained, which most of the time will decompress the urinary system.

Colostomy

Colostomies in babies with anorectal malformation should be totally diverting. Loop colostomies are contraindicated as they may allow the passing of stool from the proximal into the distal colon, producing direct fecal contamination of the urinary tract. The ideal colostomy should be created in the descending colon, with separated stomas (Figure 50-11). Both stomas should be separated enough as to allow the placement of a stoma bag over the proximal stoma. Distal to the mucus fistula, the baby should have enough length of colon to allow a comfortable pull-through at the time of the main repair.

In cases of cloaca, the surgeon must also drain the hydrocolpos through the abdomen. When the vagina is so distended that it reaches the upper abdomen, it can be drained with a vaginostomy, suturing the vaginal wall directly to the abdominal wall. When the vagina is not that large, it can be drained with a tube that is exteriorized through a separate hole in the abdominal wall.

Two to four weeks after the colostomy, a high-pressure distal colostogram should be performed. This involves injection of hydrosoluble contrast material through the distal limb of the colostomy to delineate the anatomy of the distal colon and to establish an accurate anatomic diagnosis (Figure 50-12). This is, by far, the most important diagnostic study in anorectal malformations. Trying to repair these malformations without a good distal colostogram exposes the babies to serious inju-

ries of the urinary tract, particularly in males.[32] For cloacas, a constrast study should be done to delineate all three systems; urologic, gynecologic, and colorectal (Figure 50-13). We do not do contrast studies for perineal or vestibular fistulas as their anatomy is known by clinical inspection alone.

Main Repair

Males

Perineal fistulas can be repaired performing a minimal posterior sagittal anoplasty. The baby is placed in prone position with the pelvis elevated. Multiple stitches are placed at the mucocutaneous junction of the fistula orifice. An incision dividing the sphincter mechanism, posterior to the anal orifice, is performed, and the rectum is carefully dissected to be moved back and relocated within the limits of the sphincter. During the dissection of the anterior rectal wall, special care must be taken to avoid injury to the posterior urethra, which is the most common and feared complication in these operations.[32] The babies must have a Foley catheter in the urethra. A useful alternative in a very sick baby or when the surgeon does not have enough experience is simply to subject the patient to dilatations of the fistula, with a plan for a future definitive repair.

In cases of rectourethral fistulas, after their newborn colostomy, the patients undergo a posterior sagittal anorectoplasty (PSARP). The baby is placed in prone position with the pelvis elevated and with a Foley catheter in place. A posterior sagittal incision is performed between both buttocks running from the lower portion of the sacrum to the base of the scrotum. The entire sphincter mechanism is divided exactly in the midline, making sure to leave an equal amount of sphincter muscle on both sides.

The posterior rectal wall is identified and is opened in the midline. The fistula is visualized and multiple fine silk stitches are placed taking the rectal mucosa immediately above the fistula in order to exert uniform traction to facilitate the dissection and separation of the rectum from the urethra. A submucosal plane is established in the anterior rectal wall to avoid damage to the urinary tract. About 1 cm above the fistula site, the dissection is continued full-thickness until
FIGURE 50-12. **A** Colostogram showing bulbar fistula. (Reprinted from Levitt MA, Peña A. FIGURE 50-13. 3D cloaca imaging.

the rectum is completely separated from the urinary tract. It is in this plane that one must be extremely meticulous to avoid injuries to the vas deferens, seminal vesicles, and an occasional ectopic ureter. After this, a circumferential dissection with division of extrinsic vessels of the rectum is performed until enough length has been gained to bring the rectum down to the perineum to anastomose it without tension to the skin in the area of the anal sphincter. At this point, the fistula on the posterior urethra is closed with absorbable suture. On rare occasion the rectum is very dilated and cannot be accommodated within the available space of the sphincter mechanism. Under those circumstances, the posterior rectal wall must be tapered. It must be the posterior rectal wall that is tapered, rather than the anterior wall so that a suture line is not opposed to the urethral fistula that was closed. The limits of the sphincter are electrically determined and the rectum is placed within the sphincteric complex. The only difference in the surgical treatment between the rectourethral bulbar fistula and the retroprostatic fistula is that the latter requires a more significant dissection to bring the rectum down.

Rectobladder Neck Fistula

This malformation occurs in only 10% of male patients.[27] This is the only defect that requires a laparotomy or laparoscopic assistance in addition to the posterior sagittal operation. This is because the rectum is located too high to be reached from below. The posterior sagittal incision is performed to create the path through which the rectum should be pulled down and to tack the pull through to the muscle complex. The operation begins with a midline laparotomy or laparoscopy. The rectum is dissected above the peritoneal reflexion. The surgeon must create a plane of dissection as close as possible to the bowel wall but without injuring the rectal wall. One must keep in mind that the ureters and vas deferens run in

the same direction toward the bladder neck, and, therefore, those structures must be kept under direct vision during the dissection of the rectum. The bladder neck is located about 2 cm below the peritoneal reflexion, and, therefore, it is very easy to find the end of the rectum and to divide and suture the fistula site. The rectum then must be mobilized to be pulled down through the tract established through the posterior sagittal incision. In such a case, this incistion can be opened with the patient in supine position and the legs lifted up.

Imperforate Anus Without Fistula

In cases of imperforate anus without fistula, the operation is not necessarily easier than in patients with a fistula because the rectum is still intimately attached to the posterior urethra. These patients are approached posterior sagittally, the posterior rectal wall is opened in the midline, and multiple stitches are placed in the edge of the rectal wall to exert uniform traction and to facilitate the separation of the rectum from the urinary tract. Special care must be taken during the dissection of the anterior wall to separate it from the urinary tract.

Rectal Atresia or Stenosis

These patients also require a posterior sagittal approach. The entire sphincter mechanism is divided posterior sagittally. Both rectum and anal canal are opened posteriorly. The dilated proximal rectum is anastomosed to the anal canal and then the sphincter mechanism is meticulously reconstructed in the midline. If a presacral mass is present this is removed through the same posterior sagittal incision.

Female Defects

Perineal Fistulas

The repair of this malformation is the same as that described for male patients, except that the rectum is usually separate from the vagina so there is minimal risk of vaginal injury.

Vestibular Fistulas

The complexity of this malformation should not be underestimated. The patient is placed in prone position with the pelvis elevated. Multiple fine silk stitches are placed at the rectal vestibular orifice. A posterior sagittal incision is performed, dividing the sphincter mechanism to find the posterior rectal wall, which is easy to recognize. The main technical challenge in the repair of this defect is represented by the common wall that exists between the rectum and vagina. There is no plane of separation between these two structures and one must make two walls out of one. This is achieved by a meticulous dissection applying uniform traction with multiple silk stitches into the rectal lumen. The dissection must continue until the rectum has been completely separated from the vagina. Usually the rectum requires very little mobilization because it is located quite low. The limits of the sphincter are

electrically determined, the perineal body is reconstructed, and the rectum is placed within the limits of the sphincter.

Rectovaginal Fistula

This is an extremely unusual defect. These malformations can be repaired posterior sagittally. The repair is the same as that described for vestibular fistula, except that these patients require much more mobilization of the rectum in order to move it down and relocate it in the center of the sphincter.

Cloaca

The cloaca repair represents a significant technical challenge, particularly in patients with a long common channel.[33]

Repair of Cloaca with a Common Channel Shorter than 3 cm

These patients are approached posterior sagittally. The entire sphincter mechanism is divided in the midline and the posterior sagittal incision is extended down to the single perineal opening. The common channel is also opened in the midline to expose the anatomy of the defect. The entire defect can be repaired through this incision without opening the abdomen. Once the anatomy has been exposed, the first step is to separate the rectum from the vagina, which is performed in the same manner as was described for a rectovestibular fistula. Once the rectum is separated, it should be mobilized to gain length so that it can be placed within the sphincter mechanism. The next step consists in mobilizing both vagina and urethra together, following a specific technical maneuver called "total urogenital mobilization."[34] Multiple 6-0 silk stitches are placed in the edge of the open common channel as well as the edges of the vagina. These stitches allow the surgeon to exert uniform traction on the entire urogenital structure. The urogenital channel is divided full-thickness approximately 5 mm proximal to the clitoris, creating a plane of dissection, which is very easy to find, between the common channel and the posterior aspect of the pubis. In short order, one can reach the upper portion of the pubis. Conspicuous fascial attachments exist between the vagina, the genitourinary structures and the upper part of the pubis. These fascial attachments are avascular and are known as suspensory ligaments of the vagina and urethra. These are divided and the retropubic fat is identified. By dividing these suspensory ligaments, one can gain approximately 2 cm of mobilization of the urogenital structures. Some extra dissection of the lateral and dorsal walls of the vagina gains another centimeter, and by doing that, one can repair the urethra and the vagina. Over 50% of the patients with cloacas have a common channel shorter than 3 cm, and, therefore, it is possible to repair most of these defects with this reproducible technique.[33,34] The blood supply after this mobilization is excellent. The urethra and vagina are then sutured to the labia in their new position.

The limits of the sphincter are electrically determined and marked with temporary silk stitches. The perineal body is reconstructed with long-term absorbable sutures, the rectum is placed within the limits of the sphincter, and the anoplasty is performed.

Patients with a common channel of less than 3 cm and a good sacrum have over an 80% chance of having bowel control and an 80% chance of having urinary control without bladder intermittent catheterization.[33] After the urethra and vagina have been repaired, the urethral meatus is now located 5 mm deep to the clitoris in a position that makes it perfectly visible which is important if the child needs catheterization. Twenty percent will require intermittent catheterization postoperatively in order to empty the bladder.

Surgical Repair of Patients with Cloaca with a Common Channel Longer than 3 cm

We specifically recommend these patients be referred to specialized centers dedicated to the treatment of complex malformations. The repair of these defects usually requires not only a posterior sagittal approach but also a laparotomy and a series of decision-making steps that require experience and special training in gynecology and urology. The first part of the operation consists in performing a total body preparation so that the patient can be approached through the perineum (posterior sagittally) and through a laparotomy. The posterior sagittal approach and total urogenital mobilization is attempted because occasionally one can achieve a total repair in patients with a common channel up to 4 cm. If this maneuver is not enough to make the vagina comfortably reach the skin of the perineum, one has to go into the abdomen and continue the dissection of the vagina as well as its separation from the urinary tract. This is a difficult and tedious maneuver. The bladder must be opened and the ureters must be catheterized because they run through the common wall that separates the bladder and the vagina. Often the mobilized urogenital complex can be delivered up into the abdomen and further dissected to gain length. If this is inadequate, the vagina must be entirely separated from the urinary tract. At that point, the surgeon evaluates whether or not the vagina will reach the perineum. If that is not possible, then he or she has to make an important decision as to the best way to repair the malformation. In very specific cases, with bilateral hydrocolpos, the surgeon can perform a maneuver called "vaginal switch," consisting in resecting one of the hemiuteri, resecting the vaginal septum, tubularizing both hemivaginas to create a single one and switching down what used to be the dome of one hemivagina to the perineum, taking advantage of the fact that the distance between both hemiuteri is longer than the vertical length of both hemivaginas. This maneuver is only feasible if the patient has two large hydrocolpos.

If this maneuver (vaginal switch) is not feasible, then the surgeon must replace the vagina. The alternatives are first, to replace it with rectum. The distal part of the rectum can

be used to replace the vagina, which can be done in two different ways. If the patient has enough length of rectum, one can use the most distal part (preserving its blood supply) to be separated from the fecal stream, mobilized forward, and replacing the distal part of the vagina.

In other cases, if the rectum is very dilated, one can divide it longitudinally. The anterior portion is tubularized and moved forward to form the neovagina preserving the necessary vessels from the inferior mesenteric branches. The posterior aspect will serve as a rectum. The blood supply of the posterior aspect will be provided intramurally from the branches of the inferior mesenteric vessels. This depends on the fact that the rectum has an excellent intramural blood supply. If these maneuvers are not feasible, the next choice is sigmoid or left colon. Sometimes the colostomy site is a useful location for the neovagina. If these maneuvers are not possible, then one can use small bowel.

In cases of extremely high malformations, one may find two little hemivaginas attached to the bladder neck. The rectum also may open in the bladder neck. The separation of these structures is performed through the abdomen. Occasionally the common channel can be left untouched to become the neourethra. The bladder neck needs to be reconstructed. Under those circumstances, the surgeon must have enough experience to decide whether or not the bladder neck can be repaired or whether it is better to permanently close the whole distal part of the bladder and open a vesicostomy, with a plan for a continent diversion later in life. Since these patients have the highest incidence of vesicoureteral reflux, leaving a vesicostomy in such a high cloaca is a safe maneuver with a future ureteral reimplantation and urologic reconstruction performed later in life if necessary.

All patients after cloacal repair are left with a Foley catheter, which stays in place for 2 or 3 weeks. Patients with a common channel longer than 3 cm sometimes require a suprapubic cystostomy or vesicostomy at the end of the operation. Then, 1 month after surgery, a cystogram is performed, the suprapubic tube is clamped, and the patient is observed to see if she is capable of emptying her bladder spontaneously or if she requires intermittent catheterization. Several months after cloacal repair the clinician must be sure that the bladder empties well, checking with a pre- and post-void or cath ultrasound.

The most common sequela from the urinary point of view in babies with cloaca is the incapacity to empty the bladder. These babies do not suffer from the type of neurogenic bladder that is seen in patients suffering from spina bifida and myelomeningocele, but rather have a floppy large bladder that does not empty. Most of the cloaca patients have a competent bladder neck. The combination of a competent bladder neck with a floppy hypotonic bladder, makes them ideal candidates for intermittent catheterization, which allows them to remain completely dry.

Results of Treatment of Anorectal Malformations

About 75% of all patients with anorectal malformations (when subjected to a good operation) have bowel control.[27] The bowel control is not perfect. This becomes evident when the patients suffer from severe constipation, which may produce overflow pseudoincontinence, and soiling. Also, a severe episode of diarrhea may show that the bowel control is not normal. Twenty-five percent of all patients suffer from fecal incontinence and require some form of medical management (Table 50-3).[35]

Since anorectal malformations cover a wide spectrum of defects, the clinical and functional results vary depending on the specific type of malformation. Patients with a cloaca with a common channel longer than 3 cm usually suffer from fecal incontinence and require intermittent catheterization to empty the bladder. Patients with a common channel shorter than 3 cm and a normal sacrum have bowel control 80% of the time and only 20% of them require intermittent catheterization to empty the bladder and remain completely dry. Ninety-five percent of patients with rectovestibular fistulas have bowel control. Babies with perineal fistulas have bowel control 100% of the time. Rectobladder neck fistula patients only have bowel control 15% of the time, with rectoprostatic fistula patients at 60%, and rectourethral bulbar fistula patients at 85%.[27] Patients with imperforate anus with no fistula will have bowel control between 80 and 90% of the time depending on whether or not they suffer from Down's Syndrome.[29]

Constipation is a problem in most patients with anorectal malformations in whom the rectum was preserved during the main repair and should not be underestimated. When not treated properly, the patients develop megacolon and chronic fecal impaction, which may end up producing overflow pseudoincontinence.

TABLE 50-3. Voluntary bowel movement and type of defect

Defect	Cases	Patients with VBMs	
		n	%
Atresia or stenosis	11	11	100
Perineal fistula	58	56	97
Vestibular fistula	146	131	90
Imperforate anus without fistula	40	31	78
Bulbar fistula	112	89	79
Cloaca common channel <3 cm	99	65	66
Prostatic fistula	109	71	65
Vaginal fistula	5	3	60
Cloaca common channel >3 cm	69	24	35
Bladderneck fistula	49	10	20
Total	698	491	70

Management of Fecal Incontinence

For the group of patients with anorectal malformations, who suffer from fecal incontinence (25% of cases), a bowel management program that aims to keep those patients completely clean of stool and to make them socially accepted is vital. The basis of this treatment is to teach the family or the patient to clean the colon every day with an enema. Since most patients suffer from constipation, the cleaning of the colon with an enema will prevent the patient from passing stool for 24 or 48 h.[35,36]

Occasionally, however, we find patients who had a different type of repair and lost the rectosigmoid during the main repair or suffer from intractable diarrhea or malabsorption. In those cases, the bowel management is technically more demanding, because it includes not only the cleaning the colon with an enema but also the use of a constipating diet or medications to decrease the colonic motility in order to keep the patient from passing stool for 24 h between the enemas.

The bowel management program is implemented over a period of 1 week by trial and error. Every patient needs a different kind of enema to clean the colon. The cleaning of the colon is monitored, taking X-ray films of the abdomen every day, and adjusting the volume and concentration of the enema by trial and error. The goal is to find the enema that is well tolerated by the patient, is easy to administer, and keeps the patient completely clean. When the patient complains about the rectal enema and feels embarrassed about their parents giving the enema, an operation called the Malone procedure (continent appendicostomy) is an option.[37,38] This consists of creating a connection between the tip of the appendix and the umbilicus. The cecum is plicated around the appendix to create a one-way valve that allows the introduction of a catheter through the umbilicus into the colon and prevents stool from passing through the orifice. The patient is able to sit on the toilet, pass a feeding tube through the umbilicus, administer the enema himself/herself, evacuate the colon, and remain clean the following 24 or 48 h. This allows the patient to become independent. A significant number of patients do not have an appendix. In that case, one can be created with a vascularized flap of the colon (continent neoappendicostomy). Then again, the colon is plicated around the new appendix to make it continent.[38]

Relevant Aspects for Adult Colorectal Surgeons

A large number of adolescent and adult patients may still suffer from fecal incontinence despite successful repair in infancy. Other patients these having undergone surgery for Hirschsprung and patient with spinal anomalies or pelvic trauma may suffer from incontinence. Workup of these patients should include a detailed history and physical exam which includes the type of defect the patient was born with, bowel movement and voiding pattern, type of perineum, location of rectal opening, presence of an anal dimple, and strength of sphincter contraction. A water-soluble enema or defecography, voiding cystourethrogram, sacral films, and an MRI with a rectal coil to assess the location of the rectum are essential. We then classify patients into four groups, as follows.[39]

1. Patients with a poor sacrum, flat perineum, poor muscles, no sensation, and poor bowel movement pattern who are usually incontinent for both urine and stool. These patients are good candidates for a bowel management program.[36] Alternative techniques such as an artificial bowel sphincter or stimulated gracilis muscle flap have been tried with limited success.[40] A permanent stoma is rarely indicated as a properly administered enema program works 95% of the time.[35]
2. Patients with clinical and MRI evidence of a mislocated rectum with a good sacrum and well-developed muscles. These patients may benefit from a secondary pull-through procedure.[41]
3. Patients who suffers from severe constipation but have good potential for bowel control and a contrast enema which shows a severely dilated mega rectosigmoid. These patients need aggressive laxative therapy and possibly a sigmoid resection.[36]
4. Patients who are born with a good prognostic type of malformation and have a well-located rectum, good sacrum, and good muscles but are still incontinent. They may benefit from biofeedback or other behavior modification programs to help them evacuate the rectum at controlled and predictable times.

Some children develop an IBS syndrome as they mature after a successful repair and then have difficulty later in life. They may benefit from regulation of colonic motility with diet, medication or possibly an intestinal pacemaker. We predict that control of rectosigmoid motility and coordination will be easier in the future as techniques develop in improving such patients than any artificial anal sphincter.

Other Pediatric Colorectal Disorders

Idiopathic Constipation

Constipation of unknown origin represents a serious problem in the pediatric population. At least 6% of pediatric consultations are related to this particular problem.[42] We consider this condition to be the result of a colonic hypomotility disorder with different degrees of severity, affecting mainly the rectosigmoid and sometimes the entire colon. The spectrum of colonic hypomotility or colonic inertia varies from mild constipation that can be controlled by dietary measures to severe hypomotility disorders that may fall into the realm

of what is called "intestinal pseudoobstruction" and may require intestinal transplantation.[43]

Constipation means an incapacity to empty the colon on a daily basis or the incapacity to empty it completely. As a consequence, the colon stores a large amount of stool and becomes very dilated (megacolon). Megacolon produces constipation and constipation produces more megacolon, creating a vicious cycle. The final result is chronic fecal impaction, which provokes overflow pseudoincontinence (encopresis).

The cause of this condition is unknown. Many authors claim that the origin is a behavior problem, while others believe that it is a consequence of a dietary problem. There are those who think that it is a consequence of a lack of relaxation of the internal sphincter or a consequence of ultrashort segment aganglionosis. None of these theories have been scientifically documented, and that is why we call this condition idiopathic.[43]

The treatments we use for this condition consist in trying to find the amount of laxatives that is capable of producing a bowel movement that empties the colon completely every day.[36] The amount is different in every individual and has to be determined by trial and error. When the laxative requirement is so high that it creates a problem in terms of quality of life, we offer the patient a surgical treatment consisting in the resection of the most dilated portion of the colon (usually the rectosigmoid).[44,45] By doing that, even when we know that we do not cure this mysterious condition, we make the problem more manageable and reduce significantly the amount of laxatives that the patient needs.

Rectal Prolapse

Rectal prolapse occurs in children due to conditions such as myelomeningocele, spina bifida, and malnutrition. The lack of sphincter tone explains the severe prolapse from which these patients may suffer. Also, patients with cystic fibrosis or some patients with inflammatory bowel disease or intestinal parasites may suffer from rectal prolapse. Severe constipation can also cause rectal prolapse.

Most pediatric patients afflicted with this condition are of the idiopathic type. The surgeon must try to identify one of the predisposing conditions already mentioned. If this is not possible, one must try to avoid those factors that exacerbate the problem, such as to treat constipation, and any irritating conditions of the colon, such as milk allergy. If all this fails, the surgeon can offer a surgical treatment.

An old operation designed to treat rectal prolapse includes placement of a nonabsorbable suture around the anus to restrict its caliber. The long-term results of these procedures are not good because eventually the patients develop megacolon and an anal stricture. Other surgeons have tried the injection of sclerosing substances such as hypertonic saline in the perirectal space. This has been followed by severe complications including nerve damage and bowel and urinary

incontinence. A posterior sagittal approach has also been used that allows the surgeon to anchor the posterior rectal wall to the cartilage of the coccyx and the sacrum. Some perform an abdominal approach with fixation of the rectum to the presacral fascia, usually with a sigmoid resection. A transanal rectosigmoidectomy (modified Altmier procedure) has emerged as a treatment option in these children mimicking a one-stage pull-through for Hirschsprung's disease, and is our preferred approach.

Perianal Fistula

Perianal abscess and fistula in pediatrics seems to be a completely different condition to that seen in adults. During the first year of life, many babies suffer from perianal abscesses that may be associated with a perianal fistula. The orifice seen externally next to the anus communicates with one of the crypts of the pectinate line. Traditionally, these patients have been subjected to a fistulotomy, consisting in identifying the fistula tract and cutting all the tissue, and mucosa, from inside the rectal lumen leaving the wound open for granulation.

Our experience has been that this is a benign condition that does not require any treatment. If the babies have a perianal abscess, they do not require antibiotics. Very soon, the abscess drains by itself and if not, with a minimal incision and drainage. Following that, for a period of months, it drains intermittently without any discomfort to the patient. The vast majority of fistulas disappear after 1 year of age.[46]

Occasionally, one can see a school-age child with a perianal fistula. This is extremely unusual. In such a case, the surgeon should investigate for inflammatory bowel disease before trying any of the current available surgical techniques used in adults.

Juvenile Polyps

Around the age of 4 years, patients may suffer from polyps in the rectum and in the colon. These polyps are benign. They grow and eventually amputate and disappear. The polyps are mostly located in the posterior rectal wall. A rectal examination makes the diagnosis in most cases. These polyps have a long pedicle. The symptoms in these patients are the presence of blood surrounding the fecal matter. They do not produce any pain. Occasionally, the parents describe the presence of a polyp that prolapses through the anus. The polyps can be easily resected under general anesthesia. Histologically, these are almost always benign inflammatory polyps.

Anal Fissure

Anal fissures in pediatric patients are usually a consequence and not a cause of constipation. The fissure represents a laceration that was produced with the passage of a large hard piece of fecal

matter. The patient suffers from painful bowel movements and that contributes to the constipation, and the patient becomes a stool retainer. Stool retention may provoke more constipation and more constipation will make the fissure worse.

The main treatment for this condition is to give enough laxatives as to guarantee that the patient will have soft stool passing through the rectum for several weeks until the fissure heals. No surgical treatment is necessary.

Recently, 0.2% NTG ointment has been used for intractable cases to cause a reversible chemical sphincterotomy.[47] This is a simple alternative treatment since the long-term sequelae of a internal lateral sphincterotomy in children is not known and may be associated with incontinence.

Health Care Economics

David A. Margolin and Lester Rosen

"It was the best of times it was the worst of times." How prophetic was Charles Dickens when applied to health care in America today.[1] We are currently experiencing unprecedented technologic and therapeutic advancements; however, these come at a tremendous price. Health care expenditures have increased by double digits for the past decade, physician reimbursement has decreased by over the past 10-years, and hospitals have closed and health care systems have filed for bankruptcy.[2] Furthermore, in 2009, national health care expenditures are projected to have reached $2.5 trillion, an increase of 5.7%, up from the 4.4% increase seen in 2008, while the overall economy, as measured by gross domestic product (GDP) is still in recession, and anticipated to have fallen 1.1% (Table 51-1). From 2009 to 2019 the average annual health care spending growth is projected to grow at a rate of 6.0%, well outpacing the expected average annual growth in the overall economy (4.4%). By 2019, national health spending is expected to reach $4.5 trillion and comprise 19.3% of GDP[3] (Figure 51-1).[4] It is in this environment that President Barak Obama has attempted potentially sweeping changes in the health care landscape. At the time of writing this book, health care reform has passed the democratically controlled congress. However with the republicans regaining control in the 2010 midterm elections renewed partisan opposition to health care reform has occurred.

Multiple interrelated events have led to the current state of health care finance. With the advent of the resource-based relative value scale (RBRVS) physicians have shifted from price setters to price takers. Technology costs, while providing an improvement in patient care, have skyrocketed. While the life expectancy of the population has not increased dramatically over the past decades, the "Baby Boomers" are here and continue to shift the average age of the American population to one that requires increased utilization of health care resources. In 2009, the US census bureau estimated that 46.3 million Americans were without health insurance which was an increase from 45.7 in 2007, leaving 15.4% of Americans with no health insurance, and millions more underinsured, putting a strain on state and federal budgets to provide care.[5]

Last but not least is the current professional liability crisis, resulting in increased malpractice rates and driving specialists from specific locations. Despite this, physicians still are able to provide quality care for their patients and receive reasonable compensation. Nonetheless, in the ever-changing face of the socioeconomic landscape, physicians need a solid basis that allows them to function in today's practice environment.

This chapter covers the RBVRS and Medicare reimbursement, the types of contractual agreement between insurers and practitioners and insurers and patients, and what to expect in the future.

The Reimbursement Process

Medicare

The key to begin to understand the business of medicine is to understand the basics of Medicare. While private payors vary in their reimbursement rates and policies, most are tied in some form to the Medicare system. Medicare was created in 1965 by the Federal government as a social insurance program designed to provide all adults over the age of 65 with comprehensive health care coverage at an affordable cost. Medicare is administered by the Center for Medicare and Medicaid Services (CMS), formerly known as the Health Care Financing Administration (HCFA). When the program began in 1966, 19.1 million persons were enrolled; in 2004 Medicare had over 41 million enrollees and is forecasted to include almost 80 million people by 2030 (Figure 51-2).[6] Medicare is divided into two parts.

Medicare Part A, also known as hospital insurance, helps pay for inpatient hospitalizations, skilled nursing facility (SNF) care, home health and hospice care. Part A is financed primarily through federal payroll taxes (FICA) paid by both employees and employers. In 2010, the current FICA tax was 7.65% of earned income, of which 1.45% went toward Medicare Part A. The maximum tax employees and employers will each pay in 2010 is $6,621.60. Individuals who receive

The *purple line*, for gross domestic product (GDP), and the *blue line*, for national health expenditure (NHE), in billions of dollars, measured by the right axis scale. http://hspm.sph.sc.edu/Courses/Econ/Classes/nhe00/.
FIGURE 51-2. Expected number of Medicare beneficiaries. (Adapted from The Centers for Medicare & Medicaid Services http://www.cms.hhs.gov/charts/series/sec3-b1-9.pdf. Accessed 5 Jan 2005[6]).

Social Security benefits or Railroad Retirement benefits are automatically enrolled in Part A. Individuals under 65 who receive Social Security disability or those with end-stage renal disease for over 24 months are also eligible for Part A. Despite current misconceptions, Medicare Part A is not free. Although there is no monthly Part A premium for Medicare recipients who have worked 40 quarters of Medicare-covered employment, those who have fewer than 30 quarters of coverage may obtain Part A coverage by paying a monthly premium of $461 per month for 2010. Individuals with 30 to 39 quarters of coverage, will pay a premium of $254 per month in 2010. Medicare enrollees are also responsible for copayments associated with the services provided. In 2010 there is an $1,112 copay for the first hospital stay of the year. For each subsequent hospital stay there is no out-of-pocket expenses for 1–60 days. For any and all hospital stays of 61–90 days there is a cost of $275 per day and after 150 days of inpatient hospitalization all costs were the patient's responsibility. Part A covers the first 20 days of SNF care and costs $139/day for days 21–100. Like the limits for inpatient hospitalization, there was no coverage for SNF after 100 days. It is worth noting that Medicare Part B, also known as Medical Insurance, provides coverage for payments to physicians for services provided. This includes outpatient medical and surgical services, supplies, diagnostic testing and some home health care. Part B is funded by a combination of the federal government's general revenues (75%) and individual monthly premiums (25%). In 2004, Part B did not cover routine physical examinations. However, the federal government has responded to citizens' urging and has instituted a physical examination when one enters into Medicare and covers screening for some specific diseases. Part B covers screening for breast cancer, cervical cancer, prostate cancer, and colorectal cancer. Medicare covers fecal occult blood testing every 24 months, flexible sigmoidoscopy every 48 months, colonoscopy for high-risk individuals once every 24 months or for average-risk individuals every 10 years. Medicare also covers barium enemas (BE) every 24 or 48 months depending on your risk stratification.

Unlike Part A, Medicare Part B has monthly premiums. In 2010, the premium for those who enrolled at the onset of eligibility is between 96.40 and $243.10 per month based on income. If one enrolls at eligibility, this premium is deducted from your Social Security or Railroad Retirement check. You can opt out of Part B. Similar to Part A, Part B enrollees are responsible for copayments and deductibles. For physician services deductible was $155 per calendar year and a 20% copayment of Medicare-approved rates. Copayments for outpatient procedures were charged at a different rate than office services, and the copayment varied based on the procedure performed.

While Part A and B are considered traditional Medicare, Medicare Part C or Medicare Advantage is the government's plan to shift the cost and risks of Medicare patients to the private sector. In Medicare Advantage, private payers receive a monthly payment per covered individual (capitated amount) to provide all of Part A and B services. Private payors then tailor these plans to cover anticipated needs. These plans often provide benefits not seen in traditional Medicare, such as wider prescription drug benefits, routine physicals, preventative care, eyeglasses, and hearing aids. Since these plans are privately administered, individual choice is often severely limited with regards to physicians and hospitals. Nonetheless, these plans are extremely attractive with the Congressional Budget Office (CBO) projecting that, enrollment in Medicare Advantage will grow at an annual average rate of about 7 % over the next 10 years, compared with a growth rate of about 2.5 % for Medicare overall – reaching 21% of total enrollment in 2008 and 26% by 2017. However, according to the CBO the average payment to Medicare Advantage plans is 12% above traditional FFS costs. As such, Reimbursements to private insurers that administer Medicare Advantage plans would fall by as much as 4–4.5% in 2010.[7]

In late 2003, the Federal government instituted another new category of Medicare. Medicare Part D, prescription drug coverage, was signed into law in December 2003. In response to the cost of prescription drugs for seniors the government instituted a program that started in 2006. This program provides for prescription drugs with an initial deductible of $250 and a monthly premium of $35. There is a 75% subsidy for drug cost between $251 and $2,250. The federal government pays for all drugs after a recipient pays $3,600 or $5,100 in total cost. Special assistance will be provided for low-income seniors as well. New to Part D is the institution of means testing. Individuals with incomes $160,000 and above will be subjected to higher Part B and Part D premiums.

Medicare Resources

According to the Office of Management and Budget (OMB), Medicare in 2004 had a budget of $302 billion that increased to $503 billion in 2010.[8] The Medicare budget is determined by legislation and is formula based. It involves the Medicare Economic Index (MEI), a weighted index, and the sustainable growth rate (SGR). The SGR rate compares the cumulative actual spending for physicians' services since 1997 to a cumulative target amount of spending over the same time period. The initial idea was to keep Medicare costs from spiraling out of control. As described by Jacob Goldstein in the Wall Street Journal, "The SGR says essentially that the amount Medicare pays doctors for an average Medicare patient can't grow faster than the economy as a whole. It's fine if total payments to doctors go up because the number of Medicare beneficiaries rises. And it's fine if the average payment per beneficiary rises along with the economy. But if growth in payments per beneficiary grows more than the economy as a whole, the SGR says you have to lower payments to doctors across the board to keep costs under control."[9] Without new federal spending legislation, Medicare spending is

not allowed to grow by more than $20 million/year (budget neutrality). However, the government has made exceptions to increases in Medicare spending for new technologies and pilot programs. For more details, the complete Medicare fee schedule can be found in the Federal Register on line at http://www.gpoaccess.gov/fr/index.html.

Hospital (Part A) Reimbursment

Until the mid-1980s the federal government and most private payers reimbursed hospitals retrospectively for all reasonable costs involved in the care of a covered individual. With this form of reimbursement, to compete and remain solvent, hospitals invested in the latest, most-advanced technology. This allowed hospitals to increase patient care volume and expand services; however, it was done without regard to cost or efficiency. Although this methodology had its advantage, it led to a continuing upward spiral in health care costs and a significant duplication of services.

In response to sharply rising hospital costs, the Federal government instituted a prospective payment system. This was modeled after a system developed by Fetter and associates at Yale University that categorized patients based on primary and secondary diagnosis, primary and secondary procedures, age and length of stay, and then set a uniform cost for each category.[10] These diagnostic-related groups (DRGs) set a maximum amount that would be paid for the hospital care of Medicare patients for a specific problem. In 2010, there are 745 DRGs. Each DRG contains a list of specific diagnoses and procedures based on the International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM).[11] ICD-9 is a coding system that lists specific diseases, diagnosis, and medical acuity. By using this system, Medicare has grouped related ICD-9 codes that utilize similar hospital recourses in specific DRGs.

Private payers have followed Medicare's lead and began utilizing a prospective payment system. It was felt that by utilizing a prospective payment system hospitals would have a true incentive to improve efficiency and keep cost low. While this may have initially slowed the growth of hospital costs and forced improved efficiency in health care delivery, it has not been the panacea that was expected. Hospital costs, while initially controlled, returned to double-digit increases by 2002.[12] Although the reasons for the continued rise in hospital cost are multifactorial, the failure of DRGS to truly control cost can best be summed up: "Hospitals prefer management strategies that are designed to enhance revenues over cost control measures that may be resisted by the physician staff."[13]

Despite the reluctance of physicians to change practice patterns, hospitals have tried to increase their efficiency, and with technologic advances it has been possible to shift procedures from the inpatient setting to outpatient/ambulatory center. While this had some minimal impact in physician reimbursement, it has helped decrease resource utilization. In response to this, to account for this shift in location, Medicare has developed a prospective payment system called the ambulatory payment classification (APC). APCs, like DRGs, are specific reimbursement groupings that Medicare pays to facilities. For these outpatient services Medicare pays a specific rate per procedure determined by the APC in which the procedure is grouped. Specific medical devices and drugs are exempt from this and are reimbursed in addition to the APC fee. These are called pass throughs. Other devices that do not receive pass through are often charged to the patient by private payors. In 2004, 4 APC classifications covered the majority of outpatient anorectal procedures. APCs reimburse facilities between $209 (APC 148, lateral internal anal sphincterotomy) and $1210 (APC 150, hemorrhoidectomy) with a patient copayment between $41 and $437.

With changes in location of services in a constant state of flux, Medicare needed to develop an appropriate and timely methodology to respond to this shift. To add some stability to APC payments and achieve these goals, the Secretary of Health and Human Services (head of CMS) appointed an Advisory Panel on APC Groups. This panel of physicians deals with issues concerning resource use, assigning new current procedural terminology (CPT®) codes to APCs, and reassigning codes to different APCs.

Physician Reimbursement

Currently, physician reimbursement from Medicare is a three-step process: (1) appropriate coding of the service provided by utilizing current procedural terminology (CPT®); (2) the appropriate coding of the diagnosis using ICD-9 code; and (3) CMS determination of the appropriate fee based on the resources-based relative value scale (RBRVS).

CPT® is a uniform coding system that was developed by the American Medical Association (AMA). CPT® originated in 1966 and has undergone yearly updates based on changes in medical and surgical procedures and the development of new technology. CPT® is a proprietary product of the AMA. The CPT® editorial panel is comprised of 16 members in multiple specialties as well as the insurance industry. Advisors from over 90 medical and surgical specialties advise them. They meet four times a year to consider additions and deletions to the code list. A service may be brought before the CPT® editorial panel by any specialty, private physician, insurer, or device manufacture. To receive consideration for a new code, a procedure must meet certain requirements: it must be done by a reasonable number of the specialty that presents the code, be performed at reasonable frequency, be done throughout the country and have peer-reviewed literature supporting its efficacy. The editorial panel allows advisors from other specialties to comment on any proposal. The editorial panel then reviews the clinical description of the

procedure or service that describes the typical patient. After assuring that it meets all of the above requirements and that the service should not be coded with a preexisting code, the committee will give the service a unique CPT® code. The code then moves to the Relative Value Update Committee (RUC) where it receives a value relative to other codes (RVU). CPT® also uses a series of modifiers in addition to the original code to better describe the service provided. This allows not only for better data collection regarding the frequency and complexity of services but also for appropriate reimbursement by Medicare.

Medicare implemented the RBRVS in 1992. Previously physicians were reimbursed based on "usual, customary and reasonable charges" (UCR). UCRs were based on the physician's most frequent charge for the service (usual), the average charge for that service in the area (customary), and the actual charge for the service (reasonable).[14] Individuals within the federal government, private insurers, and nonprocedure-based medical specialties felt that this system perpetuated rising health care costs and inequities in medical care. These individuals believed that this system served as an incentive for physicians to inflate charges even in those instances where actual costs were decreasing and to continue the inequities in fees between proceduralists and nonproceduralists. In response to this the federal government instituted the Medicare fee schedule.

The Medicare fee schedule was based on the work of a research team led by William Hsiao, a Harvard economist under contract to CMS.[15–17] The Harvard study ranked procedures and services relative to each other based on the amount of physician work necessary to perform the procedure or service. Work was defined as a combination of the time used to perform the service and the complexity of service (mental effort, knowledge, judgment and diagnostic acumen, technical skill, physical skill, psychological stress, and potential iatrogenic risk).[18] Work was then broken down into three time periods, pre-, intra-, and postservice.

Preservice work for surgical procedures has come to be defined as the physician work provided from the day before, until the time of the operative procedure (i.e., skin incision). This may involve any or all of the following: hospital admission workup; the preoperative evaluation including the procedural workup, review of records, communicating with other professionals, patient and family, and obtaining consent; dressing, scrubbing, and waiting before the operative procedure; preparing patient and needed equipment for the operative procedure; positioning the patient; and other non "skin-to-skin" work done in the operating room prior to incision. Preservice work does not include the consultation or evaluation at which the decision to provide the procedure was made.

Intraservice work includes all "skin-to-skin" work that is a necessary part of the procedure. The time measurement for the intraservice work is from the start of the skin incision until the incision is closed.

Unlike preservice work, postservice work varies depending on the magnitude of the procedure. In an effort to accurately assign the amount of postprocedure work, specific CPT® codes have been assigned specific global periods. There are currently three postprocedural global periods; 0, 10, and 90 days. Routine postprocedure care includes physician work following skin closure that is done on the day of the procedure, including non-"skin-to-skin" work in the OR. This includes patient stabilization in the recovery room, communicating with the patient and other professionals (including written and telephone reports and orders), and patient visits on the day of the procedure. For a surgical service with a global period of 10 or 90 days, the postservice work includes all of the above and, in addition, postoperative hospital care, including the intensive care unit if needed; other in-hospital visits; discharge day management services; and office visits within the assigned global period of 10 or 90 days.[19]

For nonsurgical services such as office evaluation and management (E/M) services, the preservice work includes preparing to see the patient, reviewing records, and communicating with other professionals. The intraservice work includes the work provided while the physician is with the patient and/or family. This includes the time in which the physician obtains the history, performs a physical evaluation and counsels the patient. The postservice work for nonprocedural services includes arranging for further services, reviewing results of studies, and communicating further with the patient, family, and other professionals, including written and telephone reports as well as calls to the patient.

While the study by Hsiao and colleagues[16] initially valued only 200 codes and ranked them according to physician work, the RUC subsequently valued and ranked each CPT® code relative to other codes. New codes were valued using provider surveys to obtain an appropriate work value. These surveys allow for individuals who perform the procedures to value pre-, intra-, and postservice work relative to established codes. According to federal law the relative value of codes is reviewed every 5 years by the RUC allowing for corrections in the relativity of the codes. Currently, physician work is not the only value used to calculate an RVU. While the work RVUs (wRVU) makes up the majority of the total RVUs (tRVU) for a specific CPT® code, RVUs are also calculated for practice expense (peRVU) and malpractice (mRVU) for each code. Similar to wRVUs, peRVUs are calculated based on the amount of resources used in the pre-, intra- and postservice time. This includes not only the nursing and ancillary staff key to the procedure or service but also supplies used during the pre- and postprocedure period. If the procedure is performed in the office, intraservice personnel and supplies are included. For procedures done in a facility, usually a hospital, these costs are reimbursed based on the DRG (Part A) and paid to the health care facility and not to the physician. Malpractice RVUs are calculated from actual malpractice premium data obtained throughout the country. Using previous CMS claims, a value for each CPT®

code is determined based on a risk factor for the dominant specialty that provides service.[20]

Final physician reimbursement by CMS is then multiplied by a geographic practice cost index (GPCI), which is supposed to adjust payments for differences in physician practice costs across geographic areas. For a given service, multiplying the service-specific Physician Work, Practice Expense, and Malpractice Expense RVUs by their respective GPCIs determines the payment amount in a given geographic area. Next, these three products are summed, yielding a geographically adjusted RVU total for the service. This number is then converted to dollars by a conversion factor, which in 2009 was \$36.0666 per RVU. Without congressional intervention, adjusting the SGR formula, it could drop as much as 21% in 2010–2011. As an example, in 2009 for CPT® code 44140 (Colectomy, partial; with anastamosis) $[(wRVU \times wGPCI) + (peRVU \times peGPCI) + (mRVU \times mGPCI)] \times 36.0666 = \$CMS$ reimbursement. As seen the amount paid varies per region:

San Francisco, CA
$(22.46 \ wRVU \times 1.059 \ wGPCI) + (8.69 \ peRVU \times 1.441 \ peGPCI) + (2.71 \ mRVU \times 0.414 \ mGPCI) \times 36.0666 = \$1,349.94.$

Boston, MA
$(22.46 \ wRVU \times 1.029 \ wGPCI) + (8.69 \ peRVU \times 1.291 \ peGPCI) + (2.58 \ mRVU \times 0.764 \ mGPCI) \times 36.0666 = \$1,309.29.$

New Orleans, LA
$(22.46 \ wRVU \times 1.0 \ wGPCI) + (8.69 \ peRVU \times 1.044 \ peGPCI) + (2.58 \ mRVU \times 0.956 \ mGPCI) \times 36.0666 = \$1,226.22.$

Little Rock, AK
$(22.46 \ wRVU \times 1.000 \ wGPCI) + (8.69 \ peRVU \times 0.846 \ peGPCI) + (2.58 \ mRVU \times 0.446 \ mGPCI) \times 36.0666 = \$1,116.70.$

While Medicare is an extremely large and at times an unwieldy way to manage health care and health care-related costs, understanding it is key to understanding both hospital and physician reimbursement by private payers. Most private payers today use CPT® codes to identify physician services. While private payer do not have to follow the rules set forth by the Federal government (for instance, they often do not recognize surgical modifiers), they find that CPT® is a well-established and familiar system allowing for correct physician coding. Private payers in noncapitated contracts often set reimbursement based on a percentage of the Medicare fee schedule. The percentage reimbursement will often vary by region. The larger payers have taken this one step further using Medicare to develop their own fee schedule. Again using CPT® terminology, companies will adjust payment based on the individual service provided; for example, paying E&M codes 105% of Medicare, office-based procedures 110% of Medicare and surgical procedures 115%. This is often modified regionally based on the rules of supply and demand. In areas with a paucity of a specific specialty, reimbursement is high as opposed to a saturated market where the insurance company can play one physician or group against

another to obtain a favorable contract. Hospital payments are similar. Private payers reimburse hospitals either as a percentage of the DRG or on a per-diem based on the service provided. For outpatient procedures, hospitals are often reimbursed as a percentage of the APC.

Private Payers

While the impact of Medicare on the economic landscape of medicine is clear, the role and type of private payers is more cloudy. Health insurance comes in many forms and has different relations with its customer and its physician providers. Traditionally, there were two types of nongovernmental insurance, individual insurance and group insurance. Individual insurance allows a person to buy health insurance for themselves and their family. However, due to the inability of the insurer to spread the financial risk among many people, individual insurance is becoming prohibitively expensive. The majority of people obtain health insurance through some type of group. This allows for cheaper individual payments as group purchasing allows the insurer to spreads the risk over a larger number of people. Group insurance can be obtained through employers, professional societies (ACS, etc.) or other organizations (AAPR, etc.).

Regardless of how insurance is purchased, the types of insurance plans are distinctly different. The most costly is the fee-for service plan, also known as an indemnity plan in which individuals are free to seek care from any physician or hospital they choose. No preapproval is required. Individuals submit the bills to their carrier and if the deductible has been met, if there is one, the insurance company pays for medical services at the UCR. These plans are often structured so that there is a copayment for all services. The use of copayments and deductibles by insurers is a method of risk sharing. Not only do these costs help defray the cost of providing care for the insurers, but they are designed to make individuals think twice before seeking unnecessary care. In traditional fee-for-service plans, an individual may be responsible for 20% of the bill. Also, they may be responsible for the difference between the UCR and the billed charges.

To help control rising health care costs and stimulate a more efficient use of health care resources, managed care organizations were developed. Since the early 1990s they have evolved into a variety of complex organizational structures. They utilize a variety of tools to manage preauthorization functions, control health care costs, and share the risks associated with group coverage.

Health maintenance organizations (HMOs) were designed to meet these ends. While the HMO model undergoes constant change, they characteristically represent the most restrictive type of health plan. In this model, the HMO restricts patient access in nonemergency incidents to HMO-contracted physicians and hospitals. Out-of-pocket costs for individuals are traditionally low for HMO physicians; however, individuals are responsible for all costs for non-HMO physicians.

Most HMOs initially utilized a "gatekeeper" or primary care physician for specialist referral. Subsequently, HMOs have loosened gatekeeper requirements for specialist referral. This model has propagated the development of health care systems, multispecialty groups that are either owned by or contract with the HMO to provide complete patient care. In these instances, the physicians function as employees of the system. The physician group is then paid a capitated fee (amount per patient per month to provide total care) which is divided among the medical care providers at a rate determined by the medical group administration.

The next iteration of managed care organizations is the preferred provider organization (PPO). Similar to HMOs, PPOs enter into contracts with health care providers and hospitals to provide member care. Often more choice and flexibility are available to the patient than in the traditional HMO model but at the cost of higher beneficiary premiums. Unlike HMOs, PPOs do not own physician practices. To have access to the PPO's beneficiaries and be listed in the "network," physicians often agree to reduce their normal fees. PPOs traditionally do not use a "gatekeeper," thus allowing patients increased access to self-referred specialty care.

The most recent variation in managed care organizations is the development of "Point of Service" plans, a mixture of traditional HMO and PPO plans. In this type of plan, if a patient first sees their primary care physician to receive a referral, much like an HMO the copay, if present, is negligible. Patients are also able to see "network" physicians with minimal financial responsibility. Patients may seek care from someone outside the "network" without a referral. In these instances, the physician is paid a rate less than is characteristically billed, usually the same rate as in network physicians, and the patient is responsible for the difference. This provides increased patient flexibility but at increased cost.

The Future

Despite hopes that managed care would provide cost stability to health care in America, after costs initially slowed they have continued to rise at a rate higher than the consumer price index and personal income (Table 51-1).[21] Is this a failure of managed care or has managed care reached its capacity with regards to improving efficiency and cost containment? The answer is unclear; however, experts now tout a "consumer-centric" or "consumer-driven" health care model as the future of health care delivery. Harvard Professor Regina Herzlinger initially described a system that allows users to become active consumers.[19] Similar to making any large purchases, individuals are given the opportunity to chose from specific benefit packages that will fit their particular need. Aside from having choice, individuals are given information allowing them to make educated and informed choices. Herzlinger and others envision a health care market place similar to a successful industry where individuals are given

control, choice, and information. With the rising number of consumers in need of health care resources, these experts see the Internet as a way of rapid dissemination of health care information.[22–25]

While consumer-centric health care and Health Reimbursement Arrangements (HRA) appear to be recreating the way health care is funded, there are potential problems. This model assumes that consumers are sophisticated enough to make sound health care choices, not just those based on cost. As Abramowitz notes, "Choosing based on price is impossible for consumers to do intelligently. The bottom line is that consumers lack the information necessary to use the money wisely. So consumer-driven health care, as it is being discussed today will be a market failure."[26] Another potential problem is that individuals will feel obligated to use all of their HRA or employer contributions, especially as the year-end approaches and individuals run the risk of losing their contributions.

The initial manifestation of a hope to address some of the potential pitfalls of consumer-centric health care is the development of defined contribution plans in which employers provide a set amount to individuals for health care, along with information regarding employer-approved health care choices. Often these are tied to a safety net for catastrophic cost. The idea is to empower individuals and to give them the necessary information to make good choices. Further development of consumer-driven health care is the creation of "health reimbursement arrangements" (HRAs). This IRS plan gives a tax advantage to employers who contribute defined contributions to employee-controlled accounts for health care spending. Any monies not spent during the year are rolled over to help fund the following year's plan. The thought was that this combined with a high deductible plan would lower health care costs. These types of plans also raise some questions: is the unused portion of the plan eligible to be rolled over in an IRA/401K? Can these funds be used for nontraditional health care? What about domestic partners? Are these funds portable? These questions will only be answered by time and possibly federal legislation. Will this next generation of changes significantly help to control health care costs? The answer is unclear; however, one current benefit is the increasing individual awareness and education that these plans foster.

Despite the many and varied attempts to control health care costs, an unacceptably large number of Americans are still unable to obtain adequate health care coverage. This has led to the call in some quarters for the development of universal coverage. The late Senator Edward Kennedy put it best in a 2003 editorial: "Health care is not just another commodity. It is not a gift based on the ability to pay."[27] Proponents of universal coverage envision a system that provides access to quality care when needed and effective preventative care in a cost-effective manner that is delivered and paid for in an equitable way. While these are laudable goals, practical application remains a long way off. As seen from above, the

increasing role and complexity of Medicare and Medicaid has not even incrementally achieved these objectives. The current acrimonious debate in Washington shows that these goals are even further than initially thought. Will the government be willing to push forward any health care reform realizing that universal health care will result in the subsequent development of a two-tiered health care system, one for the wealthy and one for the remainder of Americans? Only time will tell.

Ethical and Legal Considerations

Considerations for Surgeons

General Concepts

Defining the Problem

Professional responsibilities have been a concern of surgeons since antiquity; however, the last 25 years have displayed a dramatic growth of both professional and societal attention to moral and ethical issues involved in the delivery of health care. This increased interest in medical ethics has occurred because of factors such as the greater technological power of modern medicine, the assigning of social ills to the responsibility of medicine, the growing sophistication of patients and the information available to them, the efforts to protect the civil rights of the increasing disadvantaged groups in our society, and the continued rapidly escalating cost of health care including medical malpractice costs. All of these factors contribute to the urgency of dealing with ethical and moral issues involved in the delivery of modern surgical care.[1]

The terms *ethics* and *morals* are often used interchangeably to refer to standards regarding right and wrong behavior. *Morals* refer to conduct that conforms to the accepted customs or standards of a people. They vary with time and with the nature of society at that time. *Ethics* is the branch of philosophy that deals with human conduct and can be described as applied morals. *Medical ethics* refers to the ethics of the practice of medicine. *Clinical ethics* refers to the ethics of delivering patient care. The term *bioethics* includes the ethics of all biomedical endeavors and encompasses both medical and clinical ethics.[2] The *law* serves to delineate the *formal rules of society*. It expresses a kind of minimal societal ethical consensus, which society is willing to enforce through civil judgments or criminal sanctions. The law does not always prohibit behavior deemed unethical; however, it usually sets a minimal standard for conduct. Those of us who practice clinical surgery often have trouble differentiating *ethical issues* from *legal issues*. It is the purpose of this chapter to clarify this dichotomy. It should be stated from

the outset that it is more important to understand the *process* of dealing with these issues than to assume that anyone can clearly state what is ethically right or wrong in a complex medical/surgical dilemma. The law, on the other hand, can be very explicit and can vary from state to state.

Surgeons live and practice an intense form of applied ethics. We deliver bad news; we guide patients and their families through complicated decisions to arrive at appropriate informed consent; we live a code of truth and trust among ourselves, our patients, and our trainees; we must deal with the end-of-life issues; and we make plans for extended, palliative, and hospice care. Finally, as only we surgeons know, we must go to bed at night knowing that in the morning we will spend hours with someone's life literally in our hands.

In recent decades, although we can technically and scientifically do more for our patients than ever before, our personal, trusting relationship with them has deteriorated to the point where it is sometimes adversarial. We have allowed medicine to become a business, guided in many cases by the financial bottom line, rather than by the uncompromising concern for a sick person. Within this fast-moving corporate system, we see too many patients, do too many surgeries, and do not have time to develop a close mentoring relationship with our chosen role models or with our trainees.[3] The cherished patient–physician relationship has been undermined by our own successful advances. Many of the operations that we do on a routine, daily basis were not even imagined as possible only a few decades ago. Not only can we do more but our patients also have come to expect perfection from us. Our society seems willing to accept flaws from many sources, but not from physicians and medical delivery system. This situation is made even more complicated by a system in which individuals purchase their health-care coverage when they are well and willing to buy the cheapest plan possible but utilize their coverage, especially for surgical problems, when they are sick and want the maximum that the system can deliver, without regard to time and cost. No individual has ever admitted that he purchased a cheaper

plan and, therefore, understood that only limited care should be provided to a loved one who is ill.

Despite these difficulties, we surgeons cannot abandon the needs of our patients and their families. To help them make informed choices, we must communicate completely and compassionately the requisite information about the disease, treatment options, and long-range plans. To do so, we must learn and apply the ethical principle of *truth telling* and the doctrine of *informed consent* for the effective care, which has taken us so long to master. We must also take into account that high-speed communication via the Internet will necessitate reevaluation of issues such as *patient's rights* and *confidentiality*. Surgeons must lead in forging this new era rather than leaving it to bureaucrats, politicians, lawyers, and others who are not intimately involved in patient care.

We cannot rely on intuition or on our own personal value system. Learning the ethical aspects of delivering patient care must become an integral part of the surgical training program, and we must be held accountable for mastering the skillful application of these bioethical principles. After all, the concept of good clinical medicine and surgery implies the best use of scientific, technical, and *ethical* considerations. Just as with medicine and science, bioethics and legal underpinnings of bioethical decision making are evolving all the time. In this chapter, we do not discuss all possible bioethical issues but limit ourselves to those that may be of concern to colon and rectal surgeons and to surgery in general. Important issues relating to matters such as professionalism, research ethics, family, business and financial pressures, genetics, and reproductive considerations are discussed as well.

What Makes the Surgeon Special?

Undergoing major surgery is an extreme experience that changes people's lives. Surgeons are repeatedly involved in these extreme experiences of others. This makes surgeons uniquely placed among health-care professionals to understand the experiences of their patients.

Miles Little explains that there are special ethical considerations for surgeons.[4] These include Rescue, Proximity, Ordeal, Aftermath, and Presence. These terms help to define the ethical relationship between the surgeon and his or her patients. *Rescue*, he describes as the first pillar of surgical ethics. It deals with the fact that surgery conveys power and that power is socially endorsed and may be reinforced by the surgeon's individual charisma; but as with all power, it must be constantly renewed and re-validated. Patients have no choice but to acknowledge surgical power when they consult a surgeon. Surgeons, themselves, sometimes need help and rescue from colleagues when they have trouble with complicated diagnosis, management, or operative procedures. *Proximity* occurs in surgery as in no other act. To operate on persons involves entering their bodies and becoming privy to secrets even denied to the owner of the body. Little states, "To get to my body, my doctor has to get to my character. He

has to go to my soul. He doesn't only have to go through my anus." This proximity to the patient can make special ethical demands on the surgeon. This proximity carries with it the penalties of closeness, and particularly the pains of failure. Some surgeons find that distancing themselves from their patients makes failure easier to bear. Understanding the privileges and risks of proximity is critical for the compassionate surgeon. *Ordeals* are periods of extreme experience, capable of disrupting our lives. The author, Little, explains that all medical encounters are ordeals. Patients yield autonomy, acknowledge dependence, place trust, face risk, confront embodiment and mortality, lose control over time and space, experience alienation, pain, fear, discomfort, suffering, and boredom. Surgeons observe and participate in the lives of patients with serious illnesses. A surgeon, who understands the ordeal of the surgical episode, can better help his or her patient through such extreme experiences. *Aftermath* deals with the reality that surgery leaves physical and psychological scars that may persist for life. It is very difficult to communicate the concept of suffering to someone who has not suffered himself. Little describes surgeons as being in a unique position to understand the existential threats that their patients experience, the sense of mortality and bodily frailty they live with, and the difficulty of explaining extreme experience to others. When death approaches our patients, we must remember, not deny, our own mortality. Such an approach takes courage and a sense of personal security, and this does not suit everyone, neither the patient nor the surgeon. *Presence*, as a virtue and a duty, is what the patient desires of the surgeon during all phases of the surgical encounter. Most surgeons have the stamina and cognitive ability to be present for their patients, but not all of us process the personal attributes of charisma, confidence, energy, and empathy, which are necessary to engender *trust* from our patients and our staff. Sometimes, amazingly, our mere presence means more to our patients than defects in the manner with which we deal with them. Even if we cannot teach sensitivity, we can emphasize the importance of surgical presence.

Thus, surgeons are privileged to lead lives of great complexity and moral richness. We can acquire a profound understanding and recognition of patient experience and suffering. Our proximity to patients seeking rescue, facing ordeals, and experiencing the aftermath of surgery presents us with a great challenge.

Unique Problems of Surgery

Surgeons, unlike other members of the health-care team, take on a different level of responsibility as they encounter patients. For the surgeon, the initial contact may just be the beginning of a longer-term relationship. With no previously established doctor–patient relationship, the surgeon and the patient may well be heading to the operating room for sometimes massive and sometimes potentially "futile" surgery. The surgeon and the surgical team take on the continued

responsibility of the operative procedure itself, the postoperative care, and usually the long-term follow-up and management of any complications and dilemmas that may result from the initial encounter. This intense relationship is often established very quickly and under frequently adverse circumstances. The family and religion may not be known, and the patient may be unconscious, and certainly will be once the procedure starts.

Arthur R. Derse nicely delineates the array of ethical issues that arise in delivering surgical care. These include *informed consent*, *refusal of treatment*, *determination of decision-making capacity*, *treating patients despite their refusal*, *maintaining confidentiality* while respecting the duty to warn others, *limiting treatment* over issues of "futility," *treating pain* at the end of life, and acting as a *Good Samaritan*. Unlike surgeons, people in most professions have the luxury of time, and the opportunity to redo their work to remedy any mistakes. Attorneys can appeal their cases. Accountants can file an amended return. Movie directors can yell "Cut! Take two!" and reshoot the scene. All doctors understand that they will probably be second-guessed. As everyone who has ever watched a television police drama knows, the first thing a police officer must say to an arrested person is the famous *Miranda* warning. What most people do not realize is that the requirement for those warnings is the result of a Supreme Court decision rendered in June 1966. As a practical matter, the court is telling the arresting police officer, in the heat of making an arrest, that he should have known something, which took the court system 3 years to contemplate and research. The bottom line for surgeons who work under the same kind of time pressures is to do what you think is best. You must use your judgment, based on your medical knowledge and your experience. You are on the front line and you do not have the luxury of waiting for 3 years for the Supreme Court to tell you how to handle a potential situation. However, you also want to be as scrupulous as possible in making sure that bioethical and legal guidelines are followed, both for the benefit of the patient, and, frankly, as protection for yourself.

While it is crucial for the practice of medicine in all fields to be familiar with bioethical concepts, it is unrealistic to be expected to be knowledgeable about the nuances requiring detailed understanding of controversial bioethical dilemmas. However, it is important for surgeons to have a working knowledge of general medical ethical principles and how these principles affect decisions involved with treating patients. Our goal is to distill these general bioethical concepts and their underlying applications to specific situations, which you may face, into a cogent and concise tool for surgeons to use routinely, to include as part of their training, and to have as a reference resource. For specific dilemmas, time permitting, surgeons should obtain an opinion from the hospital ethics consultation service and/or from hospital counsel. By doing so, one can gain the experience and imprimatur of opinions from those who have dealt with such issues and whose training gives them the experience to deal

with the issues in a knowledgeable way. It also serves as a cushion of knowledge for the physician when discussing the matter with the patient or the family. Surgeons should do all they can for the patient while at the same time doing what they need to do to protect themselves from personal risk and possibly from negative legal ramifications.

Similarly, doctors have a duty to themselves to avoid situations that violate their own personal beliefs, whether religious or medical. This includes thinking a step or two ahead of the current situation to know what the ramifications of a course of treatment may be. If the anticipated actions may violate a doctor's own personal tenants, he or she should refer the patient to another physician. The most obvious of these situations comes up with regard to religious beliefs. If, for example, a doctor has religious beliefs which would preclude *withdrawal of life support*, the doctor should be very careful about getting into a situation with a patient which might later dictate putting someone on life support. It may, down the line, become bioethically or medically appropriate to *withdraw* life support. If a physician cannot do that, she needs to know that up front and be prepared to withdraw from the case. A similar situation involves doctors who do not believe in *abortion*. They should not get themselves into medical situations where an emergency termination of a pregnancy may become the best medically viable option. You must always be prepared to protect yourself *and* your patients and must recognize your duties, both legal and ethical. You need to be aware of these duties and to avoid situations where they may come into conflict. This may be very difficult at times.

Principles of Bioethics

General Concepts

Philosophical Principles

Two major fundamental theoretical philosophical concepts exist for constructing a theory of ethics: *deontologic* and *consequentialist*. A deontologic theory relies on *rules*, while a consequentialist theory relies on *outcomes*.[2] From these theories are derived *principles of ethics*, such as those delineated by Beauchamp and Childress: respect for *autonomy* (patient self-determination), *beneficence* ("doing good"), *nonmaleficence* ("do no harm"), and *justice* (fairness).[5]

Respect for Autonomy

Adult patients with decision-making capacity have a right to their preferences regarding their own health care. This right is grounded on the legal doctrine of *informed consent*. This means that patients must give their voluntary consent to treatment after receiving all appropriate and relevant information about the nature of their problem, the expected consequences of the recommended treatment, and treatment alternatives.

This is probably the most crucial legal concept in bioethics. It simply means that you as a physician cannot *touch* a person without first getting permission and without telling the individual of the possible ramifications of that "touching." Touching someone without his or her consent is, in legal terms, a "battery," which could result in a lawsuit for damages. Therefore, the principle is that *medical treatment without consent is a battery*. The first major case in this area said "Every human being of adult years and sound mind has a right to determine what shall be done with his own body; and a surgeon who performs an operation without his patient's consent commits an assault, for which he is liable for damages… This is true except in cases of emergency where the patient is unconscious and where it is necessary to operate before consent can be obtained."[6] This case was decided before the concept of *living wills* and *durable powers of attorney* came into being. These documents both facilitate and complicate the consent process because *consent* must be obtained, if time permits, through these documents or via surrogate decision making. Subsequent cases refined the requirements of consent to add to the concept of *informed consent*. The courts now require not only that the patients give *consent* to the procedure, either themselves or through a proper surrogate, but also that sufficient information be given to the patients to help them make an *informed* decision. The courts have held that the quality and quantity of information given to the patient must be sufficient for the reasonable patient to understand, not for the doctor. The law has established the doctrine of the *reasonable man* to be used in deciding what is acceptable in many areas of delivering emergency surgical care.

Doctors are duty-bound to respect the autonomy of each competent patient. The patient is the ultimate decision maker about what he or she wants. The doctor may differ, even vehemently, with the patient's decision; however, the patient has the final say. There are exceptions to this rule also, such as that in the case when a patient demands a certain kind of treatment that the doctor knows will not be efficacious. Permitting *autonomy* to trump *nonmaleficence* poses a serious problem. A simple example of this is a patient who demands antibiotics to treat a viral infection. Giving the requested antibiotic complies with the *autonomy* principle; however, in the long run, it is conceivable that giving an antibiotic in such a case would violate the principle of *nonmaleficence*, would impose the concept of *futility*, and in the long run might enhance the capacity of bacteria to become resistant to certain antibiotics, thus even bringing into play the concept of *justice*. Even this simple example illustrates how medical ethical conundrums are frequently the result of *conflicting duties*.

If the patient is unable to make his or her own decision, the treating surgeon must respect the decision made by a surrogate decision maker, such as one designated in a health-care *durable power of attorney*.

Beneficence

The principle of *beneficence*, simply stated, involves the duty of the physician to act in the best interest of his or her patients. *Beneficence* is *doing good* and is the reason most of us chose to become doctors. Beneficence, or doing good, is probably the universal tenet of the medical profession.

Nonmaleficence

Nonmaleficence is essentially the old philosophical principle, "first, do no harm." It derives from knowing that patient encounters with surgeons can prove harmful as well as helpful. This principle includes not doing harm, preventing harm, and removing harmful conditions. For physicians caring for patients in an emergency environment, it also includes the concept of security, protecting oneself and one's team, as well as the patient, from harm.[7]

This concept also incorporates the principle of *avoiding killing*. This seems very obvious on its face value; however, what is a doctor to do when confronted with a situation where the administration of sufficient medication to alleviate the pain of a patient might have the *secondary effect* of diminishing respiration, and actually hastening the patient's death? This is, of course, the crux of the major debate that is ongoing over *physician-assisted suicide*, if not actual *euthanasia*. There are other situations where avoiding killing must be taken into account. *Abortion* presents another situation which, depending on your personal beliefs, might fall into that same category. This could create a conflict between the duty to respect the autonomy of the patient and the personal religious beliefs of the treating physician. This same conflict has recently, and intensely, come into play over the issue of research and therapeutic utilization of *embryonic stem cells*.

Justice

Justice is *fairness*. It is required to ensure that medical decisions are made with reason and honesty. Selfish or biased influences must be recognized and avoided.[8] For many, the term justice includes the concept of *distributive justice*. This form of *justice* includes the surgeon's obligation not only to an *individual patient* but also to fairness in the allocation of resources for the good of the *broader society*. It is this concept of justice that becomes the basis for society-wide health-care policy determination. *Distributive justice* implies that all individuals and groups should share in society's benefits and burdens. This presents an ethical challenge for the surgeon, dealing with an individual patient, who mistakenly believes that he or she should limit or terminate care based on a need to limit health-care resource expenditures for the *good of society*.[7] It was this temptation to place the good of society before the good of an individual that led the physicians of Europe to fall prey to the fallacious doctrines being promulgated by the Nazi government.[9]

Surgeons should be prepared to respect and seek to understand people from many cultures and from diverse socioeconomic groups. In USA, emergency facilities are obligated to provide necessary care to all patients, regardless of ability to pay. Our current business-based medical delivery system makes it difficult to abide by the principle of having *access* to appropriate inpatient and follow-up medical care dictated by the patient's financial situation. Provision of emergency, and most elective, surgical treatment should not be based on gender, age, race, socioeconomic status, or cultural background. No patient should ever be abused, demeaned, or given substandard care.[1]

Religion and Medical Ethics

In many societies, religion has been looked upon as the determinant of ethical norms. In our American society, we are multicultural with no single religion holding dominance over the entire population. Therefore, a value-based approach to ethical issues depends on the individual patient's values. However, religion still influences bioethical concepts and decisions. Clinical bioethics, in fact, uses many decision-making methods, arguments, and ideals that originated from religion. It is also important for the individual clinician to understand his or her own personal spirituality to relate better to patients and families, representing a broad diversity of religious and ethnic backgrounds. Although religions may appear dissimilar, most are based on some form of the Golden Rule, which holds "do unto others as you would have them do unto you." Problems frequently arise when trying to apply religion-based rules to specific clinical, ethical situations. In so-called modern times, USA began turning away from a reliance on religious principles, relying instead for answers based on more generic secular principles, and the medical/surgical community was no exception. As previously described, we have come to rely instead on the four *ethical principles of autonomy*, *beneficence*, *nonmaleficence*, and *fairness*. These are the principles that have guided medical ethical thinking and have become instrumental in forming health-care policies in USA and other Western countries over the past 3 decades.[7]

In a recent survey of physicians' attitudes toward spirituality in clinical practice, 85% said that physicians should be aware of the patients' religious and spiritual beliefs. The survey went on to show that although many physicians believe that they should inquire about their patients' beliefs, fewer than 10% of doctors actually do so, even for their dying patients. There is no hard data to support the benefits of taking a spiritual history, but there is some indirect evidence in support of the practice. It is known that religion is one of the most common ways by which patients cope with medical illness. Religious beliefs are known to be significant influences on medical decisions, especially those made by patients with serious illnesses. In addition, the faith community is a primary source of support for many medically ill patients, and such social support is associated with better adherence to therapy and improved medical outcomes. Several surveys have revealed that from the patient's point of view, satisfaction with the emotional and spiritual aspects of care had one of the *lowest* ratings among all clinical care indicators and was one of the highest areas in need of quality improvement.[10]

The purpose for taking even a brief spiritual or religious history is to learn how patients cope with their illnesses, the kinds of support systems available to them in the community, and to learn of any strongly held beliefs that might influence the delivery of medical care. Venturing into this delicate area is obviously fraught with some hazards. We must be extremely cautious about prescribing religion to nonreligious patients, forcing a spiritual history on patients who are not religious, causing patients to believe our practice and specific ways, attempting to provide spiritual counsel to patients, and arguing with patients over religious matters.[10] It is also imperative for us as surgeons to be comfortable enough with our own beliefs to allow our patients to *pray for us*, according to the faith of their own religion. No comment more than a simple and sincere "thank you" is usually indicated.

Legal Principles

General Concepts

Types of Law

In USA, law is created in one of two systems: *Federal* or *State*, and is made by judges (*common law*), legislatures (*statutory law*), and executive agencies empowered by legislatures (*regulatory law*). The fundamental document that creates and delineates these powers is the Constitution. *Civil law*, including malpractice, is usually enforced by *monetary judgments*. *Criminal law*, including physician-assisted suicide, is usually enforced by *fines* and/or *imprisonment*.[2]

There are three kinds of law, which affect the practice of surgery: *statutes*, *regulations* promulgated by an administrative agency, pursuant to a statute, and *case law*. The legislatures are the designated policy-making entities in our system; *regulations* are written to comply with legislative directives, and the courts are charged with resolving disputes between parties, usually as directed by *statute*, if there is a relevant one. Courts issue written opinions when there is a conflict that results in a lawsuit, especially when the interpretation of a statute or a regulation is in question. The most difficult situations are those where the court is faced with a matter of "first impression," which the legislature has not specifically addressed. The courts, and their written opinions, on this type of case, frequently ask the legislature for guidance in future situations. Until the legislature acts, the written opinion of the court is the only guidance physicians have, and hospital counsel sometimes must interpret this.

Doctors should be generally familiar with *state law*. There are different state laws on many bioethical matters, such as definition of death, competency, organ donation, and now the use of embryonic stem cells, even for research only. Many doctors move from state to state during their careers, and general understanding of state laws governing situations which may confront them in surgical situations is crucial. However, most important legal principles that apply to ethical dilemmas in delivering surgical care are widely accepted among several states. There are some glaring discrepancies in these commonalities, including the neurologic *criteria for death* (a person may be legally dead in one state and not in another) and the legality of *physician-assisted suicide* (punishable as a crime in all states except Oregon, Washington, and Montana).

Statutory Law

Statutory law is made by legislatures and includes such issues as *the statute of limitations*, which defines how long after an adverse event a patient is able to sue a physician for malpractice, and, in some states, statutes on *informed consent*.

The Emergency Medical Treatment and Labor Act (EMTALA) is another example of a *federal statutory law*. It was originally enacted as part of the Consolidated Omnibus Budget Reconciliation Act of 1986. Congress enacted EMTALA as a remedy for "patient dumping." The legislature was particularly concerned about hospitals refusing to render emergency care because of lack of insurance or the economic ability to pay, but it soon came to realize that care was also being refused on the basis of race or other discriminatory criteria. The Act requires that a basic screening examination be provided to all patients seeking care. It therefore became illegal, as well as unethical, to withhold therapy from the poor just because they do not have the ability to pay.[11]

Compilation of statistics from major county hospitals across the country concluded that as many as 650,000 patients were "dumped" annually, and the resulting transfer led to substandard care and/or life-threatening situations in 25–33% of that number. The economic impact of EMTALA on hospitals and physicians has been enormous. Patients without the means to pay for medical care know that they cannot be turned away from the emergency room. Therefore, they use it as their *primary care facility*. That means that hospitals, physicians, and surgeons are carrying the burden of the nation's uninsured, often without adequate compensation. For many health-care facilities, this money lost in the emergency room can mean the difference between bankruptcy and solvency.[12]

Regulatory Law

These administrative laws are created by regulatory agencies including State Medical Boards. Recent examples of regulatory law include not only EMTALA but also the recently implemented Health Insurance Portability and Accountability

Act of 1996 (HIPAA). HIPAA, like EMTALA, was intended to protect patients' rights of privacy and to guarantee them continuation of health insurance coverage should they change employers. Also, like EMTALA, HIPAA has taken on many ramifications threatening a huge economic impact on the escalating costs of delivering medical care. Although the good aspects of it are necessary and noble, the burdens of increased costs will cripple some health-care facilities and will probably significantly curtail many clinical research endeavors.

Malpractice

The public and the legal community do not seem to accept that there is an element of uncertainty and unpredictability in a biological system. They seem to understand that eleven men on a playing field cannot score a touchdown on every play, but a surgeon is held to a standard of achieving perfection on every operation. An ethical, as well as legal, consideration is as follows: what to do when we fall short of perfection or, worse, make a blatant error while trying to do the best we can. Several factors come into play. Who is responsible if you did not actually do the damage yourself? What to tell the patient and the family? How to comply with the policies of legal counsel and risk management within your own institution?

Many successful legal actions against surgeons have been based on inadequate information about risks, complications, or adverse outcomes. A surgeon must be able to admit to unwanted events in an honest and compassionate manner. It is clearly possible to accept *responsibility* without admitting *negligence*. It never hurts to admit that you are sorry things had not gone exactly as planned, but that you must go forward, as efficiently as possible, to correct the situation. At this point, a surgeon should never hesitate to seek consultative assistance whenever it might seem helpful. It is never helpful to shift blame to a resident, an assistant, a nurse, a referring physician, or the institution itself. If anyone is to be sued, everyone will be sued, and divisiveness usually damages everyone. Unfortunately, it is also of little help to blame the patient and to invoke the existence of adequate *informed consent*. How nice it would be to tell the morbidly obese person that his postoperative complications should be blamed on his own indiscretions. Even informed consent, including risks based on the patients known status of precarious health, is of little help. A surgeon is not absolved of responsibility and concern by claiming "I told you so!"

Judges, not the legislature, establish the standards that constitute medical malpractice. The familiar elements of medical malpractice include *duty, breach*, *causation*, and *damages*. Decisions are based on the standard of care, and judges have developed the methods of determining the standards over many years, after the review of many cases. Thus, the courts rule on a specific set of facts that have already occurred. This is extremely frustrating for those practitioners

of surgery who need to know what the law *would say* in a particular situation, as it is occurring, not in retrospect.

Unfortunately, resolution of controversy over medical and surgical ethical issues has been the domain of law, not philosophy or medicine. So far, perhaps because of legal constraints, medicine has been unable to "police itself." Because the law has come to champion individual rights and hold physicians liable for malpractice, it has served to condemn medical *paternalism* as it has elevated *patients' rights*. This has had the damaging effect of encouraging many physicians to become more concerned with avoiding litigation then with "doing the right thing." The law has had understandable difficulty in sorting out the complicated *physician–patient relationship*, and thus law does not mandate ethical behavior in these relationships.

A Familiar Case-Management System

Physician-Based Ethics

General Principles

Mark Siegler, a physician, and his co-authors of "Clinical Ethics," the fifth edition, present a technique for using *case analysis* as a practical approach to solving ethical dilemmas in clinical medicine. Contrary to most texts on health-care ethics that are organized around the ethical *principles* of respect for *autonomy*, *beneficence*, *nonmaleficence*, and *fairness*, their publication provides a straightforward *method* for clinicians to use in sorting out the pertinent facts and values of any case into an orderly pattern that facilitates the discussion and resolution of ethical problems.[13] Their technique corresponds to the way in which clinicians usually analyze actual cases. It assimilates the ethical principles and circumstances that comprise a method to facilitate the analysis of cases involving ethical issues.

The *Clinical Ethics* System

Siegler and his colleagues suggest that every clinical case, especially those raising an ethical dilemma, should be analyzed by means of the following four topics: (1) *medical indications*, (2) *patient preferences*, (3) *quality of life*, and (4) *contextual features*, defined as the social, economic, legal, and administrative context in which the case occurs. The authors emphasize that although the facts of each case can differ, these four topics are always relevant. The topics organize the various facts of the particular case and at the same time call attention to the ethical principles appropriate for each case. Their intent is to show clinicians that these four topics provide a systematic method of identifying and analyzing the ethical problems occurring in clinical medicine (Table 52-1).[13]

Examination of the table shows that the authors have clearly related to clinical situations the basic ethical principles

previously described. They go on to emphasize that most ethical conflicts can be resolved by falling back on the *medical indications* that represent the medical facts of the case. This information, plus the second category of *patient preferences*, almost always will lead the clinical surgeon to a resolution of the ethical problem. If the ethical dilemma results from conflicts among the patient, the family, the health-care team, or institutional policy, then adequate resolution may become dependent on applying analysis of the additional categories, *quality of life*, and the array of *contextual features*. It is amazing how often reviewing and relying on what the medical facts of the situation actually are can clarify the intensity and emotion of even the most complex situation.

Specific Dilemmas of Colon and Rectal Surgery

Special Considerations for Colon and Rectal Surgeons

We understand that we have chosen a surgical career which includes resolving perplexing problems of anorectal disease, pelvic floor malfunction, and incontinence which cause daily significant discomfort for the patient and have frequently been mismanaged, for a long period of time, by our nonspecialized colleagues. This places us, frequently, in the position of not only having to resolve the technical surgical aspect of the problem but also having to explain the previous misdiagnosis or mismanagement by other physicians, a challenging *ethical dilemma*.

In addition to the seemingly simple anorectal disease, most of our careers also encompass management of some of the most complicated inflammatory bowel disease and cancer. This casts us into a position of having to deal with multiple components of the modern health-care team daily. We know that no one should ever have to die from colorectal cancer because it can be prevented or diagnosed at an early, or even premalignant, stage. Thus, we become actively involved with screening, preventive measures, understanding genetic predisposition to disease, and even the need for what has come to be called *preemptive surgery*. Because of the diseases that we treat, we must understand the science of current genetics as well as the appropriate clinical utilization of genetic testing, including the challenges of respecting *confidentiality* and requesting *genetic counseling* to deal with the long-term aspects involving not only the patient but also the family members who may not wish to be included in the discovery of genetic predisposition to disease. All of these present an intense need for dealing with frequent ethical challenges, especially the need for increasing *preemptive surgery*, subjecting a *well person* to major surgery with significant risk of complications or impact on lifestyle and body image. In fact, because of our experience and expertise in pelvic surgery and the construction and

TABLE 52-1. The four topics: case analysis in clinical ethics

Medical Indications	Patient Preferences
The Principles of Beneficence and Nonmaleficence	The Principle of Respect for Autonomy
1. What is the patient's medical problem? history? diagnosis? prognosis?	1. Is the patient mentally capable and legally competent? Is there evidence of incapacity?
2. Is the problem acute? chronic? critical? emergent? reversible?	2. If competent, what is the patient stating about preferences for treatment?
3. What are the goals of treatment?	3. Has the patient been informed of benefits and risks, understood this information, and given consent?
4. What are the probabilities of success?	4. If incapacitated, who is the appropriate surrogate? Is the surrogate using appropriate standards for decision making?
5. What are the plans in case of therapeutic failure?	5. Has the patient expressed prior preferences, e.g., Advance Directives?
6. In sum, how can this patient be benefited by medical and nursing care, and how can harm be avoided?	6. Is the patient unwilling or unable to cooperate with medical treatment? If so, why?
	7. In sum, is the patient's right to choose being respected to the extent possible in ethics and law?

Quality of Life	Contextual Features
The Principles of Beneficence and Nonmaleficence and Respect for Autonomy	The Principles of Loyalty and Fairness
1. What are the prospects, with or without treatment, for a return to normal life?	1. Are there family issues that might influence treatment decisions?
2. What physical, mental, and social deficits are the patient likely to experience if treatment succeeds?	2. Are there provider (physicians and nurses) issues that might influence treatment decisions?
3. Are there biases that might prejudice the provider's evaluation of the patient's quality of life?	3. Are there financial and economic factors?
4. Is the patient's present or future condition such that his or her continued life might be judged undesirable?	4. Are there religious or cultural factors?
5. Is there any plan and rationale to forego treatment?	5. Are there limits on confidentiality?
6. Are there plans for comfort and palliative care?	6. Are there problems of allocation of resources?
	7. How does the law affect treatment decisions?
	8. Is clinical research or teaching involved?
	9. Is there any conflict of interest on the part of the providers or the institution?

management of intestinal stomas, we are often confronted with such *quality-of-life* issues as body image and impairment of sexual function.

Dealing with our many patients, and their families, who have inflammatory bowel diseases such as Crohn's disease requires us to maintain long-term, perhaps for generations, contact with and care for our patients, much the contrary of our public image of being just "technicians" who do a short-term repair job and then have no other ongoing relationship with our patients.

Because of the complexity of the diseases on which we operate, including those in areas with difficult access and high risk of postoperative complications and recurrence of malignant processes, we often find ourselves on the leading edge of surgical innovation and instrumentation. This creates the ethical challenges of differentiating acceptable surgical *innovation* from truly *investigative* ventures that require research protocols and institutional approval. We must deal with the interpretation and implementation of *autonomy* versus *paternalism* as we guide our patients to the best choices for their care. Sick patients and those suffering from advanced cancer will grasp at straws. They want anything on earth that might help. In such a situation, it is important for the surgeon-scientist to avoid exploiting this universal hope of sick patients by carrying out an operation that is inadequately tested.[14] Because of these challenges of innovation, we are also frequently thrust into the potential conflict of interest between ethical surgery and the pharmaceutical and instrumentation industries.

Needless to say, because of the many things that we have to offer and the need to be concerned with our own long-term financial security in the face of reimbursement and legal challenges, we must walk the narrow line between providing the best care possible for all of our patients and complying with our own personal needs and those of our families. Claude Organ explained that "So much of our orientation today serves to erode our spirit as caregivers." He goes on to say that surgery is under increased public surveillance, and we are consumed by endless paperwork, administrative hassles, ponderous bureaucracy, professional liability concerns, inadequate reimbursement for our work, limited access for our patients, an impersonalized system, and increasingly burdensome documentation. He cites the increasing federal mandates of the Health Insurance Portability and Accountability Act,

the Emergency Medical Treatment and Active Labor Act, and the Program for Appropriate Technology in Health audits. He goes on to quote the highly respected surgical mentor, Haile Debas as saying, "professional status is not an inherent right but one granted by society…. This obligates surgeons to put their patients' interests above their own."[15]

Categories of Patient Encounters

Severe Emergency: Life in Immediate Jeopardy

An example would be a critically ill person brought in from a severe motor vehicle accident or one who has suffered a serious gunshot wound. Certainly, there is no preestablished doctor–patient relationship, there is little chance that there will be a reliable surrogate, and many ethicists have questioned if a patient in such dire straits ever has *decision-making capacity*.

Urgent: Serious Problem Needing Surgery

An example would be a patient brought in with peritonitis. The individual may be in hypovolemic shock, is terrified, is in great pain, but is still cognizant of the situation and what is happening. There certainly is no preexisting *doctor–patient relationship*, and no one is absolutely sure of the *decisional capacity*, especially if the patient disagrees with the recommendation of the surgical team. In a case such as this, where there is some but not much time, the presence of a *surrogate* and clearly described *advance directives* would be extremely helpful.

Semi-Elective: Will Probably Need Surgery

An example would be an elderly patient with known extensive intra-abdominal cancer who presents with a significant, unresolving intestinal obstruction. It is clear that the obstruction can only be relieved by surgery, but it is not clear that this will be beneficial to the patient. In this case, determination of *decisional capacity*, the existence of *advance directives*, or the presence of a reliable *surrogate* is very important, and there is enough time to pursue the intended desires of this patient.

Autonomy/Decision-Making Capacity/Competency

General Concepts

Autonomy vs. Paternalism: Trust Is the Bridge

Individual freedom is one of the basic tenets of modern bioethics. This freedom is usually referred to as *autonomy*.

This principle implies that a person should be free to make his or her own decisions. It is somewhat the antithesis of the medical profession's long practiced *paternalism* whereby the physician acted on what he or she thought was *good* for the patient, whether or not the patient agreed. The concept of *autonomy* applies to many interpersonal relationships and is essentially a respect for each person as an individual.

It has been difficult for many physicians, perhaps especially surgeons, to accept the principle of *patient autonomy*. This is not difficult to understand because accepting this principle implies a change in the physician's relationship with the patient. The physician must now be a partner in his or her patients' care, and must become an educator, teaching uninformed patients enough about their diseases to make rational decisions, and most distressing, to allow autonomous patients to make foolish choices. For physicians dedicated to helping their patients, allowing them to select what the physician considers a terrible treatment option, or even refusing treatment altogether, is a very frustrating change.[7]

On the other hand, experienced surgeons know that their patients significantly rely on them for guidance through complicated choices, often where life itself is on the line. This is, of course, a form of *paternalism* which our patients request and to which they are entitled. The key to accomplishing this ethically and successfully is based on the principle of *trust*. For surgeons, establishment of this trust must begin at the inception of the relationship and sometimes must be very quickly accomplished. It is sometimes very difficult for our nonsurgical colleagues to understand and accept this element of *paternalism* required in the surgeon–patient relationship.

The crucial issue for the surgeon seeking autonomous informed consent is the *decision-making capacity* or *competence* of the patient involved. Understanding the differences between these terms is important, especially if the patient disagrees with the advice of the surgeon or refuses potentially life-sustaining treatment.

The determination of *decision-making capacity* involves more than just completing a mental status examination and includes the ability of the patient to take in information, to evaluate a decision based on personal values, to make a decision, and to communicate the choice of decision to the physician. The concept of medical *decision-making capacity* is one based on the evaluation by the team providing medical and surgical care. This is distinguishable from a *legal determination* of *incompetence*. A patient is always assumed to be *legally competent* unless a *court* has declared otherwise. For example, patients may not have been declared incompetent by a court but may have lost the capacity to make decisions about their medical care because of their current medical status, including such conditions as intoxication, stroke, hypoxia, blood loss, dementia, or severe trauma. The determination of *decision-making capacity* varies in stringency with the seriousness of the impact of the decision. For example, the more severe the risk posed by the patient's decision, the more stringent

should be the standard of determining capacity. This provides an increased protection for patients of questionable capacity when the potential harm from their decision is greater. This reaches the pinnacle of importance when a patient refuses treatment for a potentially life-threatening condition. These decisions are often difficult to make in the emergency environment, and the treating surgeon must sometimes make practical ethical decisions that go beyond the basic law of informed consent.

Refusal of Treatment

Ethical dilemmas usually occur when there is disagreement among the patient, the family, and the health-care team. The clearest example is a patient's refusal to accept the recommended treatment. This is especially critical for the patient who has *decision-making capacity* and refuses potentially life-sustaining treatment. The US Supreme Court, in the *Cruzan case*, upheld the right of persons to refuse lifesaving medical treatment, including resuscitation, ventilators, artificial nutrition and hydration, and lifesaving blood transfusions. The Court based its decision on "the right of every individual to the possession and control of his own person, free from all restraint or interference of others, unless by clear and unquestionable authority of law under the *liberty interest*, protected by the Due Process clause of the Fourteenth Amendment of the Constitution." The courts have, however, identified four *state interests* that override the refusal or termination of medical treatment on behalf of competent and incompetent persons, including the preservation of human life, the protection of the interests of innocent third persons, the prevention of suicide, and the maintenance of the integrity of the medical profession.

In exercising their rights under the autonomy principle, each competent patient has a right to refuse treatment, even if the results of such refusal will be their death. This type of situation comes up most often in the case of religious or cultural beliefs. Jehovah's Witnesses are probably the most familiar example of this type of dilemma. They refuse to accept blood transfusions, based on their religious beliefs. Such refusal, especially where major surgery is indicated, clearly poses the likelihood of avoidable death. Still, the competent patient's *autonomy must rule*. There may be situations where the treating surgeon feels that the competency of the patient refusing treatment may be in doubt. In such a case, if time permits, to protect the doctor and the hospital, it may be appropriate to get a court order permitting the indicated procedure or blood transfusion. The courts will weigh the possible benefits of the treatment against the potential negative effects, risks, and the potential burdens on the patient, and they will issue a ruling. This ruling will insulate the treating physician and the institution from legal liability. There are situations where parents or guardians are involved in refusal to accept and allow treatment on behalf of miners. These are the most common instances where court intervention is sought, and to resolve the problem, the courts must

balance the best interests of the child against the desires of the parents.

For sure, *refusal* of a life-sustaining medical treatment should be accompanied by a full assessment of *decision-making capacity* and by an understanding from the patient of the consequences of refusal. If uncertainty prevails, the surgeon on the firing line should still "err on the side of life."

Telling the Truth/Disclosing Errors

General Concepts

Physicians have a duty to tell the truth to their patients. This seems so obvious that it merits no further discussion. However, there may be circumstances where telling the *whole truth* to a patient will have a negative impact on his or her overall well-being. If the physician believes that telling the patient everything about the condition in question, which is a duty, will have a dramatic negative effect on the patient's well-being, the physician must decide which duty is more important in each particular situation.

Truth telling also would apply in situations involving *medical mistakes*, even those mistakes that are minor and arguably have no detrimental effect on the patient. To illustrate this point, let us consider a doctor awakened in the middle of the night who orders 1 mg of a drug, when the appropriate dose is 0.1 mg. The overdose has no detrimental effect on the patient; so, does the doctor still have a duty to reveal the error that he made? Ostensibly, this question would seem to be easy to answer: just tell the truth! However, if informing a patient whose confidence in the medical profession is very low, and his mental stability might be diminished by finding out about a medical error, notwithstanding the fact that the error had no detrimental effect, do doctors still have a duty to tell the truth? In this situation, it might violate the duty of nonmaleficence by doing something that will hurt the patient.

Prognosis: Balance Between Giving False Hope and Removing All Hope

We are all involved in operations whose desired outcomes are not met. Managing these patients through the entire course of their disease, and sometimes death, is an important part of being a good physician and surgeon. This becomes even more important as the population ages and we encounter older patients with multiple comorbidities. Especially in these older, high-risk patients, even what is anticipated to be a fairly straightforward operation may have unexpected, adverse results. It forces us to remember the old adage that not everyone needs to die with an incision. Predicting prognosis, much less conveying it well to the patient and the family, is a difficult skill with little data to help us. We need to communicate with the public the fact that we would welcome

the ability to forecast outcomes accurately especially for older patients, with higher risks, and in emergency situations. We truly cannot distinguish which ones may actually do well from such high-risk operations. This necessitates us, as surgeons, to assume an important role in providing *palliative care* even when complete surgical *cure* is no longer a possibility.[16]

Discussing prognosis with our patients and their families is one of the situations, which forces us most carefully to choose our words precisely. Even when we are forced by patients and families to use specific statistics, we must use them in a manner that is helpful and not totally destructive of hope. It helps to explain that statistics are better for 100 people rather than for any given individual. It can be very expeditious for us to use statistics as a form of *truth dumping*, but such an act can be devastating to a terrified, desperate, and inadequately informed patient who is desperately clinging to any possible hope.

Patients with Impaired Decision-Making Capacity

Examples of patients having impaired decision-making capacity include minors, mentally handicapped persons, those with organic brain disease or in toxic states, and those with psychiatric conditions, including suicidal risk. Determining the point at which a "minor" has the capacity to make medical decisions is often very complicated and varies with the laws of an individual state.[17] For example, an "emancipated minor" can make his or her own medical decisions. This includes individuals younger than the age of majority who are living on their own, are married, or are in the military.

Even patients with some forms of dementia cannot be regarded as having lost their *decision-making capacity*. Depending on the severity of their disease, they may well be able to participate in much of the decision-making process. This of course depends on the status of their disease and on the complexity and implications of the decision to be made.

Suicidal Patients

Respect for autonomy has always had its limits. When treating a suicidal patient, the surgeon is faced with a conflict between the ethical principle of *beneficence* and *respect for autonomy*. Sorting out this dilemma is usually based on whether the suicidal patient is currently capable of making a rational, autonomous decision. It also raises the perplexing question "can suicide sometimes be a rational choice?" Generally, surgeons intervene with the suicidal patient based on the assumption that the person is suffering from mental illness and impaired judgment. This assumption is usually correct, with 90% of suicides being found to be associated

with mental illness such as depression, substance abuse, or psychosis.[18]

Therefore, relying on the principle of beneficence, surgeons almost always treat the injuries inflicted by suicidal patients despite their expressed intention to die. The conflict arises when the reasons for suicide appear "good," such as in the case of the terminally ill cancer patient with severe, uncontrollable pain. Is the application of lifesaving intervention truly a beneficent act in the patient's best interest? Several studies have shown that physicians rendering care in the emergency department are not likely to recognize treatable depression in their patients. These studies go on to confirm that 80% of patients who attempted suicide subsequently show that they do not continue to wish to die. Thus, although some patients might make a rational decision to commit suicide, in most cases the surgeon delivering care must assume that the person's judgment is impaired and proceed with full indicated, lifesaving measures.[18]

Advance Directives

General Principles: Talking About Death

Facility in routinely addressing end-of-life issues with surgical patients is critical because it allows the surgeon to raise difficult questions with patients during the earlier phases of their disease process. Often, the issues that are most difficult to address when patients near the end of life are those that have not been attended to earlier in the patient's course of treatment. Such early discussion allows the surgeon and the patient to discuss limits on treatment at a time when the patient is able to participate in the process. Usually, we surgeons are intent on cure, and the prospect for death after most of our routine procedures seems very remote. However, these discussions are more important than ever because we now have more options available to prolong life than existed just a few decades ago. In addition, social changes have led to greater participation by patients in the medical decision-making process. With the increasing mobility of our society and the changing allocation of primary care physicians, we as surgeons often do not have the backup of a well-established physician–patient relationship. Add to this the very visible rise in public debate over *euthanasia* and *physician-assisted suicide;* and we can understand the concern the public has over-perceived, or actually, deficiencies in how patients are managed at the end of life.[19]

When a patient does not have the decision-making capacity to give informed consent, or when there is no time to ask the patient or his or her surrogate about treatment preferences, *advance directives* express in written form what the patient's choices would have been if he or she had decision-making capacity. Advance directives include living wills, durable powers of attorneys, and other written documents. In 1991, the federal government passed the Patient Self-determination

Act (PSDA), which required that health-care institutions advise and educate patients regarding advance directives. This affected all institutions participating in the Medicare and Medicaid programs. This law was supposed to increase the use of advanced directives and thus prevent unwanted care. In fact, a major study of advanced directives and seriously ill patients revealed that the PSDA had little impact on health care in USA. This was revealed in the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT), which showed that only 20% of seriously ill patients had advance directives even after the SUPPORT intervention and the PSDA.[20]

Despite these studies, it is still imperative for surgeons to understand the principles involved and the advantages of advocating for appropriate advance directives for our patients and their families. An *advanced directive* is any proactive document stating the patient's wishes in various situations, should they be unable to state their own wishes.

Some states have specific language for each of these documents and provide reciprocity for other states. Both the *living will* and a *durable power of attorney* can be prepared without the benefit of state-approved language as long as the intention of the person executing the document is clear. Such directives provide advanced informed consent for a myriad of courses of treatment, whether it be related to pain medication, "do not resuscitate orders," or management, should the individual enter some level of persistent vegetative state. In a complete set of these documents, the patient has given full thought to all of the possibilities that might occur and has decided what course of treatment would be his or her choice. Unfortunately, most patients have not executed these documents, or they have not given sufficient thought to what their wishes are. Furthermore, many times, when a power of attorney is granted to a surrogate decision maker, the surrogate does not have a full discussion of the wishes of the signatory.

Living Will

The *living will*, which was adopted by many states in 1990, is a document suitable for *terminally ill patients* where the treating physician accepts the patient's wishes regarding withholding of care, including requests restricting heroic resuscitative efforts, in advance. Many state that no life support be used in cases where meaningful recovery will not occur. In a *living will*, the signatory indicates what his or her choices would be for medical treatment in the situation where *death is imminent*, and the individual's wishes are unable to be communicated to the treating physician. Under most state laws, *living wills* indicate the signatory's desire to die a natural death and indicate unwillingness to be kept alive by the so-called heroic measures. This usually amounts to a "Do Not Resuscitate" order. In some states, this also indicates the patient's wishes concerning the level of pain medication, hydration, and nutrition, which the patient would desire if he or she lapses into a nondecisional condition. In most states,

the activation of the terms of a living will require an *imminent demise* and a second physician's opinion corroborating that determination. Unfortunately, many people believe that the *living will* is the best form of advanced directive and do not realize that it is intended only for the *terminally ill*.

Durable Power of Attorney

A *durable power of attorney for health care* specifies a surrogate decision maker in the event that the patient no longer has the capacity to make medical decisions. The *durable power of attorney* is a written document that gives the authority to another person, usually a spouse or a relative, to make decisions regarding health care if the patient is incapacitated and unable to make decisions for himself or herself. The reason it is called "durable" is to ensure that the signatory knows that it can be revoked and/or changed at any time. This provides the freedom to change both who the surrogate is and what the patient's stated wishes, if any, are. This is important in situations such as divorce were the person executing the power of attorney may want to change the surrogate before the divorce becomes final or in those family situations where dynamics create a desire to change the surrogate.

Thus, the patient designates a *surrogate decision maker* who should participate in all significant treatment decisions and be kept up to date regarding the patient's health care. The *durable power of attorney* works best when the patient has discussed with a surrogate his or her values and beliefs, as these would apply in making complex decisions regarding health-care issues. If there is no durable power of attorney, surrogate decision makers may be sought based on state laws. There is usually a defined hierarchy regarding surrogate decision makers: spouses, adult children, siblings, and so forth. Such a surrogate decision maker must be acting in the best interest of and according to the wishes and values of the patient. The *durable power of attorney* is a better form of advanced directive than the *living will* because in the former, a surrogate can be educated about the nuances and options regarding each stage of treatment or nontreatment.[20]

Problems

In many situations, the surrogate has the legal authority to make a decision but is not aware of what the patient would want. This is the fault of the patient. All persons, when naming a surrogate decision maker, have a responsibility to fully explain what they would want in certain medical treatment situations. Failure to do so puts the burden on the surrogate to speculate what the patient would do if he or she was able to make the decision.

There are two standards that apply in the situation where the surrogate has not been informed of the patient's wishes. One is the *substitute judgment* standard. When using this standard, the surrogate bases a decision on a prior expressed statement of the patient's preferences or on an in-depth

knowledge of the personality of the patient and a willingness to do what the surrogate believes the *patient*, not the surrogate, would want in that specific situation. The second standard is that of the *best interest* of the patient. This is obviously a far more nebulous concept and occurs where the surrogate has not had any specific communication with the patient about the specific type of situation and is not cognizant of any particular patient preferences. In this situation, the surrogate is supposed to do what he believes is in the best interest of the patient. This is an important distinction to make and emphasizes the difference between doing what the patient would want done in a given situation, and having someone else decide what he or she thinks is best.

A further problem with advanced directives that limit full implementation of medical care is the application of such directives in situations for which they were not intended. An example that confronts the colon and rectal surgeon is an elderly patient who is recovering from a complicated colon resection for curable cancer and develops postoperative pneumonia requiring presumed short-term ventilating support. Should such a patient not be intubated because of an advanced directive indicating "do not resuscitate"? In such a case, it would be a serious error to respect the advanced directive and not to treat the patient aggressively. It is clearly probable that the patient would have wanted treatment under these circumstances.

There must also never be confusion when the patient is able to relate his or her preferences to health-care providers. *Verbal communication takes precedence over any written advanced directive*. In addition, when there is any confusion about the advanced directive, disagreement among family members, or concern that it was not meant for the clinical circumstance at hand, *advanced directives limiting treatment should be ignored in favor of prudent medical care*. In general, it is always wise for health-care providers to err on the side of life and to begin standard medical treatment. Treatment options, such as mechanical ventilation and hemodynamic support, can always be withdrawn at a later time once issues are resolved and the family is present. In such situations, the hospital *ethics consultation service* can often prove very helpful.

Perhaps the major problem, at this point in time, is that there is little evidence that advanced directives have made a significant impact on health-care delivery in USA.[20] We, as surgeons, should do all within our power to reverse this situation.

Informed Consent

General Concepts

Studies have revealed that doctors may not adequately inform patients, patients may not understand the information, and such information rarely affects the patient's decision to follow the physician's recommendations. Despite these facts,

American courts have long held that a patient's *informed consent* to a medical or surgical procedure or test is *essential*. The physician must give the patient sufficient information to make an intelligent decision before any action is performed. The laws dealing with informed consent require the surgeon to describe to the patient the nature of the procedure, risks, benefits, and alternatives, including no treatment at all. Ethical consensus on just how much disclosure is adequate is still very controversial. What is clear is that permission must be given *voluntarily*, that is, *without coercion* from the physician or anyone else involved in rendering health care or, especially, those participating in the implementation of a *research* project.

The current interpretation of the law requires several elements to constitute *informed consent*. These are the *criteria* that the physician must disseminate to the patient or acting surrogate to meet that standard:

(a) What is the treatment that the doctor wishes to pursue, including a full explanation of the procedure and what it involves, including the necessity for anesthesia and other support functions?

(b) For what reason has the doctor selected this particular treatment, including the doctor's judgment as to why this procedure is chosen to alleviate, cure, or minimize the medical/surgical problem?

(c) What are the risks of the recommended treatment, including an explanation of both the risks of the treatment itself and of any corollary threats to the patient? Surgeons should, in satisfying this requirement, include discussion of their own particular *experience with the procedure* as well as that of the hospital and the medical/surgical colleagues who will be assisting.

(d) What benefits will the patient receive from the proposed treatment? This is similar to the choice of treatment information previously described in that it requires the doctor to explain what the potential benefits will be from the procedure.

(e) What are the chances that the proposed treatment will remedy the problem? This is similar to the information included when describing "benefits and risks" and should also include a description of the *past experience* of the surgeon in performing this specific procedure, as well as the *outcomes* that the surgeon has obtained.

(f) What alternative treatment options exist for the given problem? This is similar to explaining the choice of treatment but emphasizes what other treatment options are available, and why this surgeon has chosen this particular procedure.

(g) What effect will refusal to accept the proposed treatment have on the patient? This must entail a frank discussion of the ramifications of failure to receive the suggested treatment and whether it is life threatening, or of a lesser degree of medical difficulty. This is the part of the discussion where the surgeon must be most sensitive to the patient's religious, cultural, and ethnic background.

Here, the law requires that the sufficiency of the level of information will be judged from the *patient's point of view*, not the doctor's. If a surgeon explains a proposed treatment to the patient in terms that only another surgeon can understand, then the patient is not truly *informed*. This simply boils down to communication skills and the obligation to accurately *record* this discussion in the medical chart prior to performing the recommended surgical treatment. Every profession has its own terms of art or jargon. Physicians must strive to ensure that the language they use is clearly understandable. Achieving acceptable levels of communication may be complicated by language, cultural, and socioeconomic factors. A manager responsible for building a new jetliner was credited with saying, "The main problem with communication is the illusion that it has actually occurred." All too frequently patients and families come away from discussions with surgeons where the surgeon thinks he has effectively communicated and the patient and family seemed to understand, but they did not. Sometimes it just boils down to faith in the doctor, or an individual's unwillingness to reveal his or her lack of comprehension. The physician must use *common sense* in determining whether fully informed consent has truly been granted, taking into account that some cynics claim, "The problem about common sense is that it is not common."

As with every rule of law, there are certain *exceptions* to the requirement for informed consent. When there is an emergency situation that could result in the death of the patient, when time is of the essence, and when there is no surrogate decision maker present, the *consent requirement is waived*. Similarly, when the situation is not an emergency, but the patient is for one reason or another not able to give consent due to unconsciousness, coma, mental disability, or other cause of inadequate decision-making capacity, and when there is no advance directive, or surrogate, informed consent is not necessary. There is also a *therapeutic exception* to the rule. If the physician believes that revelation of the normally required information would have a negative effect on the patient's health, fully informed consent is not necessary. This usually arises in the context of a psychiatric patient. Also, when a competent patient *refuses* to receive information upon which to base a decision, this requirement is waived. There can also be a waiver of the necessity for informed consent when the *government* requires certain medical tests or treatment in the face of possible medical or national security emergencies.

A common misconception among those rendering emergency care is that anyone who presents to an emergency facility falls into the *emergency exception* to informed consent. The *emergency exception* allows a physician to treat a patient without obtaining informed consent. This exception requires the following: the patient must be unconscious or without the capacity to make a decision, and no one else legally authorized to make such a decision is available; time must be of the essence in avoiding risk of serious bodily injury or death;

and under the circumstances, the action proposed would be that to which a *reasonable person* would consent. The emergency exception does not apply if the patient has decision-making capacity and is able to communicate a decision about medical care.[2]

Patient–Surgeon Relationship

Siegler explains that the three central ethical aspects of modern surgical practice are (1) clinical competence, (2) respect for patients and their health-care decisions, (3) maintaining the primacy of the patient's needs in the face of external pressures in a changing social, economic, and political climate. Successful clinical practice has always been a unique blend of technical proficiency and ethical sensitivity, which together constitute the art of the physician and surgeon. Once sought out by the patient, the surgeon becomes involved in the patient's problem. He or she is no longer a mere observer. Over the last few decades, the relationship between patients and physicians has been evolving from one of *paternalism*, in which surgeons make choices for their patients, to a more equal and *autonomous* relationship of shared decision making, by which surgeons provide information that allows competent adult patients to make their own choices.[21] For complicated surgical dilemmas, this can never evolve completely because patients depend on the surgeon and their other physicians to guide them to the correct choice.

Sometimes surgical procedures considered "standard of care" by the surgeon are refused, based on the patient's values and beliefs. Such cultural challenges can affect the success of the patient–surgeon relationship and ultimately the health outcome for the patient. Ultimately, the surgeon must learn to take into account the cultural components of the relationship and find ways to respond to them in an ethically and medically responsible manner. In order to deal with these complicated situations, the surgeon is often required to reassess and be secure in his or her own religious and cultural foundations.[22]

As Peter Angelos explains, the relationships that individual patients have with their surgeons are as varied as are the different types of surgical problems with which patients present. Perhaps patients are required to have a great deal of trust in their surgeons because of the nature of surgical intervention itself. This may result in patients frequently feeling a deeper personal bond with their surgeon than with many other physicians who may be involved in their care. Surgeons, as well as their patients, frequently feel the closeness of this bond. Angelos quotes Charles Bosk as explaining

> The specific nature of surgical treatment links the action of the physician and the response of the patient more intimately than in other areas of medicine... When the patient of an internist dies, the natural question his colleagues ask is, "what happened?" When the patient of a surgeon dies his colleagues ask, "What did you do?"

When patients consider the surgeon to be "their doctor," the surgeon must not ever underestimate the importance of maintaining this relationship even, or perhaps especially, as the patient approaches the end of life. The impact of a concerned surgeon on a patient who is dying, or is incurable, can serve to dramatically affirm the appropriateness of comfort care instead of desperate, ineffective, and costly attempts to ward off death.[19]

Communication and the Internet

It seems so easy to be able to respond to a patient's problem or to deliver information to them and their physicians by e-mail. With e-mail delivered via the Internet, there is no problem with timing of the conversation, no recordings, no time on "hold" for the doctor or for the patient. The only limitation seems to be the typing and spelling skills of the surgeon, usually problem enough.

Most of us have learned not to deliver complicated or bad news over telephone, unless we have made a previous agreement with the patient and family to convey such information to save significant travel or other inconveniences that are significant enough to preclude a face-to-face personal communication. Such situations are now increasingly complicated because communication over the Internet is usually not secure, and the information delivered can become a permanent part of the patient's record. A patient's employer and family can usually acquire easy access to the electronic message, potentially to the detriment of the patient, and potentially leaving this sending physician legally liable.

For the medical and medical legal aspect, some of the material we send by e-mail we would never consider sending by "hard copy" unless we had obtained the patient's specific permission to release such information. Currently, there are no guidelines available for the ethical transfer of confidential medical information via the Internet. Until such exists, and it is critical for physicians to participate in the establishment of such principles, all doctors are probably well advised to record in the patient's permanent record that discussions were held and permission was given to communicate *specific* information electronically. Especially with the implementation of HIPAA requirements, until clearer guidelines are defined, surgeons should err on the side of no sensitive information to be delivered by e-mail or telephone.[19]

Of course, the other massive impact of the Internet is the availability of unlimited access to potentially confusing and harmful information to our patients. Remember, there is no quality control for the Internet. Unlike traditional publications with editors, peer-review standards, and vigorous screening, on the Internet, anyone with a computer can be a self-designated author, editor, and publisher. And this can be done anonymously with no attached responsibility. This will continue to have an enormous impact on the patient–physician relationship because "knowledge is power," and our patients and families are making use of that power.[23] Not infrequently patients come to us with confusing and conflicting material from the Internet. A new part of our responsibility, as surgeons, is not only to guide our patients to appropriate and helpful Web sites but also to actively participate in the construction and quality control of electronic information provided by the Internet in our own areas of expertise.

Using Newly Deceased Patients for Teaching Purposes

A unique problem exists for the medical/surgical team caring for patients in the emergency department of a teaching hospital. It involves using the newly dead for teaching purposes. This most commonly involves teaching medical students and residents the techniques of endotracheal intubation. The issue is, of course, do we have the right to perform procedures on this newly deceased person without obtaining permission (informed consent) from the surviving family. The dilemma is complicated by the fact that no better teaching opportunity exists for our trainees who can then go forward, when adequately trained, to save lives and relieve suffering in the future. Clearly, no harm can be done to one who is dead. Furthermore, to our knowledge, there are no state statutes that specifically prohibit the teaching of procedures using newly dead patients, and no court has considered this issue. Although, before death a patient has constitutional protection against nonconsensual invasion of his or her body, it has been established by various state courts that constitutional rights do terminate at the time of death.

Although the law in this situation is very forgiving, compassionate and ethical considerations should supervene. Several medical studies have found that patients and families are likely to consent to such procedures but prefer to be asked permission first. Even the law advises that in this day and age of increasing recognition of personal autonomy, it is probably prudent to approach the next of kin for permission before performing procedures on the newly deceased.[24]

Special Concerns for Participation in Research/Innovation

General Concepts

Surgeons, by our very nature, are innovators. Sometimes, the only way we can complete an operative procedure is by making a deviation from what has been standard procedure in the past. Since we operate on biological systems, we can never predict exactly what will be required for a given procedure. We often use old procedures for new purposes and without much hesitation use new equipment to accomplish old tasks. Thus, we often find ourselves in what McKneally refers to as

"the zone of innovation" where it is unclear whether what we are doing is an evolutionary variation on a standard procedure, a unique departure from accepted standards, or the first stage of what should become recognized as a formal surgical research project.[25] When should our deviations be subjected to full evaluation by an Institutional Review Board? How can a surgeon participate, with *equipoise* (the presumption that both arms of a study are equally efficacious) in a prospective randomized trial to evaluate a change that the surgeon has created to be better than the known standard? As Martin McKneally explains, most of the important advances in the history of medicine, such as anesthesia, appendectomy, antibiotics, intensive care, and immunization, were introduced through an informal, unregulated innovative process that has been enormously productive but can easily lead to ratification of an effective or even harmful treatment by well-intended physicians.[25]

Look at the recent challenges facing colon and rectal surgeons. We adopted the construction of ileal and now colonic pouches to improve the quality of life of our patients with inflammatory bowel disease and rectal cancer. The true efficacy of these innovations came significantly later than their description and implementation by many of our colleagues. The use of minimally invasive techniques to accomplish what we were all trained to do via abdominal incisions was clearly initially driven by the new technology and by enthusiastic entrepreneurs who wanted to work on the frontier of innovation. The premature exposure of these new techniques to the lay literature drove the process with even more intensity. Only recently have completed prospectively randomized trials verified the realistic advantages of the new technology. We continue to sort out the appropriate use, for the benefit of our patients and their quality of life, of issues such as circular stapled hemorrhoidectomy, Natural Orifice Translumenal Endoscopic Surgery (NOTES) procedures, and robotic technology. What we need is a process for evaluation of surgical innovation, which provides ethical oversight without the ponderous slow pace inherent in most IRB-approved protocols. Surgical investigators and ethicists are currently crafting such a mechanism, which protects the rights and well-being of our patients without stifling progress and creativity.

Good research is described as that which enhances our ability to prevent illness or injury, to improve the quality or decrease the cost of care, or to improve the lives of our patients. Such research also must protect subjects and patients from harm, preserve their confidentiality, and allow them to enter freely as participants. Subjects and patients must be allowed to make an informed choice to participate, or not, without fear that their treatment might be compromised if they decline the request of the investigator. For a research project to be ethical, it must also be well designed and must investigate an issue of importance for which the answer does not yet exist. Protocols must be scientifically sound and likely to yield meaningful conclusions. Good research is therefore ethical, and bad research is unethical.[26]

In June 1966, Henry Beecher published an analysis of "Ethics and Clinical Research."[27] This benchmark article accelerated the movement that brought human experimentation under rigorous federal and institutional control. Although Beecher was not the first to direct attention to abuses in human experimentation, this presentation of 22 examples of investigators who endangered "the health or the life of their subjects" without informing them of the risks or obtaining their permission was a critical element in reshaping the ideas and practices governing human experimentation.[28]

Special issues for informed consent arise when the surgical patient is asked to participate in a *research project*. The time for decision making is usually short, and the principal investigator of the project may also be the one administering care. This raises the issue not only of adequate informed consent but also of the *risk for coercion* of the patient to participate in the study. The surgeon-researcher should abide by basic principles as outlined by the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research and by the Declaration of Helsinki. There are also prevailing federal, institutional, and professional guidelines that govern human and animal research. To be ethical, studies must be well designed and worth the risk to patient and society. The institution's review board should approve the study, and the investigator should take the responsibility to assure adequate informed consent, confidentiality, and appropriate protection of the patient's well-being.[1]

All physicians must ensure that trials involving human subjects are of potentially significant value and are conducted ethically. The Nuremberg Code obligates researchers to prepare descriptions of the probability and magnitude of all physical, psychological, social, and economic risks, and to minimize unnecessary pain and suffering. Consent must be voluntary and without any element of force, coercion, or deceit.[11] When discussing the potential *risks* of a proposed procedure, it is essential for the person seeking consent to quantify minimal, low, or high risk using examples from everyday life. Potential benefits from a research project may apply to the individual, to society, or to both. When discussing the benefits of a proposed study, one must distinguish clearly between *therapeutic* and *nontherapeutic research*. Researchers must clearly differentiate, for the patient, the balance between *potential benefit* to the patient and any *potential risks* associated with the protocol. No matter how great the benefit to society, it would not be ethical to expose a subject to anything greater than minimal risk if there is little direct benefit to the patient.[26]

Consent must never be assumed. Many would question the validity of truly "informed" consent rendered by someone who is acutely ill or severely injured. Especially for research, the principle still holds that for consent to be valid, it must be informed, understood, and voluntarily given. Subjects, or their surrogates, must have enough information, in comprehensible form, to enable them to make a proper judgment as to whether or not to participate in the requested study.

Normally, this requires time for reflection before a decision to enroll. This concept is frequently stressed in the emergency situation. In an emergency, the surgeon may be forced to act in the patient's best interests and to presume consent on the basis of necessity. Clearly, this is only appropriate for interventions that will benefit the patient directly; and actual consent should be obtained as soon as possible afterward. In a research context, the intervention must be part of a protocol approved by an independent institutional committee, such as an IRB, and should present no more than minimal risk to the patient.[26]

Placebo Surgery

As investigators sort out the mechanism for insuring that surgical research is carried out ethically and with true *informed consent*, the issue of the use of *placebo surgery* appears based on recently published trials. Horng and Miller, commenting on these trials in the *New England Journal of Medicine*, state that the issue of using *placebo surgery* in clinical trials appears to violate the fundamental ethical principles of *beneficence* and *nonmaleficence*. Specifically, this means that surgeons should not invade the body except for purposes of cure or amelioration of suffering. In evaluating the studies, they emphasize the fact that clinical research always involves the inherent tension between the ethical values of pursuing science and those of protecting subjects from harm. To be considered ethical, overall, they must present a favorable risk–benefit ratio. The burden is on the investigators to justify *placebo surgery* as a warranted means of evaluating the efficacy of a surgical procedure. They conclude that absolute prohibition of *placebo surgery* is not appropriate, but the standard of justification for its use must be extremely high and rigorously enforced.[29]

Conflict of Interest: Industry and Drug Money

Many colon and rectal surgeons interested in research have difficulty obtaining extramural support for their projects and thus turn to private sources, namely, the biomedical and pharmaceutical industry. Industry support for biomedical research now exceeds the financial support from all federal funding sources. The liaison between academic surgery and industry introduces the possibility of remarkable benefits especially to our patients; however, differences between the fundamental goals of physicians and industry can create serious conflicts. Industry strives to complete clinical trials expeditiously and to publish positive results. Conversely, the primary goal of the surgical investigator is to advance and disseminate knowledge by the unimpeded exchange of ideas, despite secondary professional, financial, institutional, and sociopolitical objectives. Critics maintain that the physician–industry relationship will only serve to potentiate bias, and loss of objectivity will fundamentally poison the way research is conducted. Currently, however, the lifeblood of clinical research is external support requiring a productive relationship with the biomedical industry. This potential conflict of interest can only be resolved by scrupulously implementing the principles of integrity, honesty, respect, and equity. Even the mere appearance of a conflict of interest could jeopardize the investigator's integrity and undermine public trust. Surgeon investigators involved with industry-sponsored research should meticulously divorce themselves from any personal or commercial conflict that could compromise patient loyalty or well-being.[11] Ethical recruitment of patients into research protocols is especially challenging for surgeons who, under the current system of financial remuneration, may receive more money by having the patient participate in a study than he/she would receive for doing the surgical procedure indicated for the patient.

A common challenge involves investigators who receive industry-funded materials, discretionary funds, research equipment, and trips to meetings. They must be aware that subsequent restrictions and expectations can create conflicts of interest. These seemingly innocent economic factors become a conflict anytime they influence study design, interpretation of results, or the timing and method by which results are reported. The personal gain of the investigator such as ownership of stock or receipt of funds for testing drugs or devices can introduce bias and compromise objectivity. On the other hand, it is not inappropriate for an investigator to receive economic rewards from a drug or device that is commensurate with his or her efforts involved in the development of the product. It is also acceptable for investigators to receive consultant and lecture fees from companies whose product they are testing, provided that the remuneration is proportionate with his or her efforts and that it is clearly reported, in advance, of all presentations and is clearly stipulated in any publication. It is unethical, however, to sell or purchase stock or have a direct financial interest in the product under investigation until the relationship between the investigator and the company has been terminated, and the results of the research have been published or made public. Although opponents argue that disclosure cannot heal the financial conflicts of interest, it does recognize public concerns, protect the credibility and reputation of investigators, and alerts readers as they access the published report.[11]

The practice of pharmaceutical companies bestowing gifts on physicians is well documented. These gifts, however, cost money, and this cost is ultimately passed on to our patients without their explicit knowledge. The biomedical industry has clearly made outstanding contributions toward the advancement of modern scientific medicine; however, obvious conflict of interest occurs when physicians accept personal gifts that have no benefit to their patients. Acceptance of individual gifts that do not benefit patients, such as

trips and subsidies for medical educational conferences in which physicians are not speakers, is strongly discouraged. The acceptance of even small gifts has been shown to affect clinical judgment and to heighten the perception (or reality) of a *conflict of interest*. Until specific guidelines are established, commonsense should always prevail: no gifts should be accepted if suspected *strings are attached*.[11]

Confidentiality

General Principles

Surgeons are bound by the same rules of *confidentiality* as other doctors. Especially with the new restrictions and significant penalties imposed by HIPAA, all health-care personnel must be very cognizant of preserving *confidentiality*. In the hectic morass, which is the waiting area of most big hospitals, it is sometimes difficult to take the time to ensure that doctors convey sensitive and private information to patients, families, or surrogates in a full and complete manner and yet ensure the confidentiality of their information. Certain health information can be very significant in the treatment of a patient, including medication history and psychiatric history. Yet, some patients or families might be reluctant to give such information to the treating physician if the situation is not conducive to confidential communication. Similarly, the families and the patient are most certainly due confidentiality of the information, which the physician is going to impart.

A surgeon's duty to maintain confidentiality regarding information disclosed by the patient has been a long-held medical precept. On occasion, however, the ethical duty to prevent harm to others overrides the duty to keep confidences of a given patient. Although the law generally prevents the divulgence of confidential information, it also *mandates certain exceptions*, such as reporting patients with infectious disease and those who are likely to harm others, the latter being elucidated by the famous 1976 Tarasoff case in which nondisclosure of a patient's homicidal thoughts resulted in the death of the threatened person. This case raises a confusing possibility of preventing harm to others becoming a legal not just an ethical duty. This broadens the concept of mandatory reporting to include more than the currently accepted requirements for reporting child, elder, or domestic abuse. Such legal requirements may force us to compromise the ethical norm of respecting our patient's decisions with regard to confidentiality.[2]

Making and Managing a Genetic Diagnosis

As the results of untangling the mystery of the human genome are translated into clinical considerations, the ethical challenges to the colon and rectal surgeon become significant. Although the presumption is that facility and managing genetically predetermined disease is the lot of the primary care physician, in fact, patients with phenotypic presentation of genetic diseases such as colon and rectal cancer depend on surgeons for final diagnosis, administration of surgical treatment, initiation of long-term follow-up, and clarification of the implications of the genetically predetermined cancer for other family members and other generations. Most commonly, we deal with the autosomal dominant mutations, which cause familial polyposis or hereditary nonpolyposis colorectal cancers.

The ethical hazard involves obtaining the results of a genetic test without adequate counseling of the patient to determine what will be done with the results obtained. Clearly, this should all be determined prior to obtaining the information. Many individuals fear that determination of a genetic abnormality will have adverse effect on their insurability and employability. These risks are supposed to be protected by law, but many members of our society are not willing to take that chance. Because of these fears, many patients and their family members refuse to have genetic testing done in the first place. Once the test is done, a patient may insist on absolute confidentiality to prevent dissemination of the information to others, even those at risk, in the family. Think of the dilemma in which this places the surgeon. You may know that 50% of children and siblings of the patient are at risk for potentially fatal yet preventable cancer. Yet, the patient has forbidden you to inform them. This situation can even ethically and legally justify the physician breaching the patient's confidentiality to save the lives of those potentially at risk. There have even been cases in the courts where the treating physician has been held liable for *not* divulging such risks to family members.

Most of these unpleasant situations can be avoided by appropriate genetic counseling *before* any genetic information is obtained. This should ideally involve the use of professional genetics counselors, since most of us surgeons have not been adequately trained in the skills required to obtain and verify such familial and generational information.

Abuse of the Elderly Patients

It is claimed that approximately two million elderly Americans are mistreated each year, with a significant number falling into the definition of *abandonment*. Although this treatment of elders is a problem that has occurred for centuries, only recently has society become significantly concerned. The problem and concern will increase as does the elderly components of our population. Surgeons are ideally suited to play a significant role in the detection, management, and prevention of elder abuse and neglect. The surgeon may be the only person, outside the family, who sees the older adult and is qualified to intervene in a preventive way. This means we should be aware of risk factors and their detection. It requires an astute clinician to detect abuse based on history alone. Even in the face of injuries, such as fractures at

uncommon sites, the elderly patient may continue to conceal the possibility of abuse for fear of embarrassment or abandonment by the abuser. It may well be the surgeon called to see the patient for injury or neglect, who picks up the clues such as evidence of pressure sores, malnutrition, old injuries, or new injuries in unusual locations, such as on the scalp or behind the ears.

The first priority of the physician is to ensure this victim's safety. The surgeon should never hesitate to ask for social service consultation or to report suspicions to the appropriate adult protective services. Such acts are not breaches of confidentiality; they represent implementation of the most sincere duty of the physician.[30]

Futility/Withholding Treatment

General Concepts

Significant, and perhaps inappropriate, concern continues to exist in medicine with regard to the difference between *withholding* and *withdrawing* medical treatment. This has become more of an issue as the potential for resuscitating critically ill patients has become a progressive reality. Depending on the clinical situation, surgeons and other physicians attribute higher legal risk of one procedure over another. Apparently because of this fear of legal retribution, or ridicule and condemnation by professional peers, employing full, almost ritualistic, resuscitation has become the default position of those delivering critical care in cases where no advanced directive exists. In fact, no physician has ever been successfully prosecuted for withholding or withdrawing of medical care from any dying patient in the legal history of USA. This leaves one wondering what actually fuels the fears of legal retribution for making the wrong decision.[31]

The dilemma could of course be alleviated by early meaningful discussion with patients, families, and surrogates with regard to care *options at the end of life* and honest estimates of *prognosis*. Studies have shown, however, that many physicians and surgeons fail to take these opportunities. A disturbing example of this inadequacy can be found in the 1995 Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment (SUPPORT). This expensive, multi-institutional study demonstrated the physicians' *failure to meet all outcome markers*: failure to include patient and family in pivotal care discussions, failure to provide realistic estimates of outcomes valued by patients, failure to treat pain adequately, and failure to prevent prolonged death in patients with extremely poor prognoses.[31]

Sometimes confusion is created over the venue in which surgical or medical care is delivered. In the usual setting, a decision to *withhold* further medical treatment is done quietly, often without input from the patient or the surrogate decision maker; whereas *withdrawal* of ongoing medical treatment can be more obvious and difficult. Some clinicians and ethicists feel that the *withholding* of medical treatment is more problematic than later *withdrawal* of unwanted or useless interventions. This discrepancy in the urgent situation probably exists because the physicians involved usually lack the vital information about their patients' identities, medical conditions, and expressed wishes. In addition, perhaps because of frequent, but inaccurate, representations on television, society has come to expect only spectacular results in the delivery of surgical care in USA. This concept is in marked contrast to the attitude that those clinicians who *withdrew treatment* (an act leading to death) were more culpable than those who *withheld treatment* (an omission leading to death). This distinction between acts and omissions is now thought to be more of a difference in psychological preference than an ethical norm.[32] For all of these reasons, despite the fact that the law has clearly spoken, the distinction between *withdrawal* and *withholding* of medical treatment will continue to be a challenge.

The surgeon's decision to limit or withhold treatment can be based either on the patient's refusal or on the physician's determination that the treatment would not be of benefit. Although the patient has the ethical and legal right to forego treatment, the physician must be very careful about withholding a treatment that might be beneficial. Such issues are usually intensified by the need for rapid intervention versus the desire to verify the meaning of the patient's current or preexisting desires. The classic example is the patient who is unresponsive, has reversible pulmonary or cardiac disease, and needs cardiopulmonary resuscitation, but is said to have a preexisting DNR (do not resuscitate) order.

Withholding treatment because of a judgment of *futility* is even more of an ethical challenge. *Futility* has been defined as "any effort to achieve a result as *possible*, but that reasoning or experience suggests is *highly improbable*, and cannot be systematically produced." Physicians, as moral agents, should exercise professional judgment in assessing patient's requests. If the request goes beyond well-established criteria of reasonableness, the surgeon ought not feel obliged to provide it. Some ethicists believe that the appropriate *allocation of resources* is another important consideration when one is making decisions regarding invasive, costly, or lengthy procedures. John Lantos even stated that, "given limited resources, it is ethically justifiable to limit access to treatments that are expensive and offer minimal benefit… decisions by doctors to curtail use of those treatments are socially responsible."[33] *Futility* is such a complicated word that it may be of little use in most situations. The classic challenge is the decision not to start resuscitation when a patient with extensive metastatic cancer and cachexia presents in cardiac arrest. The initial emotional inclination is to treat the patient, even if the medical situation, as emphasized by Siegler,[13] leads to a judgment that such a resuscitation will not be beneficial. This requires the difficult objective determination of *ineffectiveness,* rather than any subjective decision based on the worth of the intervention or on the

value of the patient's continued life.[2] It should be noted that assertions of *futility* come about in two contradictory situations. One is where the patient or surrogate wants the doctor to refrain from a further treatment, which the doctor thinks is not futile, and the other is where the doctor wishes to refrain from treatment which he or she believes to be futile. The only measure of what should be done is the standard of care in a given region for similar cases. Dealing with this concept of *futility* or other *end-of-life* concerns is usually a problem only when disagreement arises among the patient, the family, and the health-care team.

Many ethicists agree that physicians are under no obligation to render treatments that they ascertain to be of little or no benefit to the patient. Many, however, believe that it would be advantageous to abandon the word "futility" and to use instead the construct of "clinically nonbeneficial interventions." We all know that one of the greatest fears of both patients and families is their *abandonment* by the health-care team. It is easy to fall into this trap by declaring that further treatment for a given patient is *futile*. When it is decided that certain interventions should be appropriately withheld, special efforts should be made to maintain effective communication, comfort, support, and counseling for the patient, family, and friends. Although we, as surgeons, may not always proceed with potential technologically advanced nonbeneficial interventions, we always must continue to *care* for the patient and the family.[34]

DNR and the Need for Surgery

There is, and should be, confusion regarding operating on a patient with existing "do not resuscitate" orders. Since there is no universal agreement as to how this situation is to be handled, each surgeon must be aware of specific institutional guidelines. First of all, it is not at all unusual for surgery to be indicated for patients where *cure* is no longer the goal of treatment. Even patients with advanced cancer or severe medical conditions will be offered surgical relief of acute intestinal obstruction or an abscess causing sepsis and pain. The problem usually gets defined when administering anesthesia becomes a consideration because it can be accurately stated that the act of anesthesia is *ongoing resuscitation*. As amazing as it seems, most hospitals have a policy, which allows suspension of the DNR order during the procedure and administration of anesthesia, only to have it resume when the surgery and required anesthesia have been concluded.

Withdrawal of Treatment

General Principles

Taking into account the preceding discussion, an important line of reasoning for the moral and legal equivalents for the two actions of *withholding* or *withdrawing* is the important

concept that if a medical intervention will not result in the desired or beneficial results intended for the patient, it makes no difference whether the clinician withholds the intervention before beginning it or discontinues its use after it has been started and found to be not effective.[32]

Special moral issues may arise in the care of *terminally ill patients*. We must be willing to respect a terminally ill patient's wish to forego life-prolonging treatment, as expressed in a living will or through a health-care surrogate appointed via a durable power of attorney for health care. Those of us caring for patients should be willing to honor "do not resuscitate" orders appropriately executed on behalf of terminally ill patients. We should also understand the established criteria for the *determination of death* and should be prepared to assist families in decisions regarding the donation of the patient's organs for transplantation. This involves knowing the specific regulations in our own states and in our own specific institutions, especially the criteria for death and the mechanisms for initiating the conversation relative to organ donation. It is usually not the surgeon, nor any member of the treating team, who first raises the issue with family regarding donation of the dying patient's organs for the purpose of transplantation.

Euthanasia/Physician-Assisted Suicide/Terminal Sedation

The terminology of activities related to the end of life is confusing to the public, has been misused in the press relative to the notorious activities of individuals such as Dr. Kevorkian, and, in fact, is probably not clearly differentiated by many surgeons. The terms all have separate meanings and implications, requiring us to understand them and not use them interchangeably.

First is *euthanasia*, which literally means "good death." Its consideration arises when patients or surrogates claim that the quality of life is so diminished, the pain and suffering is so unbearable, or they have become such a burden on others that they request their physicians to *cause* their deaths quickly and painlessly. Specifically, this implies "mercy killing" of an individual, by a physician, to relieve pain and suffering. Such terms as "voluntary," "nonvoluntary," and "involuntary" have been applied in an attempt to clarify the various ramifications of this process, but, in fact, *euthanasia* is the act of killing by a physician and is *not legal* anywhere in USA.[13]

Physician-assisted suicide, on the other hand, implies a death that a competent person, with decision-making capacity, chooses and *causes* by self-administration of drugs that a physician has prescribed but *did not administer*. Advocates feel that prescription of drugs that a patient can take at will removes the physician from direct participation. The decision and the act of ending life remain in the patient's control. This invokes the important fallback concept for physicians

and nurses who deal with patients who are suffering, in an irreversible medical condition, and near the end of life: the distinction between "killing and allowing to die." This distinction is invoked during the process of *terminal sedation* as well as for participation in *physician-assisted suicide*. Currently, the latter is legal only in the states of Oregon, Washington, and Montana.[13]

Terminal sedation, another frequently misunderstood term, is the practice of sedating a patient to unconsciousness to relieve the horrible symptoms, which may occur during the process of dying, including pain, shortness of breath, suffocation, seizures, and delirium. As the sedating medication is administered, other life-sustaining treatments are withdrawn, including ventilatory support, dialysis, artificial nutrition, and hydration. It is critically important to understand that in this frequently employed process, *no lethal doses of opiates or muscle relaxants are administered*. Thus, the intent of the act is to relieve suffering and symptoms by making people unconscious and unable to eat or drink, so that they will die within a short period of time. As in *euthanasia*, *terminal sedation* directly intends the death of the patient.[13] The difference is that, in the latter, the sedating medication is not the agent of death. This differentiation is of utmost importance to avoid the feeling of killing by *double effect* (which will be explained in more detail later) on the part of the health-care team. It invokes the concept of "letting nature take its course" as opposed to the homicidal act of "killing." Cynics claim they are the same, and those of us who claim otherwise are not being honest with ourselves.

Applying the Principles

In order to comply with the principle of *autonomy*, when a competent patient requests, or demands, the withdrawal of further treatment, the treating physician is in a situation analogous to that of the patient who initially refuses treatment. *Autonomy governs*! The surgeon should ensure that the patient is given all the information necessary to allow proper informed consent regarding withdrawal of treatment, but once that is done, it is the ethical duty of the surgeon to withdraw the specified treatment. This is true no matter what the patient requests, whether it be withdrawal of feeding tubes, ventilators, or nutrition and hydration. As long as the patient is fully aware of the consequences, both short term and long term, his or her stated wishes should be respected and acted upon appropriately by the health-care team.

The same principle should be invoked if the patient is not able to understand but has provided, in an advanced directive, an indicated desire with respect to withdrawal of treatment under specified circumstances. It is still the duty of the physician to withdraw the specific treatment because the patient has, in the advance directive, given prior informed consent. The duty of the physician is identical if a designated surrogate requests or demands the withdrawal of treatment.

This is the patient speaking through the surrogate, and once again, autonomy governs.

When the surgeon determines that withdrawal of treatment is appropriate and further treatment would be ineffective, consent of the family or surrogate should be sought. In this situation, it is very important and helpful to know what if any *surrogacy laws* exist. These do vary from state to state, and the surgeons faced with potential decision making should know in advance the laws of their state. In states where such laws exist, they can be very helpful in delineating the hierarchy of surrogate designation. In the absence of advanced directives, surgeons have the responsibility to judge what they believe the patient would want, or what is in the best interest of the patient. If no family is available, close friends of the patient may be asked to give their opinions about what the patient would want.

Courts have upheld the principles of *autonomy* and *self-determination*, affirming the right to refuse life-sustaining treatment. The classic illustrations of this include the 1976 ruling by the New Jersey Supreme Court that Karen Ann Quinlan, a woman in a persistent vegetative state, had the right to decide to be removed from a respirator and that this right could be asserted, on her behalf, by her family. This right was extended to include the withdrawal of nutrition by the 1990 Cruzan case in which the US Supreme Court ruled that a life-sustaining feeding tube could be removed from another young woman in a persistent vegetative state.[18]

Should the surgeon have moral or religious beliefs that would preclude her from *withdrawing* treatment, she should remove herself from the case. It is important to recognize this possibility of need for withdrawing treatment at the beginning of the clinical encounter because a physician with such beliefs should extricate herself from the case at the earliest possible stage. As the clinical course evolves, and as the surgeon develops a relationship with the family and the patient, it becomes progressively more difficult for him or her to remove himself or herself from the treatment team.

Palliative Care / Hospice

General Principles

Focusing on making the last months, not minutes, of life meaningful is especially appropriate where death has a significant predictability. Chronic progressive diseases such as cancer, congestive heart failure, and chronic obstructive pulmonary disease account for 50–70% of deaths, compared with the sudden death attributed to stroke, heart attack, trauma, and suicide. In USA, patients' perceptions of human finitude lead them to deny death and to rely on medical achievements that they think will let them live forever. Physicians grapple with their technological power, the imperative to tell the truth about fatal conditions, and despair at denying hope and the promise of cure for their trusting patients. It is probably

this mutual self-deception that becomes the central issue in rendering appropriate end-of-life care. It is the management of these intense psychological and spiritual challenges facing terminally ill patients that has come to form the basis of what is called *palliative care*.[31]

A brief definition of *palliative care* is as follows: the act of *total* care of patients whose disease is not responsive to *curative* treatment. Although *palliative care* has been a major focus in Europe for the past 20 years, interest in USA only became significant in the late 1990s with an Institute of Medicine report that evaluated end-of-life care. It revealed significant deficiencies in how we manage end-of-life care. These deficiencies include the management of pain and other symptoms, including nausea and vomiting, dyspnea, depression, and anxiety. Geoffrey Dunn explains that "palliative care is not a concept defined in terms of the amount of time remaining in a patient's life or the terminal nature of his disease. It is defined in terms of the type of need that is being met by the care."[35]

The concept of *palliative surgery* refers to surgery for which the major intent is alleviation of symptoms and improving quality of life, *not necessarily cure*. As the age of our surgical patients increases, we will be progressively involved in performing operations whose desired outcomes are not met. Managing these patients through the entire course of their disease, including death, is an important part of being a good physician and a good surgeon. Surgical emergencies are often the first encounter with older patients, and they often have multiple comorbidities. An example is the 80-year-old person who presents with an acute abdomen. The risk of surgery will be high, the prognosis may be poor, and cure may be impossible. Perhaps, offering surgical treatment would even be inappropriate. Thus we, as surgeons, are immediately thrust into contemplating *palliative care* for the surgical patient, and it becomes clear that surgeons need to be aware of the concepts involved in delivering such care.[35]

Pain Relief and the Doctrine of "Double Effect"

Confusing Principles

When it comes to adequacy of pain control, especially for patients near the end of life, physicians and surgeons have been caught in a complicated dilemma. On the one hand, most of us entered medicine to relieve suffering. On the other hand, we know that administration of excessive doses of pain medication can suppress respiration and run the risk of contributing to the death of patients already near the end of life. At the same time that we are criticized for not giving enough pain medication to our suffering patients, we are also challenged by the law for prescribing medication with the *double effect* of potentially *hastening death*. This doctrine of *double effect* is intended by the courts to recognize the

difference between provision of adequate pain treatment that *unintentionally* hastens death and the ordering of medication that *intentionally* causes a patient's death. This concept of *intent* is confusing not only for the courts but also for the physician who is ordering the pain medication.

Double Effect

The application of the principle of *double effect* is controversial because it places significant weight on physician *intent*, which is impossible to prove, and no weight on a patient's right to self-determination. This seems to contradict a paramount principle of American bioethics: *patient autonomy*. Why, when death is on the line, should concern over the physician's *intention* take precedent over the *patient's informed consent*? The physician's fear over misinterpretation of his or her actions often leads to inadequate use of pain medication, leaving patients unjustifiably suffering. It is clearly recognized that opioids should be considered early in the care of the dying patients and in dosages that often exceed the standard range. These analgesics are not only effective in reducing painful sensation but also have an effect in adjusting the sense of well-being, thereby improving the patient's ability to cope with pain. Adjustment of dosage can be aided by using one of the known *pain scales* or by observing patients' objective signs of distress, especially useful in the noncommunicative patient. Despite its significant effect on several components of respiration, respiratory arrest from opioids, in the absence of other central nervous system depressants, is rare. In caring for dying patients, surgeons must acknowledge that they are one part of the often-fragmented medical team. They must accept the goal of providing care where they can, comfort always, consult when necessary, and coordination of the remaining end-of-life issues.[31]

Hastening Death: The "Code"

Since the overwhelming admonition to the physician is "above all do no harm," society has implored the surgeon, in life-threatening situations, to waive informed consent requirements and to act presumptively to save life or limb in situations where the usual consent is impossible to obtain. This leads to our current default in dealing with the critically ill or moribund unknown patient: resuscitating with "a full code" and asking questions later. This practice is probably acceptable as long as the surgeon realizes that *withdrawing life support* is just as acceptable as *withholding life support* initially. The initial full resuscitation may make it possible to assess the patient's end-of-life desires more fully and carefully. If the initial intervention is unsuccessful or is inconsistent with the patient's preference, it can and should be withdrawn, consistent with the patient's identified goals.

What are ethically frowned upon are such deceitful practices as the "slow code," a charade consisting of a halfhearted resuscitation that seems to allow the surgeon to take the moral

middle ground by giving the family a false impression of respecting patient autonomy, while knowing full well that the act will not be effective. Experience suggests that this hedge is used fairly commonly. Although no ill is usually intended, the slow code is usually an indication that the surgeon has not realistically communicated with the patient and family to express the medical opinion that resuscitation, in the face of cardiac or respiratory arrest, would be inappropriate.[31]

The concept of "no code" should be clear and is usually instituted at the request of the patient, his advance directive, or an appropriate surrogate. It is ethically inappropriate for the physician to disrespect the patient's autonomous decision even when faced with despairing surrogates requesting interventions over a clear directive to the contrary. The patient with decision-making capacity is, of course, free to change any prior stipulation, even those written in an advance directive. In the absence of any directive, including a decisional patient, the physician must employ *best interest standard*, which requires implementing what a *reasonable patient* would want done in a similar situation.

In order to understand these previously discussed concepts, the surgeon must realize the implications of the three means of accelerating death for patients in USA: *double effect*, *voluntary euthanasia*, and *physician-assisted suicide*. The *rule of double effect*, as previously described, involves the dichotomy of treatment versus side effects, where death is the *unintended* side effect of adequate symptom control. *Voluntary euthanasia*, which is requested by the patient, can be either active or passive. *Passive euthanasia* is the result of withdrawing or withholding life support in situations judged to be medically futile. In USA, this is both ethically and legally acceptable. On the contrary, *active euthanasia* occurs when the physician *intentionally* administers an agent to cause a patient's death. This act is considered *unethical* and *illegal* everywhere in the world except in the Netherlands where it is practiced openly. *Physician-assisted suicide* occurs when a physician supplies a death-causing agent to a patient with the knowledge that the patient intends to use this agent to commit suicide.

In multiple decisions, the courts have emphasized the importance of distinction between "letting a patient die and making that patient die."[18] This, in our opinion, is the most distressing conflict for the physician who must make such decisions. We know full well that when we give high dose opioids or withdraw ventilatory support, we may be hastening the patient's death. The callous ones among us see this as euthanasia and strongly criticize those who claim otherwise. When confronted with this challenge, in a personal communication, Dr. Edmund Pellegrino, one of our most respected medical ethicists, immediately responded with his comforting interpretation of such a situation. In his mind, and in his conscience, he recognizes and acts upon the difference between actively and intentionally hastening a patient's death as opposed to relieving pain and suffering or withdrawing artificial life support, thus "letting nature take its course."

Determination of Death

The attending physician has the discretion and the responsibility to determine death. Statutes in different states use different criteria for death. In some cases, they have not caught up with the science available. Some states use the "irreversible cessation of cardiopulmonary function" criteria, as do some religions. The complete cessation of respiration and circulation constitute "death" under this definition. The concept of *intensive care* has advanced dramatically since these statutes were enacted and have superseded this now antiquated definition. In most states where this is the statutory definition, the courts have now ruled that "brain death" suffices.

Most states use the brain death criteria. There is debate currently about whether the "whole brain" definition of death is no longer valid; and that the appropriate ethical standard for definition of death is cessation of "higher brain" function. Higher brain function includes the cognitive functions or the capacity for consciousness. Once there is irreversible cessation of that capability, a judgment usually made in consultation with a neurologist, then death can be declared. Most neurologists are trained to determine whether death has occurred or whether the patient is in a "permanent vegetative state."

It should be noted that in some states the definition of death includes *either* the *cessation of cardiopulmonary function or irreversible cessation of all brain function*, including the brain stem.

The health-care team, however, should realize that no matter which criterion is being used, it may be appropriate to continue cardiovascular support for the purpose of maintaining perfusion during the eminent birth of a fetus, or to sustain viability of transplantable organs.

Organ Donation

Criteria for organ donation are not always clearly understood. Many patients and families are mistakenly concerned about having death declared prematurely just to facilitate the harvesting of organs for transplantation. Here, the surgeon's bioethical responsibilities are clear. The medical ethical principle of *patient autonomy* dictates that the desires of the patient and the family be respected.

Federal law requires most hospitals to make an inquiry of all patients, during their admission, for any procedure, whether emergency or elective, about their wishes to be a potential *organ donor*. While this can be somewhat of a shock to patients who are coming in for elective surgery, especially a minor procedure, it obviates the need for physicians to make the painful inquiry when a patient is actually facing eminent death. If the admitting personnel ask for this information on a routine basis, the patient is more likely to

render a competent decision, and the potential problems of dealing with surrogates, sometimes under difficult circumstances, are alleviated.

However it is obtained, *informed consent* of the *donor* is required. Most states provide organ donor options on driver's licenses, and many people possess other documents such as donor cards, which indicate their desire to become organ donors. In some cases, donors request limits on the organs they wish to donate. For example, some donors have indicated that they do not wish to donate their eyes or some other specific organ. Even though patient autonomy should guide the physician, there are circumstances where the family emphatically wishes to override the clearly stated intention of the donor. These situations are difficult, and while the surgeon's clear ethical duty is to respect the wishes of the donor, the body of the donor, after death, belongs to the family. The treating physician would be well advised to leave the resolution of this situation up to the transplant coordinator. In fact, it is usually inappropriate for anyone on the treating team to initiate the discussion of organ donation. Most hospitals have in place a procedure whereby the discussion of potential organ donation is initiated by a person specifically trained for this purpose. It is often the transplant coordinator, a social worker, or a hospital chaplain.

Insisting on compliance with the donor's clearly stated wishes, in the face of strong family opposition, does not affect the legal position of the surgeon; but it can result in unfortunate lawsuits because of the animosity created with the family. In cases where there are no previously expressed wishes by the potential donor, the family, as custodians of the body, may agree to organ donation. The duty of the physician in this case is to obtain the consent of the family *before* doing anything to preserve the functioning of the organs for potential transplantation.

In cases where there is no surrogate or family, or any evidence of previously stated intention to donate, the ethical position of the doctor is less clear, but absent permission to do something to the body in a situation which is no longer an emergency, assuming that the organs should be harvested for transplantation, would seriously violate the concept of informed consent. While it can be argued the dead person cannot give informed consent, the family whose property the body is, would have to give their consent to have any procedure done at all to the newly dead person. In cases with no directives at all, the best course of action, unfortunately, is to do nothing postmortem.

Ethics/Legal Consultation

Most surgeons work within an institution. Most of these institutions provide a mechanism for obtaining help in sorting out challenging ethical dilemmas. This help usually comes in the form of consultation from the hospital

Ethics Committee or from in-house *legal consultation*. It is critical to realize that utilization of such resources does not commit the surgeon to accepting an arbitrary decision of what is right and what is wrong in a complicated ethical situation. Consultation is meant to provide a process for most expeditiously sorting out the issues which have arisen and for providing rapid access to the potential mechanisms for solving the problem. Hospital ethics committees are specifically charged to advise physicians, patients, and families who face ethical dilemmas. These situations usually arise when there is *disagreement* among these groups and the health-care team. Consultation from the ethics committee is usually rapidly facilitated through such agencies as the hospital nursing service. Consultation should be available, instantly, 24 h a day. Frequently, it is the hospital chaplain who facilitates the consultation. By bringing in appropriate resources and facilitating meeting with the health-care team, patients, and families, consultation with the ethics committee should help resolve even the most complicated medical ethical challenges. The hospital ethics committee should be charged with what is the right thing to do for the patient. It should have no vested interest in protecting the institution at the risk of embarking on an action, which is ethically unsettled for the good of the patient.

A word of caution, however, is necessary for surgeons working within a given institution. Once *legal counsel* or *risk management* is brought in to deal with a complicated situation, it must be remembered that *they work for the institution.* Their job is to protect the institution, and the advice that they give will be aimed toward that end. This commitment to the institution is important for the physician to realize if there is potential for placing oneself in personal jeopardy. It is also important to realize that legal standards are not always reliable guides to determining what the best ethical and medical decisions are.

Good Samaritan

A Case

The most skilled colon and rectal surgeon in town is out to dinner. At the next table, he sees the local crime boss choking to death over a piece of prime beef. What are the ethical and legal considerations he must consider before performing an emergency tracheotomy? What is he ethically obligated to do? Is the old medical oath binding? Can anyone give consent? Must he identify himself? If he performs the procedure and there is a bad outcome, is it malpractice? What if he is a medical student instead of a famous surgeon? Is a bad outcome here considered battery? What should the surgeon do when the EMT arrives and wants to take the dying crime boss to a known inferior local hospital? What are the obligations and risks for the surgeon?

General Concepts

Good Samaritan acts or deeds are defined as those in which aid is rendered to a person in need, where no fiduciary or legal obligation exists to provide such aid, and neither reward nor remuneration for the aid is anticipated. The aid provided can include a survey of the situation, protection of the victim, notification of other care providers, or personal provision of immediate treatment. The Good Samaritan Ethic is one that is generally endorsed by our culture, which strongly supports assisting an individual who is in danger or in need of help. Surgeons may be regarded as having a greater responsibility to provide Good Samaritan aid than a layperson by reason of the special training and knowledge and commitment to duty for the benefit of individuals and society, which generally drive us to become physicians and surgeons. Clearly, in a situation of sudden medical need, a surgeon will be better able to assess the medical condition of the victim and to render immediate treatment if indicated and feasible. Many feel that the mere status of being a physician entails the duty to use one's skills and knowledge in cases of sudden or emergency need; for some, this duty is an inherent feature of the role and even of the definition of a physician.[38]

Briefly stated, in almost every state, an off-duty surgeon who comes across a person with an emergency medical condition has no *legal duty* to come to the aid of that person. However, a physician's *ethical obligation* inspires him to help in such an emergency. All states in USA have enacted the so-called Good Samaritan statutes, which protect the physician from liability incurred for good-faith efforts to help at the scene of an accident or emergency. The ethical duty should far exceed the legal excuse for inaction.[2]

Generally, Good Samaritan acts include the following principles: (1) There is no legal obligation of doctors to answer or treat emergencies. (2) If the doctor chooses to intervene, the expected standard of care is modified by circumstances of the situation. (3) If aid is given, it needs to be stabilization only and not definitive treatment. (4) Implied consent exists to treat the victim if he or she lacks the capacity to consent. (5) These criteria apply whether or not the physician is paid for his or her services rendered. Despite the establishment of these principles, the extensive coverage in the media of spectacular medical malpractice suits causes many surgeons to develop a strong aversion to the performance of Good Samaritan acts. In order to alleviate this apprehension, Good Samaritan Laws were enacted, the first in California in 1959. Since then, every state has enacted such law. The laws all share the following provisions: there is no legal obligation to provide aid; there is immunity from malpractice suit if aid is provided; there is exception from immunity for gross negligence or lack of "good-faith"; acts are restricted to application outside of hospitals; and there is withdrawal of legal immunity if the doctor accepted payment for aid rendered.[38]

Professionalism and Interpersonal Relations: Working as a Team

General Considerations

There is an ever-increasing challenge to deliver the very best surgical care in the current medical environment which thrives on its speed and frequently impersonal delivery of generic medical care, often at multiple institutions, and without one consistent team of support. Often it becomes difficult to fulfill the responsibility requiring communication, collaboration, respect, and confidentiality as we interact with the components of our health-care team which frequently includes nurses, enterostomal therapists, primary care physicians, consulting physicians, surgical and medical trainees, and the vast array of ancillary services required within our institutions.

Teaching Residents and Fellows

Learning and teaching are critical components in our career choice of medicine, and especially, surgery. At some point in our training, a more senior person turns over to each of us the responsibility to perform the major part of an operative procedure. And then, the converse occurs: each of us, in turn, relinquishes the major part of an operation to one of our trainees. We know how the process works and the importance of a surgical team with "graded" responsibility. The ethical challenge arises when, often the night before surgery, the patient asks "who is going to do my surgery?"[39] The honest answer becomes blurred, especially for those colon and rectal surgeons working in a program with trainees who are senior residents or fellows. We usually fall back on the explanation that we, the attending surgeon will be present and responsible, even when we know that the trainee will be doing the critical part of the procedure. What is the truth? The fellow claims on the training record that he or she did the case, and we charge the payer as if we did the procedure. What is true *informed consent* in such situations?

Previous Suboptimal Care

General Concepts

As colon and rectal surgeons, we are specialists, frequently seeing patients as requested consultation by and referral from other physicians and even other surgeons. It makes the nature of our care, often, "the end of the road." We have no place else to send the patients and frequently find ourselves in the position of correcting or undoing the poor results of the action of another surgeon. This becomes an ethical

and personal challenge, especially when the patient or the family asks "Why wasn't that done by the other surgeon, or what did she do wrong?" We can easily become caught up in the dilemma between taking credit for heroic restoration of health and condemnation of the other surgeon, or covering up for incompetent care in an attempt to avoid litigation against another doctor and/or preserving a lucrative source of referrals.

Generally, our surgical and specialty training does not prepare us for the ethical differentiation between "bailing out" and "condemning," responding to patients' pointed questions, communicating with the doctor responsible for the suboptimal care, and certainly not "blowing the whistle" on another surgeon and going to court, when requested, as an "expert witness." Albert Wu suggests that a surgeon who discovers a major error made by another physician has several options, which include the following: waiting for the other doctor to disclose the mistake, advising the other physician to disclose the error, arranging a joint meeting to discuss the mistake, or telling the patient directly. He and his coauthors believe that based on the requirements of the doctor–patient relationship, surgeons have an obligation to facilitate disclosure. Many surgeons are reluctant to say anything because they are not 100% sure of what actually happened, they fear hurting the feelings of colleagues, they wish not to strain professional relationships, or because of the terrifying thought that "there but for the grace of God go I." Wu further suggests that we fulfill our obligation to our patient by advising the doctor who erred to inform the patient; but he goes on to say that if that fails, it is our duty to tell the patient what happened.[40] Each of us must then rely on compassion and tact to tell our patients the truth without unduly condemning the other physicians. We surgeons need to realize that what we take for granted in our weekly *morbidity and mortality* conferences, especially in a teaching hospital, is not the norm for other branches of medicine. We know, and perhaps are obligated to pass on to others, that admitting a mistake may help us to accept responsibility for it and may help to make changes in our practice. Physicians should be able to learn vicariously from mistakes made by others and thus avoid making the same mistake themselves.[40]

"Blowing the Whistle" and Going to Court

The next echelon of concern and potential activity, of course, involves serving as an "expert witness" in medical malpractice litigation. Again, this is an arena of involvement in the medical-care system for which we surgeons are generally ill prepared. Just recently, the American College of Surgeons and the American Society of Colon and Rectal Surgeons has issued some guidelines in an attempt to insure that surgical specialists not abuse the system by offering false testimony or

by presenting as "experts" in areas beyond their expertise. Many of our true experts refuse to serve in this capacity when it involves saying something against another surgeon; yet, when any of *us* are involved as the accused, we want only the finest experts available and are repulsed when "hired guns" with little knowledge boldly testify against us. The problem seems to be that many of us do not differentiate *malpractice* with severe damage to a patient from the poor results from proper treatment, which we surgeons all experience in dealing with the complex biological system of the human body. Again, the principle of not stepping up to the plate for fear of the dictum, "There but for the grace of God go I." We should understand that credibility in the medical-legal system should be based on true expertise and on telling the truth, be it for the plaintiff or for the defense of our colleagues, and, in fact, we can be of much greater help to inappropriately accused physicians by establishing such a record of credibility.

Managed Care

All of us, in the current system, participate in some form of managed care, where someone other than the treating physician becomes involved in the mechanism of delivering care to our patients, usually without sharing in the responsibility of rendering the care and the untoward outcome that may be engendered by that care. This presents a true dichotomy for doctors, most of whom have taken an oath or by law are committed to being *advocates* for our patients. It seems an impossible, and perhaps unethical, task to make a decision, which favors the economic advantage of a managed care organization over what we know, medically, is required by an individual patient in need.

Rationing Care/Cutting Corners

Surgeons have a special obligation to deal with these systems because of the loneliness of making the decision and ultimately doing a surgical procedure on another human being. It is a desperate feeling to realize, in the middle of an operation, that our quest for perfection has been compromised by some inadequacy in preoperative management foisted on us by another remote physician hired by a managed care organization to protect the financial interests of a group. We know, as well as others, that medicine, as a system, is in trouble, but the problem is rarely to be solved by rationing or withholding what we know is surgically best for our individual patients. Perhaps it is our job to invoke our "surgical personalities" to become the strongest of all patient advocates and to fully participate in achieving needed improvements in the overall system. We must communicate to others the special understanding and compassion few outside of the field of surgery understand.

Personal Challenges: Competition of Interests

Professionalism

McKneally describes the profession of medicine and surgery as a vocation that requires extensive knowledge and skill. It also requires a high level of discretion and trustworthiness, even in individual practice. The social contract between the profession and the public holds professionals to very high standards of competence and moral responsibility. He goes on to explain that a profession is literally a declaration of a way of life "in which expert knowledge is used not primarily for personal gain, but for the benefit of those who need that knowledge."[19] In our current society, bombarded by endless advertising and hype, many groups call themselves "professionals" sometimes to the point of humor, but for those of us in medicine, and especially surgery, the definition means that when confronted with a choice of what is good for us or what is good for our patient, we choose the latter. This occurs and is expected sometimes to the detriment of our own good and that of our families. Tom Krizek even goes so far as to question if surgery is an "impairing profession."[41] Perhaps it really is an *ethical* concern, which is encouraging us to modify the working hours and conditions for our trainees to offer more of an incentive to enter the surgical specialties. Now that we have appropriately tended to the training programs, it behooves us to explore the same lifestyle improvements for ourselves. It is neither an ethical breach nor a sign of weakness to allocate high priority to our families and to our own well-being.

Family

As financial and professional pressures become more intense, the challenge increases to appropriately prioritize and balance the demands of patient care, family, education, teaching, and research. Mary McGrath presents an all-too-frequent dilemma for the surgeon: choosing between attending a child's graduation or operating on an old patient who requests you instead of your extremely well-trained associate who is currently seeing the patient. How many times have we not chosen wisely? Someone else can competently care for your patient, but only you can be a parent to your child.[19] Time literally flies, and we must often remind ourselves that our lives are not just a "dress rehearsal"!

Among the many considerations of *family* is the issue of caring for, and perhaps even operating on our own family members. What is not only ethical but also what is appropriate for the practice of medicine and surgery with regard to this issue is not as clear as you might, at first, believe. For example, if your spouse cuts her leg while skiing and the only available physician is a psychiatrist who is covering the ER, should you, a trained training surgeon, suture her laceration? On the contrary, if you feel that you are the most experienced colon and rectal surgeon in the community, what should you do when your own mother is found to have a complicated cancer of the low rectum? After all, if you are the "best" why would you deny the best care to your own mother? Many hospitals have dealt with this issue and have a stated policy. The AMA has issued a statement on "Self-Treatment or Treatment of Immediate Family Members." In essence, it speaks against treating family except in emergent situations and for short periods of time. It is, of course, based on the risk of compromise of professional objectivity and influence on medical judgment because of the influence of personal feelings, thus interfering with the care that needs to be delivered.[42]

Competence/Impairment/Insight

Surgical certifying organizations are currently struggling with the definition and determination of *surgical competence*. McKneally stresses that a patient's trust is based on the surgeon's diligent pursuit of competence in both judgment and technical skill. Surgical training programs have diligently attempted to guarantee the competency of individuals completing the process. The board certification process attempts to ensure that the interests of society are represented in these professional processes. Thus, competency is an integral part of the *entry-level*. The problem arises in maintaining a level of competence and assuring that established surgeons who take on new procedures both acquire and maintain competence in these new skills.[15] Perhaps the most obvious recent example for us colon and rectal surgeons has been the advent of laparoscopic, minimally invasive surgical procedures. Now that they are part of all Fellowship training programs, it is less of a problem. But the issue will arise again with the next new wave of technology: how to teach old surgeons new skills.

Related to competence is the issue of *impairment*. Jones emphasizes that drug and alcohol abuse, with the associated functional impairments, are the leading cause of sanction against physicians by professional oversight bodies in USA. More than one in every seven physicians is affected by substance abuse at some time in their careers. He goes on to explain that the surgical patient is potentially at greatest risk in the care of a cognitively or physiologically impaired physician because the surgeon's competence requires simultaneous application of fine neuromuscular, cognitive, and intellectual skills. This is coupled with the emotional composure and critical judgment required to make urgent decisions and the physical endurance of standing for long hours at the operating table. He cites Percival's admonition that the medical profession is a "public trust" that should be relinquished when a physician or surgeon no longer possesses the skills that are essential for clinical care. Unfortunately, most surgeons do not possess or exercise the insight required to know when we are impaired or when it is time to retire.

Jones goes on to quote Verghese's observation on the impaired physician: "the doctors had one common feature – namely, exquisite denial – that allowed them to believe they could still care for patients perfectly well."[43] These observations place great responsibility on those of us who observe *impairment* or *incompetence* in our colleagues who at times may also be close friends. We should never hesitate to request intervention because correction of substance abuse in physicians is highly successful. If we stand by and allow patients to be mismanaged by inadequate physicians, we will not only see the patients suffer but will also allow our colleagues and friends to be destroyed professionally and perhaps devastated emotionally by malpractice suits, condemnation by institutions and colleagues, loss of licensure, and eventually the ravages of substance abuse or personal humiliation.[43] Most state boards of healing arts function best when it comes to providing support for physicians in trouble.

A Final Thought

Perhaps Richard Hayward, who compares a surgeon to the young sea captain in Joseph Conrad's novel, "The Shadow Line," best describes a successful career in surgery. Hayward explains that there are so many variables in the interaction between patient, surgeon, and disease that it is not surprising that the prediction of results becomes uncertain. Even routine procedures can produce complications and can become much more difficult than had been anticipated. As the surgeon crosses Conrad's Shadow Line, energy, enthusiasm, ability to make firm decisions and then act upon them, optimism, self-confidence, and resilience in the face of adversity become necessities without which an individual will have difficulty coping with the pressures of a surgical practice, especially one involving the care of critically ill emergency patients. There becomes a time when a surgeon must learn to come to terms with the inadequacies and, sometimes, downright failures of his or her actions that will be the inevitable companions during a surgical life.[44]

Legal Considerations

Michael J. Meehan

Introduction

The dawn of the twenty-first century brought with it many of the same court room challenges for colon and rectal disease practitioners as did the latter half of the twentieth century. The increasing frequency and crushing severity of malpractice claims and lawsuits, data bank reporting, Web-based consumer claims data, new privacy requirements, increasing clinical demands, greater government regulation and enforcement activity, and spiraling malpractice premiums have caused many physicians to leave practice, retire early, or move to more lawsuit-friendly jurisdictions. This chapter addresses many of the causes for these concerns – from communication to documentation, from practice to research – as they relate to colon and rectal surgeons who face these challenges.

Medical Malpractice

Elements of Malpractice

In July 2003, a 12-day trial occurred in Seattle, Washington. The plaintiff, a married 53-year-old computer salesman, presented to his family physician with rectal bleeding and a painful anal lump that looked like a hemorrhoid. When the condition did not improve with treatment, the patient was referred to a general surgeon, who evaluated the condition, thought the patient had a hemorrhoid, and recommended a hemorrhoidectomy. The patient, however, said he thought the condition was improving and declined the procedure. The surgeon told the patient that he should have a hemorrhoidectomy if the condition did not continue to improve and resolve. The patient did not return to the surgeon for 4 months, at which time a hemorrhoidectomy revealed an advanced anal cancer. The patient underwent chemotherapy and radiation, developed impotence, and suffered two recurrences of his cancer. The patient-plaintiff sued both doctors and contended at trial that earlier diagnosis would have resulted in less extensive treatment and a prognosis that he would have survived his cancer (from which he was probably going to die). The defense argued that both the family practitioner and the general surgeon acted appropriately and that an earlier diagnosis would not have made any difference in the treatment or the outcome. Fifteen medical and surgical experts were used in the case. The pre-suit demand of $2.75 million had been met with an offer of $125,000. At trial, the plaintiff asked the jury for $7 million and the defendants requested a defense verdict. The jury awarded no money.[1]

The requisite elements that must be proved by a plaintiff in a medical malpractice case are determined by the laws of the various states. Washington state law governed in this case. Generally speaking, a case for medical malpractice is established when it is shown by a preponderance of the evidence that a patient's injury was caused by the act of a physician or surgeon that would not have been done by a physician or surgeon of ordinary skill, care, and diligence under like or similar conditions or circumstances (or by the omission of an act that a physician or surgeon of ordinary skill, care, and diligence would have done), and that the patient's injury was the direct and proximate result of such act (or omission).[2] What a "physician or surgeon of ordinary skill, care, and diligence would or would not have done under like or similar conditions or circumstances" is called the standard of care. The standard of care for a physician or surgeon in the practice of a board-certified medical or surgical specialty should be that of a reasonable specialist practicing medicine or surgery in that same specialty, regardless of geographical considerations or circumstances.[2]

Family practitioners and surgical specialists, as in the Washington case described above, are usually held to different standards of care, depending on variations in state law. In a case like this, for there to be a plaintiffs' verdict the jury must believe that (1) there was a departure from the standard of care *and* (2) that the departure from the standard of care was the cause of the patient's injury. In order for the defense to prevail, the jury must believe that either (1) or (2) above was not proved by a preponderance of the evidence – or that neither was proved.

Both of these issues were actively debated in the Washington case. (1) The recommendations, treatment, and decision to defer a hemorrhoidectomy were contested by both sides; (2) whether the cancer had metastasized prior to the critical involvement of the doctors was also argued. (If the cancer had metastasized prior to physician mismanagement, if any, then even a timely hemorrhoidectomy would not have changed the outcome or treatment – so physician mismanagement could not have logically been the *cause* of the patient's injuries).

In some cases, the defense attorneys give up on item (1) above, i.e., liability, if they think they cannot prevail on item (1) but if they think they can prevail on item (2), i.e., causation. Such a strategy is challenging at best – consider the following case tried to a Savannah, Georgia jury in November 2001 in which defense attorneys conceded liability and tried to convince a jury that the plaintiff was entitled to receive an award, but that the amount sought by the plaintiff exceeded that to which he should be entitled. The plaintiff had been in an automobile accident and had suffered a rectal tear when thrown from his vehicle. The trauma surgeons who tried to repair the tear negligently stapled the wrong end of his colon. As a result, he suffered a complete obstruction of his digestive tract for 7 days and developed a massive infection, causing the loss of approximately 70% of his abdominal wall. He was left with massive scarring, no abdominal muscles, only a thin layer of skin covering his intestines, and the prospect of constant diarrhea for the remainder of his life. The defendants conceded that the stapling procedure was handled improperly, but disputed the extent of the patient's injuries, including over $1.2 million alleged to represent the present cash value of the patient's future lost income. The jury was not asked whether the trauma surgeons had departed from the standard of care, but rather whether all of the injuries complained of were caused by the negligence (whether too much money was being claimed for the injury). The jury awarded the plaintiff $6.25 million.[3]

Recently, case law has developed expanding the standard care in some instances to include a duty to warn a patient's relatives of their increased genetic risk for colon cancer due to the patient's diagnosis. A New Jersey appellate court has held that a physician not only has a duty to warn the patient of the genetic or hereditary nature of his or her illness and its possible impact on the patient's close relatives, but also may have a duty to inform the patient's immediate family members who may be adversely affected. In that case, the Plaintiff was diagnosed with colon cancer at the age of 36 and sued the estate of a physician who had treated her father for polyposis, some 30 years prior. The woman alleged that the physician had a duty to warn her father's immediate family members of the hereditary nature and risks of polyposis, which may have permitted her to receive earlier detection, prevention, and treatment of polyposis, possibly preventing the development of colon cancer. The court held that ordinarily, a physician's duty to warn of a genetically transferable disease is satisfied by warning the patient, but that a physician must also take reasonable steps to assure that the information actually reaches those likely to be affected or is made available to their benefit.[4] The release of private health information is regulated on the federal level by the Health Insurance Portability and Accountability Act (HIPAA) (discussed below), which authorizes disclosure without consent in the case of a serious and immediate threat to an identifiable third party when the physician has the capability to forestall that harm.

Recurring Malpractice Themes

A study of medical malpractice cases involving colon and rectal disease involved a retrospective review of all cases tried in the federal and state civil court system over a 21-year period from 1971 through 1991[5] and remains instructive today. The study identified 98 malpractice cases over this period of time from a computerized legal data base, involving 103 allegations of negligence. The nature and frequency of allegations were as follows:

- 43% Failure to timely diagnose disease, principally cancer and appendicitis
- 24% Iatrogenic colon injury
- 15% Iatrogenic medical complications during diagnosis or treatment
- 10% Sphincter injury with fecal incontinence from anorectal surgery or midline episiotomy
- 8% Lack of informed consent, usually regarding the extent of procedures or endoscopy

More recent commentators have warned about patients who present with fully developed cancers within 4 years of colonoscopies that apparently cleared the colon of neoplasia. The fear expressed is that the presenting patients may assume their colonoscopies were performed negligently, despite legitimate alternative explanations.[6] A study reviewing 38 malpractice claims against radiologists performing contrast examinations of the colon between 1985 and 1994 revealed the following major allegations: failure to diagnose caused a delay in treatment and death and colon perforation due to improper performance.[7]

Risk management suggestions relevant to colon cancer screening include using authoritative screening guidelines, documenting informed consent and refusals, assessing family histories, recommending that family members of at-risk patients be contacted, repeating sigmoidoscopies and colonoscopies when the preparation is inadequate, and documenting cecal intubation and careful withdrawal techniques.[8]

Lawsuit Stress

Many if not most physicians who are sued experience stress and other normal emotions when their professional care and judgments are criticized in a public lawsuit. The initial stressor typically occurs when the claim letter, summons and

complaints, or insurance company notice arrives in the mail. The simple reality is that the profession which you have chosen frequently lends itself to the frustrations and anxiety of litigation. Anger, uncertainty, and even depression are common symptoms among physician defendants, especially those sued for the first time.

Attorneys representing physicians usually advise their clients not to discuss the case with others for fear of losing the protections available through the attorney–client privilege. The tension and vulnerability that you may feel about being sued may be exacerbated by this inability to seek emotional comfort by discussing the case with colleagues and others. It is normal to feel isolated – to assume that colleagues and even subordinates are talking about you and your lawsuit. It is equally important to place your predicament in perspective; many of your colleagues have been in the same situation before you.

If you are involved in a claim or lawsuit and are experiencing any of these normal reactions to litigation or the threat of litigation, you should have a candid conversation with your attorney, risk manager, or insurance company claims representative. Many insurance companies and medical institutions provide resources for defendant physicians that enable them to discuss their lawsuit and their feelings of uncertainty and isolation with counselors or colleagues in a protected fashion. Conversations with psychotherapists should normally be privileged and not admissible in the courtroom as evidence in the case. Remember that your emotional stability is critical to the successful defense of the litigation. You serve yourself best by sharing your feelings with your attorney and asking him or her for a way to receive emotional coaching throughout the stress of the lawsuit and afterward as well.

Informed Consent

The failure of a physician to obtain proper informed consent is often cited as a major component of medical malpractice litigation. In reality, few cases are prosecuted exclusively on the issue of informed consent, and juries do not customarily award damages solely for a lack of informed consent. Nearly every malpractice lawsuit, however, contains a supplementary count that informed consent was not obtained. Properly obtaining and documenting informed consent, therefore, can be critical to the defense of the entire lawsuit. The informed consent discussion is at the heart of physician–patient communication and is usually an important component in the defense of the main medical or surgical issues in every case. You do not have to wait until the day of or the day before the procedure to obtain informed consent. A study involving 60 patients who underwent either colonoscopies or esophagogastroduodenoscopies revealed that patients remember essentially the same information whether consent is obtained immediately prior to a procedure or several days earlier.[9]

Obtaining of Informed Consent

Obtaining informed consent is primarily a physician obligation. Nurses and other nonphysicians cannot normally be blamed for failing to obtain informed consent[10] because they do not have the requisite legal capacity to fully inform patients of issues on which only a physician is licensed to advise. Hospitals, the typical employers of such professionals, do have an obligation to maintain an effective informed consent process within their institutions. Informed consent actions can be successfully brought against hospitals if they breach hospital standards and other duties imposed by law, e.g., where a patient is injured by an experimental procedure without being advised of the experimental study.[11]

Obtaining a patient's informed consent involves more than having the patient sign a form. It is a communication process, in which the physician should disclose and discuss the following information with the patient:[12]

- The patient's diagnosis, if known
- The nature and purpose of the proposed treatment or procedure
- The risks and benefits of a proposed treatment or procedure
- Alternatives (regardless of cost or insurance coverage)
- The risks and benefits of the alternatives
- The risks and benefits of not receiving or undergoing the treatment or procedure

Patients should have the opportunity to ask questions and have their questions answered.

Proving a Case of Lack of Informed Consent

Depending on variations in state laws, plaintiff attorneys typically must prove the following elements to establish a *prima facie* case of lack of informed consent by a physician:

- The physician failed to disclose to the patient and discuss the material risks and dangers inherently and potentially involved with respect to the proposed therapy, if any.
- The unrevealed risks and dangers which should have been disclosed by the physician actually materialize and were the proximate cause of the injury to the patient, and
- A reasonable person in the position of the patient would have decided against the therapy had the material risks and dangers inherent and incidental to the treatment been disclosed to her prior to the therapy.[13]

Whether risks are material or not is normally a jury question,[14] and juries are often instructed that risks are normally considered to be material if a reasonably prudent person would attach significance to the risk in deciding whether or not to accept the treatment. A risk that is either *severe*, like death, or *frequent* are usually risks that are considered material. Some states regulate the information that must be conveyed to patients, while other states leave the determination of materiality to judges and expert witnesses.

You should become familiar with the informed consent laws in the state where you practice. Withholding material risks from patients for cultural, ethnic, or paternalistic reasons is not acceptable.

Documentation of Informed Consent

Informed consent is usually documented with formal consent forms that patients sign. Nearly all hospitals require the use of consent forms for inpatient procedures to comply with applicable law, to abide by the standards of the Joint Commission,[15] and to facilitate patient education of the treatment information. Informed consent is a process and not a form. Forms can be challenged and criticized in the courtroom, and a form with errors or that is incomplete can distract a jury from the real issues involving informed consent.

Claims of lack of informed consent are best defended when a jury is persuaded that the physician had a meaningful conversation with the patient. In addition to a consent form, a chart notation made by the doctor, in the doctor's own words or handwriting, is usually very helpful. A jury that believes that the physician never saw the patient, or had a brief or cursory discussion with the patient, may become more inclined to decide that a surgeon departed from the standard of care in performing the procedure. Producing a diagram that was drawn for the patient can be persuasive for jurors. Similarly, patient information sheets or pamphlets are effective communication devices and serve well in the litigation defense.

Listen carefully to your patients' questions and answer them in a friendly but candid fashion. Chart the presence of any family members who are present for the informed consent discussion. Patients who are minors – usually those under 18 – may not legally consent for themselves unless they are living apart from their parents or are sufficiently mature to provide consent. Regardless of a minor's emancipation or maturity, it is wise to always obtain parental consent for elective procedures performed on minors. Unless parental consent is obtained, there is probably no binding contract enabling you or the hospital to receive payment for services.

Documentation

A patient's medical record is the star witness in any medical malpractice lawsuit. The chart is the one witness whose memory never fades. The medical record can be your best friend when you are sitting on the witness stand, or it can be your worst enemy. Make it your best friend.

Defensive Charting

"If it's not documented, it didn't happen." As a practical matter, this old adage is mostly true, and in any event serves as a good rule of thumb for all caregivers. Defense lawyers like to see professional comprehensive charting because it conveys the appearance of professional and comprehensive care – not only to a jury, but also prior to the suit when a plaintiff's attorney is reviewing records and deciding whether or not to take the case.

Chart notations, as a general rule, need not be cluttered with overwhelming details to be defensible in the courtroom. A good defensive chart notation is written with an eye toward deflecting practical and obvious criticisms that would be made of the healthcare team or the writer of the notation. Examples of concepts to insert, as appropriate, would include the following:

- Descriptions of bedside visits, especially when multiple pages made
- When you were there and what you did, including date, time, and signature
- Your thought process and differential diagnosis
- Presence of family members
- "Spoke with husband at bedside."
- "Patient states that she understands a change in bowel habits should be reported."
- "Patient refuses to comply with treatment recommendations because …"
- "Patient not able to perform fecal occult blood test because …"[16]

Etiology Speculation

The charting of not only the facts, but also speculative opinions can be as damaging as too little charting. It is not uncommon that one member of the medical team may speculate as to the etiology of an adverse event, and that the surmised etiology gets parroted by other members of the healthcare team.

> Example: Physician undertakes a second look laparotomy to rule out recurrence of cancer. During the procedure, the bladder and bowel are perforated, but the perforations are identified and repaired intraoperatively. A bowel leak, however, is detected three days later when the patient is admitted. A second year resident records in the medical chart, "Iatrogenic perforation resulting in sepsis." This reference is repeated by two attendings on other services.

A perforation that is diagnosed within 24 h of an endoscopic procedure may have been iatrogenic, but then again it may have been spontaneous. To assume in the medical chart that a perforation occurred during a procedure, if repeated by others in the medical record, becomes a "reality" that may be insurmountable in the courtroom, even when an expert testifies that the perforation in retrospect was clearly spontaneous.

Everything that is written in the medical chart is critical, and key phrasing is often highlighted or enlarged for juries to see on poster boards. Remember that causation is one of the four elements of medical malpractice, and is frequently the most difficult of the four elements for the plaintiff to prove.

- *ALERT!* – *Iatrogenic* means "caused by manner or action of physician, not by medical treatment." Do not use the word if you are not absolutely certain that the injury was practitioner-induced.

Also remember that physicians need not always be correct in treating patients. Rather, they must comply with the standard of care. A defensible chart notation reflects a physician's attention, thought process, and a differential diagnosis, even if the working diagnosis turns out to be incorrect in retrospect.

Plaintiff's Pre-claim Review

Because plaintiffs' attorneys are paid on a contingency fee basis, the better plaintiffs' attorneys conduct a review of a new client's medical records before agreeing to take the case and further expending the resources of the law firm. Because nearly all medical malpractice cases are tried before juries (as opposed to judges), attorneys representing patients look for flaws in medical record documentation that juries can understand. For example, a physician's criticism of a colleague in a medical record is easier to showcase before a jury than the related medical facts, which often are too complicated for all jurors to completely understand. While professional differences of opinion are expected, professional conflicts are best resolved verbally. Disagreement with colleagues that appear in the medical records should be kept to a minimum, unless necessary or appropriate to properly document the patient's course of care.

Other items which attorneys and their reviewing physicians look for are missing lab reports, radiology interpretations, or the results of any tests or procedures that were ordered but not present in the chart. Multiple page attempts by the nursing staff that go unanswered are also fertile ground for review and focus.

> Example: Elderly male patient with debilitating back pain underwent spinal surgery. He was on anticoagulation medications due to a mechanical heart valve. Postoperatively he developed a hematoma at the base of the spine. In response to complaints of pain, he was seen three times by a house officer who did perform an appropriate examination but who neither stopped the patient's heparin nor order an MRI. Permanent paralysis and urinary and sexual loss ensued.

A plaintiff's lawyer would be immediately drawn to nursing notes stating that multiple page attempts were made and that no corresponding notes were made by any physician responding to the pages. The attorney immediately assumes that he or she can prove in the courtroom one of the following scenarios: (1) no physician ever responded to the pages; (2) a physician did respond but the response was not timely; or (3) a physician responded but did not conduct a proper examination.

In this example, a comprehensive chart notation by the house officer, reflecting the thought processes and the extent of the examination, may obviate a claim, a verdict, and tens of thousands of dollars in legal fees.

Record Tampering and Deception

Improper altering of the medical record or tampering with the medical record may be grounds for punitive damages and even loss of licensure and should be avoided at all costs. Post-event recording in a medical record should be done with proper disclosure of the timing and reason for the entry and with the advice of risk management or legal counsel if appropriate. You should remember that your medical records are copied for multiple reasons – like insurance, compliance, and quality review – and those copies of any given patient's medical records may exist elsewhere, even at other healthcare facilities. Plaintiffs' attorneys routinely request copies of the same medical records from multiple sources to ensure that all records are gathered, and discrepancies among the various copies may be detected, e.g., a late entry on one copy that does not appear on another copy. When lawyers are suspicious of entries made at different points in time, color copying can be requested and even a handwriting analysis. If a jury were to believe that a physician intentionally altered a medical record to lessen his or her own liability in a malpractice case, the physician would lose credibility with the jury.

Similarly, a surgical error known to the physician but kept from the patient could flame juror anger if it later becomes known to the patient. Surgical needles and other "foreign objects" inadvertently left behind and discovered later by X-ray should be immediately disclosed to patients. The following 2003 Maryland case[17] illustrates this point.

The plaintiff, a 49-year-old married grocer, with a long history of uncontrolled diarrhea and stomach pain diagnosed as ulcerative colitis, presented to a colorectal surgeon for a total proctocolectomy. A temporary ileostomy was performed contemporaneously. The surgeon performed a reanastomosis 90 days later, but the patient experienced a return of her uncontrolled diarrhea and stomach pain. She sought the advice of another physician, who discovered via colonoscopy that one-half of her rectum remained following the proctocolectomy. A second surgeon performed a second proctocolectomy and removed the remaining portion of the rectum, after which she made a full recovery. According to the plaintiff's attorney, the first surgeon's medical notes indicated that he had performed the procedure incorrectly but failed to so inform his patient. The defendant surgeon contended that it was an acceptable practice to leave one-half of the rectum. Her medical expenses had been $51,438. Experts testified on both sides. The jury deliberated one and a half hours and returned a verdict for the woman and her husband in the amount of $591,438. Usually, a jury spends one and a half hours selecting a foreperson and beginning to review the medical records. This jury appears to have been angered by the facts and spent relatively little time deliberating.

Electronic Medical Records

The age of electronic medical records has brought enormous efficiencies and improved medical quality to the healthcare delivery system. All patient records, whether paper or electronic, are discoverable and admissible in medical malpractice lawsuits. In addition, the American Recovery and Reinvestment Act of 2009 amended HIPAA privacy regulations to require providers who use or maintain electronic health records with respect to protected health information (PHI) of individuals, to provide to a patient, upon request, an electronic copy of the patient's electronic health records.[18] This change becomes effective on February 17, 2010. Physicians who record entries in computerized medical records must become familiar with how to use electronic medical systems and should understand that danger lurks in these more efficient computerized systems. For example:

- *BEWARE* drop-down menus and checklists
- *BEWARE* prefabricated medical descriptors
- *BEWARE* prefabricated informed consent notations
- *BEWARE* easy click-on techniques

Not all patient evaluations and regimens can be preformatted. There is a natural tendency for caregivers to pick the "closest" option in a menu of options. Physicians should use "free text" whenever appropriate. It is much easier to defend "your own words" than the words of a computer programer who has written a menu of typical patient diagnoses in drop-down menus or other coded formats.

Communication

Adverse Events, Bad News, and Apologies

When an untoward unexpected event occurs involving a patient, several avenues of communication are critical. First and foremost, the patient's medical needs must be promptly addressed. Coordination of ongoing care, including consultation and follow-up if appropriate, is a critical first step in deflecting a lawsuit.

As soon as practical after the event, the patient and family should be informed of the consequences to the patient in a respectful and sympathetic manner. This discussion should be preliminary to a more detailed discussion that should occur once more facts are obtained as discussed below. Without assigning blame or criticism of other practitioners, the patient and family should be informed of the fact that the event occurred, the current and future consequences to the patient, and what steps have been taken to address the patient's medical condition. If the underlying causes for the event are not yet known, which is frequently the case, care should be taken not to speculate about the underlying causes for the complication. This conversation is usually best handled by a physician well known to the patient

and family, although differing circumstances may warrant placing others in that role. Questions should be answered honestly and factually. The patient and family should be told that additional information is conveyed to them as it is known, but in any event that a more thorough discussion occurs within a set period of time, ideally 24 h. It is usually advisable to contact the risk manager or legal counsel if applicable, e.g., when the critical incident occurs in an institution, where such personnel are available. Depending on institutional policy, risk managers, or quality management personnel frequently assist in the interactions with patients and family. They also begin any appropriate administrative activity, such as initiating a sentinel event analysis, notifying an insurance carrier, sequestering medical devices or equipment, initiating an equipment analysis, and reporting device failures to the FDA. The administrative staff may also wish to convene a risk management and/or quality management review that would be protected from discovery in a lawsuit under applicable state privilege statutes. It is also advisable for one member of the institutional team to be designated as the spokesperson to the patient and family so that consistent information is being delivered.

When more facts are gathered and a better understanding of the sequence of events is known, but ideally within 24 h, a family meeting is advisable. The spokesperson should lead the discussion and the patient's attending physician, if not the spokesperson, should be present. The anticipated medical consequences and prognosis for the patient should be discussed, as well as the factual circumstances leading to the incident. Physicians and institutions should be willing to express sympathy and perhaps even apologize for what happened.

In recent years, a number of prominent institutions have urged their physicians to say they are sorry for a patient mishap and provide lawsuit-deflecting apologies. A handful of states have even enacted legislation immunizing various forms of apologies from courtroom use.[19] Advice should be sought from institutional or local legal counsel regarding the admissibility of apologetic statements.

At family meetings, the family members should have an opportunity to ask all of their questions, and they should be given the name and contact information of someone to reach if additional questions arise later. The team should anticipate questions about writing off medical bills and the possibility of a malpractice claim. Any questions about malpractice can be deferred at that point with the explanation that institutional legal counsel or an insurance representative contacts the family if desired. Keeping in touch with the patient and family spokesperson is critical during the next several days and weeks.

A senior member of the medical team, perhaps with the assistance of risk management or legal counsel, should be consulted in reviewing the chart and recording the events involving the untoward incident. The sequence of events, the timing, and the identity of personnel should be completely

and accurately recorded. All discussions with the patient and family members after the incident should also be clearly described, including the identity of persons present at the family meetings and what was said.

Many patients and family members at this juncture are considering whether to seek the advice of a lawyer, and they may be urged to do so by friends and other family members. Care should be taken by all members of the health care team to provide a courteous, qualitative, and sympathetic continuity of care and interaction with family members. Physicians and other members of the health care team serve themselves and their patients well by using this time to provide as positive and supportive an experience as possible for patients and family members.

Emails

Because of the efficiencies associated with electronic mail communication, many physicians communicate with both patients and other health care providers by using electronic mail (email). Special care should be taken when using email that contains patient identifiable information.

Clinicians may communicate with other clinicians and patients by email. The Federal HIPAA of 1996[20] (discussed later) provides regulation for electronic transmission containing PHI, such as confidential medical information. HIPAA provides that health care providers have in place appropriate administrative, technical, and physical safeguards to protect the privacy of PHI.[21] The HIPAA regulations do not provide a specific regulatory scheme for email communication, but they do require that providers have procedures that limit disclosures of PHI to the amount reasonably necessary to achieve the purposes of PHI disclosures.[22]

The Notice of Privacy Practices that providers give to their patients must explain in a separate statement that the provider may contact the patient to provide appointment reminders or information about treatment alternatives or other health-related benefits or services that may be of interest to the individual.[23] If this is done by email, it is advisable to state that in the Notice of Privacy Practices.

You may wish to inform your patients that email transmission involves privacy and security issues that may be of interest to them. Patients may even be asked whether they wish to communicate by email or not. Email that is sent to a patient's business may be intercepted by the patient's business colleagues, and emails can be inadvertently transmitted to unintended addressees. The Internet is not considered a secure media for transmitting confidential data unless both parties utilize encryption methodology. These types of warnings can be provided to patients who wish to communicate with their physicians by email. Patients may even be asked whether they wish to communicate with you by email or not.

It is advisable for physicians to keep either paper or electronic copies of emails to and from patients that are relevant to patient treatment. These email copies should be maintained in the patient's medical records just as traditional paper correspondence would be.

Physicians may wish to include a Confidentiality Notice that is preprinted at the bottom of email transmissions. A sample Confidentiality Notice appears below:

> Confidentiality Notice: This email message including attachments, if any, is intended only for the person or entity to which it is addressed and may contain confidential and/or privileged material. Any unauthorized review, use, disclosure or distribution is prohibited. If you are not the intended recipient, please contact the sender by reply email and destroy all copies of the original message. If you are the intended recipient, but do not wish to receive communications through this medium, please so advise the sender immediately.

HIPAA

The Federal HIPAA of 1996 provides national privacy protection for patients. Administrative Regulations (The "Federal Privacy Rule")[24] have been promulgated by the US Department of Health and Human Services (HHS) pursuant to HIPAA. The Federal Privacy Rule establishes minimum privacy standards for health care providers, health plans, and health care clearing houses (referred to in HIPAA as "covered entities") to follow when using and disclosing patient-identifiable PHI that they create or maintain. Generally speaking, PHI is any information that is created (or received) and maintained by a covered entity related to the health or health care of a patient (or payment related to the health care) that directly or indirectly identifies the patient.[25]

The Federal Privacy Rule also requires compliance with state laws that afford greater privacy protections than HIPAA. Compliance with the Federal Privacy Rule was required on and after April 14, 2003. All covered entities must have policies and procedures in place that demonstrate compliance with the Federal Privacy Rule.

HIPAA provides that health care providers must make a good faith effort to give each patient a Notice of Privacy Practices that describes the privacy practices of the health care provider. Patients must be asked to acknowledge in writing that they have received this notice. Once a provider makes a good faith effort to provide a Notice of Privacy Practices to a patient and gets the patient's written acknowledgement of receipt of the Notice, the health care provider may use and disclose PHI for reasons related to the treatment of the patient, payment for the patient's health care, and the health care operations of the provider (TPO). Generally, physicians who are independent practitioners of the hospitals of which they practice are part of those hospitals' "organized health care arrangements," enabling the disclosure of PHI between the hospital personnel and the independently practicing physicians. To use or disclose PHI for reasons other than TPO or as otherwise permitted by law, a physician must obtain an additional written permission from the patient called

an "authorization."[26] Clinical research, for example, is not considered "treatment" and usually must be separately approved by research subjects by signing an authorization. In many medical centers, authorizations for clinical research are integrated into the consent form approved by the institutional review board. The Federal Privacy Rule requires that authorizations contain certain elements.[27]

HIPAA permits treating physicians to disclose to a patient's family members, other relatives, close personal friends, and others identified by the patient any PHI that is directly relevant to such person's involvement with the patients care or health care payments. Prior to making any of these disclosures, a physician should either obtain the patient's agreement to the disclosure or reasonably infer from the circumstances that the patient does not object.[28]

A physician needs to be aware, however, of the potential for improper disclosures that this situation creates. Prior to the enactment of the American Recovery and Reinvestment Act of 2009, providers had no obligation to notify patients in the event their PHI was improperly disclosed. The amendments made by the Act to HIPAA require that providers notify their patients and HHS when there has been a "breach" of their PHI. The HHS published regulations pertaining to breaches in August 2009 that became effective September 23, 2009. A "breach" is defined as the unauthorized use, acquisition, access, and disclosure of PHI. The definition excludes unintentional or inadvertent acquisitions made by employees or other authorized persons as long as the PHI is not further used or disclosed.[29] In the event of a breach, a provider is required to notify the patient within 60 days. The notice must include a description of what happened, the information involved, the recommended steps the person should take to protect themselves, and a description of any investigation or mitigation efforts made by the provider.[30]

Research and Innovative Surgery

Research Versus Innovative Practice

The emergence of evidence-based medicine has brought new challenges to the academic medical community. Surgeons and other physicians who serve as investigators in clinical trials are very familiar with the review and approval process of institutional review boards – ethics committees established under federal law to oversee the conduct of research. Many disciplines, especially surgery, have evolved historically in an environment of unregulated innovation. It is often not clear when innovative therapy crosses the line into the research arena.

The Belmont Report[31] states that the distinction between research and practice is blurred and that both often occur together. Research is usually described in a formal protocol, and departures from standard practice are not necessarily "research." The Belmont Report also states:

The fact that a procedure is "experimental," in the sense of new, untested, or different, does not automatically place it in the category of research. Radically new procedures of this description should, however, be made the object of formal research at an early stage in order to determine whether they are safe and effective. Thus, it is the responsibility of medical practice committees, for example, to insist that a major innovation be incorporated into a formal research project.

Regulation of the practice of medicine has historically been the exclusive province of the state medical boards and other state regulatory authorities. When medical practice crosses the line into "research" involving "human subjects" or investigational drugs, devices, or other test articles, however, the activity becomes subject to the regulation of the federal Office for Human Research Protection (OHRP)[32] for the US Food and Drug Administration.[33] "Research," as regulated, is a systematic investigation, including research development, testing and evaluation, designed to develop or contribute to generalizable knowledge.[34] "Human subjects" are living individuals about whom an investigator conducting research obtains data through intervention or interaction with the individual or identifiable private information.[35] Traditional examples of research studies include prospective industry-sponsored trials.

Data Base Registries

In theory physicians who engage in innovative treatment that does not involve a systematic design, a research protocol, a prospective intent to publish, or an investigational item are not regulated by either OHRP or FDA. Over the past decade, however, OHRP has expressed its view that those systematic collections of data performed off-chart, especially if published, carry an implicit prospective intent and are considered research. These may include ongoing patient registries, including outcomes data; tissue banks; static databases, including ad hoc research from closed trials; and even retrospective studies, including chart reviews, if a prospective intent to publish was present.

In recent years, the OHRP has investigated a variety of innovative techniques to determine whether or not the activities should have been prospectively reviewed by an institutional review board as research. Examples are: 14 patients treated with fractionated stereotactic radiosurgery for the treatment of large arteriovenous malformations prior to IRB approval;[36] publication of a retrospective chart review that was conducted without IRB approval;[37] publication describing partial left ventriculectomies performed in the management of patients with dilated cardiomyopathy without IRB approval[38] and fetal surgery procedures.[39] Many if not all of these scenarios involved publications that used research jargon and implied that a prospective research trial had been conducted (without IRB review and approval). In each of these investigations, OHRP suggested that the applicable institution consider the development of "innovative practice

committees" or similar institutional vehicles to evaluate major innovative therapies. Physicians, especially surgeons experimenting with minor surgical modifications to accepted techniques, should use care when authoring articles about clinical experiences that did not involve "research" as defined above. When in doubt physicians are encouraged to consult with their local institutional review boards for guidance.

Promotional Prohibitions

Physicians who conduct FDA-regulated research are prohibited from representing in a promotional context that an investigational new drug, device, or other test article is safe or effective (or otherwise beneficial) before it has received regulatory approval.[40] Physicians should carefully review press releases and other promotional disclosures prepared by commercial sponsors or manufacturers before permitting their names to be associated with such test articles prior to approval.

Insider Trading

If you are involved in clinical trials for pharmaceutical companies or medical device companies whose securities are publicly traded, you may have certain obligations to protect the confidentiality of sensitive information you acquire. Your duties may stem from not only being a company officer or holding another fiduciary position, but also from being an investigator or from serving on company advisory committees like scientific advisory boards, clinical trial steering or executive committees, or data safety monitoring boards. The securities laws widely prohibit fraudulent activities of any kind in connection with the offer, purchase, or sale of securities.[41] These provisions are the basis for many types of government enforcement activities, including actions against illegal insider trading. Insider trading is illegal when a person trades a security while in possession of material, nonpublic information, including information from medical research trials, in violation of a duty to withhold the information or refrain from trading in that security. "Tipping" other traders of such information who then trade a security affected by the tip is also illegal as is acting on an illegal tip.

Conclusion

In recent years, the demands and pressures on physicians and surgeons have grown dramatically. Lawyer advertising and malpractice awards and settlements are greater than ever before. Web-based consumer awareness has increased the knowledge base of patients. Government regulation and enforcement activities have become more focused. Greater understanding and awareness of legal and risk management concerns is critical for health care practitioners facing these challenges.

54
Surgical Education

David J. Schoetz

Surgical education is undergoing exciting and challenging major transformational change within the broader context of healthcare reform, physician shortages, and financial uncertainty. Spurred by seemingly diverse forces such as altered lifestyle expectations among residents and attending physicians, the quality/safety movement, and improved recognition of the evolution of effective educational techniques, the training of surgeons has become extraordinarily complex. Pressures on the educators to provide a more nurturing environment for the students while at the same time performing more clinical work to maintain the financial viability of the teaching institution threaten the ability to train the next generation of surgeons adequately. The traditional "see one, do one, teach one" paradigm of bygone years is no longer feasible; patients do not expect a partially trained and sleep-deprived resident to practice on them without supervision.

Traditional "modern" surgical residencies are generally attributed to Halsted, who initiated the competitive pyramidal system at the Johns Hopkins Hospital based on his early observations in Germany. Prior to this, surgeons were trained in a haphazard manner in a strict apprenticeship model. In the Halsted system, residents spent an average of 8 years in training; following gradual assumption of greater responsibility for patient management over the first 6 years, the chief residency experience was 2 years in duration.[1] During these final 2 years, the resident was, in essence, a junior staff with independent operating privileges. Many of the graduates of this particular training program went on to become professors of surgery, and the success of the program prompted other institutions to follow suit.[2]

Objections to the Halsted model revolved around the master/apprentice relationship and thus the total reliance on the master without regard for validation of the qualities of the teacher. The unnecessary interpersonal competition among colleagues within the residency and the extended period of servitude, resulting in loss of a period of potentially great independent productivity, prompted the development of an alternative training plan by Edward Churchill of the Massachusetts General Hospital.[3] Churchill believed that the junior residents were exploited to provide service to the hospital. He was also convinced of the need for flexibility in training, recognizing differing individual resident capabilities. He was strongly supportive of the need for progressive responsibility for the trainee over the course of the training program. Finally, he abolished the pyramid of Halsted and replaced it with a "rectangular" plan; those who wished to pursue academic careers would need to pursue extra experience outside the residency period.

Cognitive Learning

During the first 60 years of the twentieth century, learning was often by osmosis, without a standardized curriculum. Clinical observation, self-study, and independent patient care were the manner of learning, with obvious individual variations for both the teacher and the student. Supplementation of this process might be by independent reading of relatively scarce textbooks and journals. The need to develop and teach a standardized basic body of knowledge was stimulated in part by the Accreditation Council for Graduate Medical Education (ACGME) and the various Residency Review Committees (RRC). In addition, certifying boards were in the process of creating qualifying and certifying examinations that reflected quality patient care as determined by expert practitioners; this also created a standard curriculum.

Definition of a curriculum is an essential step in education, and graduate surgical education is no exception.[4] Curriculum may be "syllabus based," meaning a list of topics that forms the basis of what is being studied. This is convenient, but treats the learner as a passive recipient. "Objectives-based" curricula are predicated on the faculty identifying behavioral objectives and creating learning-based activities and evaluation tools based on these objectives. These two types of "curriculum as product" are relatively simple and are most commonly used for medical education. More complex is "curriculum as process," requiring continuous interaction between teacher and learner. The main advantage of this

latter type of curriculum is the active participation of the learner in the process. However, it is much more challenging for the faculty; moving toward process-based curriculum will necessitate faculty development programs that move the teachers to a more interactive environment.[4]

Current understanding of adult learning theory would suggest that the lecture format, in which the learner is a passive participant in a unilateral process determined solely by the teacher, is grossly inefficient.[5] Rather, the learner should be an active participant who learns best when actively involved in an individualized interactive learning program. Consequently, the traditional lecture formats that are very comfortable for the teacher are becoming progressively less valued by the new generation of learners. Interactive media and case-based discussions are more beneficial.

Academic conferences in surgical programs consist primarily of lectures, case presentations, and Morbidity and Mortality (M&M) conference. Traditional M&M conferences have been ideally used as a platform to teach both process improvement and personal responsibility. Ultimately, the goal is to improve patient care by identifying factors that contributed to the complication and suggesting ways to prevent them in the future. Regular participation in M&M conferences has been shown to cover much of the curriculum of surgery.[6]

Curriculum redesign is being driven in part by the ACGME Outcome Project, introduced in 1999 as the basis for the development and evaluation of a new curriculum for training physicians.[7] Initially, the ACGME endorsed six competencies:

1. Patient care
2. Medical knowledge
3. Professionalism
4. System-based practice
5. Practice-based learning and improvement
6. Interpersonal and communication skills

Since their introduction, all specialties have been stimulated to embrace competency-based curriculum design and evaluation. The American Board of Medical Specialties has also adopted these competencies for primary board certification and maintenance of certification, lending some continuity in concept over the spectrum of postgraduate medical education and subsequent practice.

Within this construct, conferences must be redesigned to reflect these competencies. M&M can be entirely based on the competencies in order to enhance learning and improve the educational content for all participants.[8] In preparation for the conference, participants should identify the competencies that participate in the adverse outcome and take steps to rectify system problems in a collaborative fashion. The same is true for didactic lecture series, which can and should be redesigned to fit within the framework of the Outcome Project.

Evaluation of the quality of the program and of the educational commitment of the institution is also defined by the competencies. Not only are the program goals and objectives centered around them, but the means of evaluating each

individual resident is also based on new methods of evaluation within the framework of the competencies. Strategies such as the creation of a self-defined but externally evaluated educational portfolio, 360° evaluations by other care givers and patients, and scheduled formative evaluations with much more constructive feedback to the trainees are an integral part of the ACGME Outcomes project. Consequently, the demands on program directors and institutions are considerably greater than ever before.[9]

Technical Skills

Unique to the education of proceduralists, including surgeons, is the need to provide technical training resulting in sufficient competence to practice independently at the completion of the training period. Debate continues on whether technical skill should be considered part of medical knowledge or a separate seventh competency. Needless to say, technical performance of various procedures is a core curricular requirement for numerous specialties; validated teaching techniques for procedures are perhaps the most challenging aspect of present-day educational programs.

Traditional teaching of technical skills centered around a brief period of observational learning, perhaps with some training in "dog labs." Pressure to "go to the operating room" resulted in a junior level trainee first observing, then assisting, and finally performing actual procedures with variable supervision and input from master surgeons. Assessment was subjective and relied on the opinions of the faculty as well as excessively on pure numbers of cases performed without a formalized system of technical training with constructive feedback. Attempts to substitute formalized objective written tests have not translated into better or more valid technical skills acquisition; measurement of cognitive capability has been shown to not correlate with technical competency.[10] Rather, the challenge has been to develop methods for not only teaching but also evaluating technical performance.[11] This forms the basis of modern technical training and evaluation.

As learning theory has progressed, methods of acquiring and refining motor skills have been applied to surgical training.[12] Early teaching of technical skills should take place away from the operating room, allowing practice until there is a basic fluidity in the mechanical performance of the task. Expertise is developed by repetitive deliberate practice, from which master technicians are formed.[13] Since the traditional apprenticeship model of training does not often offer this environment for learning, new methods of training and evaluating must be developed, validated, and applied in a formalized curriculum.

The Objective Structure Clinical Examination (OSCE) is a proven accepted method of assessing clinical competence of medical students. Utilizing the same basic philosophy, the University of Toronto developed the Objective Structured Assessment of Technical Skill (OSATS) for surgical

residents, in which residents were observed performing various structured operative tasks.[14] Bench model simulation, which is less expensive and more widely applicable, provided equivalent results compared to the use of live animals. Since the initial descriptions of OSATS, it has been demonstrated to be consistently effective in imparting proficiency to surgical residents.[15,16]

With the Residency Review Committee in Surgery requirement for access to simulation and skills facilities in all general surgery residencies,[17] development and utilization of validated curricula for skills acquisition will assume central importance for surgical educators. Creation of a skills laboratory to accomplish training objectives for most surgery residencies need not be prohibitively expensive. Costs can be distributed over all of the intended users.[18,19]

Increasing frequency of the performance of laparoscopic surgical procedures has provided an impetus for the development of curricula and devices that provide basic skills prior to a trainee actually performing surgery on a patient. In fact, teaching laparoscopic skills in the simulation environment is very attractive and much easier than that with an open surgery. Various partial task training exercises have been used by the Society of American Gastrointestinal and Laparoscopic Surgeons (SAGES) to devise the Fundamentals of Laparoscopic Surgery (FLS) program.[5] This program, using box trainers and trained observers, teaches and evaluates five psychomotor skills of basic laparoscopy; it has been endorsed by the American College of Surgeons and the Association of Program Directors in Surgery; the American Board of Surgery requires FLS certification for all graduating general surgery residents. Other specialties involved in the performance of laparoscopic techniques will either use this program or develop their own.

Higher fidelity computer-based systems, although more costly, may provide more advanced procedural skills for residents and practicing surgeons. Students with experience in computer games are more adept at these types of exercises. As in the case of FLS training, which provides transferrable skills to the clinical setting, virtual reality simulators improve performance in the operating room.[20] The major shortcoming of these devices, which are image based, is the lack of haptic feedback; this also limits their application in open surgery.[21] More sophisticated computer applications, particularly with Internet2, are apt to eliminate these limitations in the future. At present, there are considerable challenges regarding validation of various protocols and devices for possible incorporation into a skills curriculum.

Highest fidelity simulation refers predominantly to immersion into an operating room or other interactive scenarios. Secrets to the success of these educational activities are the ability of the participants to suspend reality and a detailed debriefing among those involved after completion of the exercise.[5] In order to optimize the benefit of these activities, which are time intensive for the participants and expensive to provide, validation of the benefits must be built into each learning scenario. Whether a team-based activity, with nursing, operating room staff, anesthesia providers, and surgeons and their trainees, or an individual communication exercise using professional patients or retrospective evaluation of real patient/family interactions, it is clear that this type of learning will find greater application in the near future.

Endoscopy, including both upper endoscopy and colonoscopy, is now a requirement for general surgery graduates. Acquisition of endoscopic skills is facilitated by the use of endoscopy simulators, which can teach basic manipulation of the shaft and dials as well as steering maneuvers. Preparation of the novice endoscopist in the simulation lab accelerates the pace of the development of procedural adequacy.[22] At present, expert colonoscopists can be evaluated but are unlikely to benefit in terms of increased procedural proficiency.[23]

SAGES has parlayed their success in development of the FLS activity to develop a Fundamentals of Endoscopic Surgery (FES) program, which is nearly ready for beta testing. Presuming demonstration of validity of the FES curriculum, it is likely that it will also be adopted by major teaching organizations and the ABS.

Computer-based endoscopy simulators are expensive; their application in the training environment is more limited than that of basic laparoscopy trainers, making recuperation of the cost of the investment in these devices more difficult. Like all simulation exercises, however, they may find much broader applicability in ongoing credentialing and re-entry programs for practicing physicians. The American College of Surgeons has developed a program of accreditation for Basic Skills Labs and Comprehensive Education Institutes in order to extend research and education in teaching of surgeons and other physicians. The basic vision is to create regional education centers that concentrate expertise and share resources.

Challenges

The quality and safety movement, fueled by the highly publicized and excessively politicized report from the Institute of Medicine "To Err is Human: Building a Safer Health System,"[24] has leveraged the belief that exhausted and overworked residents and fellows are significant contributors to substandard patient safety into pressure to change the working environment for trainees. Publicity associated with the infamous "Libby Zion" incident in New York City ultimately resulted in the creation of the Bell Commission in the state of New York and ultimately the national adoption of the 80-h work-hour restrictions by the ACGME in 2003.[25] The currently required duty hours regulations include the following:[26]

1. Duty hours must be limited to 80 h per week.
2. One day in seven free from all educational and clinical responsibilities.

3. 10-h time period provided between all daily duty periods and after in-house call.
4. In-house call must occur no more frequently than every third night.
5. Continuous on-site duty, including in-house call, must not exceed 24 consecutive hours. Residents may remain on duty for up to six additional hours to participate in didactic activities, transfer care of patients, conduct outpatient clinics, and maintain continuity of medical and surgical care.
6. At-home call (or pager call).

    (a) The frequency of at-home call is not subject to the every-third-night, or 24 + 6 limitation. However, at-home call must not be so frequent as to preclude rest and reasonable personal time for each resident.
    (b) Residents taking at-home call must be provided with 1 day in seven completely free from all educational and clinical responsibilities, averaged over a 4-week period.
    (c) When residents are called into the hospital from home, the hours that residents spend in-house are counted toward the 80-h limit.

These regulations initially resulted in numerous violations, particularly by procedural specialties, resulting in the development of alternative patient care schemes. Night float rotations, nonphysician providers, and staggered shifts were creative ways devised to control hours of resident work; however, these efforts were met with objections that continuity of care would suffer as a result of adoption of a "shift" mentality.

Initial concerns that numbers of cases would be adversely affected by the 80-h rules have generally not been substantiated.[27] There has been a shift in operative experience, however. As the inpatients in the hospital have become more acutely ill, junior residents spend less time in the operating room. Expectations for acquisition of technical capabilities have been lowered for interns, who spend most of their time in the hospital outside of the operating room environment. Performance of complex cases is delayed until later in the residency, often resulting in residents who complete 5 years of training not having the skills or confidence to practice independently. As a result, a greater percentage of graduates seek additional fellowship training.[28–30]

Residents do appreciate the improved quality of life that they enjoy as a result of hours regulation; not all are equally enthusiastic about the effects on their training, with a potentially more adversarial relationship with their attendings, who must do extra work and hire physician extenders to perform tasks previously done by residents. Certainly, residents and attendings must be more resourceful in allocating index operative cases within defined time periods. While the benefits and detriments of the 80-h rules have been debated, a recent report from the surgical services at the University of Vermont has demonstrated a significant reduction in morbidity and mortality after adoption of the hour regulations.[31]

In fact, since the hour restrictions have been in effect for only 5 years (the duration of training of a general surgeon), the real end result of current regulations cannot yet be measured and is certainly more complex than some would suggest. Despite this uncertainty, in December 2008, the Institute of Medicine released a report and recommendations on resident duty hours.[32] This report recommends doing away with averaging of hours worked and in so doing, essentially reduces the number of hours that can be worked to much fewer than 80 h per week. It also does away with moonlighting during residency, which is a threat to residents in training who are often significantly in debt from student loans and who are expected to begin to repay these loans after completion of school and during residency. This most recent IOM report has resulted in a maelstrom of activity directed against adoption of the IOM recommendations predicated on the belief that we have not yet accurately assessed the effect of the 2003 regulations on training of physicians.[33–35] The ACGME has responded to the IOM by creating a task force with multiple stakeholder representation. Their work has recently been summarized as follows:[36]

1. The safety of patients is of utmost importance; the responsibility for safety resides with the resident, the attending and the systems of care.
2. Graded authority and responsibility on the part of residents are substantially diminished, with concerns for inadequate training.
3. There is a need for some flexibility in standards between specialties.
4. There are effects (in some instances unintended consequences) of alterations in training schemes on other specialties.
5. Residents are more rested and do have more satisfaction with their life.
6. Absolute rules and "substantial compliance" are very different in practice; rigid adherence to absolute rules often challenges professionalism and patient care.

Suffice it to say that multiple competing agendas must be acknowledged and resolved by reasonable compromise. Clearly, the training of surgeons is affected by the hours regulations.

Financing of graduate medical education from the Medicare budget is also an enormous long term challenge to the training of physicians. A summary of the method of federal payment for residents and fellows[37] indicates that the direct payment for residents has become inadequate to pay for resident training; an adjustment for teaching hospitals designed to reimburse the anticipated greater cost of care due to inefficiency and waste has been progressively reduced as the pressures on the Medicare trust fund have increased. With the exception of one redistribution of unused positions (which was not an absolute increase), the numbers of residency positions have been capped at 1997 levels by the Balanced

Budget Act; this is at a time when there is a public mandate to increase the number of graduates from medical school by 20–30% over 10 years and also during significant growth in the numbers of eligible Medicare recipients.[38]

Highly publicized Medicare fraud allegations resulting in substantial monetary fines and even the threat of prison have resulted in stricter requirements for documentation and supervision guidelines. Increasingly litigious and adversarial relationships among physician, attorneys, and patients have undermined confidence in the system of training physicians. The opportunity to provide an environment of progressive independent practice within a residency program has become difficult at best. Extension of the duration of training in ACGME recognized training programs is financially unattractive, since the initial period of full reimbursement for each resident/fellow is fixed by law and not likely to be lengthened; increasing the length of training is at the expense of institutional operating budgets.

Colon and Rectal Surgery

Needless to say, since general surgery residency is the foundation for colon and rectal surgery training, these factors that are challenging the quality of the 5-year trainee in general surgery have a substantial effect on colon and rectal surgical training. At present, the duration of training in colon and rectal surgery is 1 year beyond general surgery; in the past, this had been sufficient to essentially double the volume of cases done by a 5-year surgery trainee in the one additional year.[39] Competition for an increasing number of available residency positions in colon and rectal surgery is brisk, with 1.4 applicants per available position.[40] The changes in general surgery training just outlined have pressured colon and rectal surgeons to consider increasing the duration of training to 2 years, which may make the specialty less attractive to general surgery trainees who are considering advanced training.

In 2006, the primary constituents of the specialty, led by the American Board of Colon and Rectal Surgery (ABCRS) but also with representation from the RRC, the Program Directors Association (PDA) and the American Society of Colon and Rectal Surgeons (ASCRS), created a Blue Ribbon Committee. This was in response to the much heralded American Surgical Association Blue Ribbon Committee, which reported in 2004.[41] This latter committee also included major stakeholders in general surgery including the American Board of Surgery, the RRC and the American College of Surgeons as well as the American Surgical Association. Prompted by an apparent loss of interest by medical students in seeking a career in general surgery, this effort was an introspective examination of the factors that might make the specialty more attractive to medical students. The executive summary is a comprehensive document in which the foundation of traditional general surgery education is challenged at all levels. Proposed restructured training would provide for a basic core curriculum followed by advanced specialty and subspecialty training, divorced from practical considerations of funding of residency positions.

The American Board of Surgery has been the primary motivator of the development of the SCORE (Surgical Council on Resident Education) project.[42] Other members of this transformational project are the American College of Surgeons, the American Surgical Association, the Association of Program Directors in Surgery, the Association for Surgical Education and the RRC for Surgery. SCORE is in the process of developing specific learning objectives for each of the topics within 28 organ system-based categories. Operations and procedures are classified as Essential-common, Essential-uncommon and Complex. Procedural competency is not expected for complex procedures.

For colorectal procedures, total proctocolectomy including ileoanal reservoir, is considered complex.[42] For anorectal procedures, complex procedures include:

(a) Stapled hemorrhoidectomy
(b) Repair of complex anorectal fistulae
(c) Operation for incontinence/constipation
(d) Abdominal operations for rectal prolapse, both open and laparoscopic
(e) Perineal operations for rectal prolapse
(f) Operations for rectal cancer, including transanal resection and abdominoperineal resection

The implications of these changes in the anticipated experience for a general surgery trainee are obvious for colorectal surgeons. The colon and rectal surgeons must evaluate all aspects of colon and rectal training in light of possible significant future changes in general surgery residency.

One consideration has been to increase the duration of training from 1 to 2 years for colon and rectal surgery. A survey of graduates of colorectal training programs taking the ABCRS examination from 2005 to 2007 was administered and determined that general surgery residents decide relatively late in their training to pursue additional colorectal surgery residency positions.[43] This reflected the effect of mentoring and exposure to the field relatively late during general surgery residency. Shortening the overall duration of general surgery training was not favored by a 2:1 margin; if the general surgery training in preparation for colon and rectal surgery was diminished to 4 years, all acknowledge that colorectal training would extend to at least 2 years. Financial considerations for funding of 2 year residencies, as outlined above, would be a substantial impediment to this schema. Furthermore, a change to a 4/2 scheme would be disruptive to general surgery training programs, with the loss of approximately 80 chief residents.

An important factor to consider when evaluating a change in residency design/construct is that a significant percentage of practicing colon and rectal surgeons continue to perform some general surgery as part of their practice.[44] While the amount of non-colorectal tends to diminish as their practice

matures, 48% of board certified colorectal surgeons still perform general surgery to some extent. Maintaining certification in both general and colorectal surgery may be unattractive unless there can be recognition of a shared body of knowledge and some reciprocity in the accreditation process; since the numbers of general surgeons are critically low, losing that percentage of general surgery performed by colorectal surgeons because of failure to maintain certification would have negative consequences.[45]

The Program Directors in Colon and Rectal Surgery have developed an essential curriculum, which has been ratified by the ABCRS. The ASCRS, which is the educational arm of the specialty, has arranged for the publication of this curriculum as a textbook, which is based on the agreed-upon curriculum. As a living document that reflects changes in core concepts of the specialty, the curriculum has formed the basis for didactic teaching and testing in colon and rectal surgery.

Technical requirements for satisfactory completion of a colon and rectal residency are in flux. For some time the ABCRS used 17 categories developed from the case lists of applicants for board certification.[45] Deficiencies in more than five operative categories were sufficient to prevent a candidate from qualifying for examination, with the presumption that the individual had not received adequate training to become a certified specialist. While the use of a rolling average acknowledged the changing practice patterns in tertiary centers, it has become increasingly clear that numbers of cases are a poor surrogate for technical competence. Furthermore, the rather liberal allowance of five category deficiencies allowed candidates with significant inadequacies in their overall education to sit for the examination. The Colon and Rectal Surgery Blue Ribbon Committee recommended to the ABCRS that absolute minimum standards be adopted and this is currently in transition as data are collected and analyzed; it is anticipated that these new more stringent requirements will be fully operational by 2011–2012.[46,47]

Since it is increasingly clear that numbers of operative cases performed do not necessarily equate to technical competence, considerable energy must be directed at the development of formative and summative evaluation instruments for assessment of procedural training. These efforts are cosponsored by all of the parties involved in training of colon and rectal surgeons. In addition, non-technical components of training must be scrutinized and, where necessary, altered to increase their overall contribution to training. If the primary aim of residency training is to prepare safe practitioners and protect the public, then all efforts must be directed at improving our ability to do so and to continue that capability for a professional lifetime.

Continuing Medical Education

Martin Luchtefeld

Background

In today's world, the pace of increasing medical knowledge is unprecedented. The challenge for the practicing physician is to stay abreast of relevant new information in their field of practice. For the surgeon, there is the additional challenge of learning new techniques that have evolved since their surgical training period. The American Board of Medical Specialists and ACGME have attempted to define the competent physician by outlining six core competencies (Table 55-1).[1] This definition of the competent physician has gained widespread use in graduate medical education and several of these competencies speak directly to this issue of maintaining one's ability to practice medicine competently after residency: practice-based learning and improvement, medical knowledge, and patient care. Unfortunately, there is not a well-defined infrastructure to continue a practicing physician's education, such as that exists for medical students and residency/fellowship education.

In the surgical world, this problem is particularly acute. The consequences of performing procedures before being fully trained can be disastrous to the patient.

The relatively recent experience of the introduction of laparoscopic cholecystectomy illustrates the consequences of insufficient training and less-than-rigorous credentialing. When first introduced, there was a strong public demand for the laparoscopic approach to cholecystectomy. At the time, cholecystectomy was the most common procedure done by general surgeons at approximately 500,000 cases per year. A surgeon who could not do the procedure laparoscopically soon found that referrals diminished and practice suffered. As a consequence, there was a rush to provide training in the procedure. Unfortunately, there was no system in place to provide this training to the surgeon and surgical team. Courses were provided but were quite variable in the quality of education. The best courses included didactic sessions, videos, training in black boxes and procedures done in animal models that closely simulated the experience of laparoscopic cholecystectomy in humans. The courses certified attendance, but there were no specific guidelines to certify competence in the procedure. Hospitals faced the same economic pressures as the surgeons and credentialing standards and the awarding of privileges was lax. It was not uncommon for a surgeon to take a weekend course and schedule procedures the following week.[2] The result of this combination of unfortunate events was a great increase in the number of bile duct injuries.[3]

One of the concepts to emerge from this was that of the "learning curve." For cholecystectomy, the learning curve has been estimated to be 50 cases. This estimate is based on reports that 90% of bile duct injuries occur in the first 30 cases and that the calculated risk for injury is 1.7% on the first case and 0.17% on the fiftieth case.[4]

In an effort to avoid the problems encountered with the initiation of laparoscopic cholecystectomy, the American Society of Colon and Rectal Surgeons (ASCRS) approved a registry that was housed by the American College of Surgeons (ACS) Commission on Cancer and endorsed by the Society of Gastrointestinal and Endoscopic Surgeons (SAGES).[5] In addition, the ASCRS issued a position paper that colorectal cancer should best be treated laparoscopically only if the surgeon was participating in a trial or a prospective registry that would allow the evaluation of results at a later date.[6] Lastly, it was recommended that only surgeons who had performed at least 20 laparoscopic colon surgeries should attempt a laparoscopic colectomy for cancer with curative intent.[7]

Surgeons, with industry support, combined to provide a better mechanism for training and for the initiation and application of new technology. Over the past two decades, the laparoscopic approach was adopted for many procedures in addition to colectomy, such as Nissen fundoplication and bariatric surgery without the problems seen with laparoscopic cholecystectomy.

However, despite the successes of the introduction of various laparoscopic procedures, there is still a lack of a cohesive system to provide ongoing education for the practicing physician as well as lack of a defined curriculum and/or standards

1. Patient care
2. Medical knowledge
3. Practice-based learning and improvement
4. Interpersonal and communication skills
5. Professionalism
6. Systems-based practice

of accreditation. Most of the present system revolves around Continuing Medical Education (CME) credits.

CME, as defined by the Accreditation Council for Continuing Medical Education (ACCME), "constitutes educational activities that serve to maintain, develop, or increase the knowledge, skills, performance, and the relationships a physician uses to provide services for patients, the public, or the profession."[8]

History of Ongoing Education

The first requirements for CME began in 1934 when the American Board of Urology mandated this as a way to enhance specialist education of recent scientific advances.[9] CME remains the primary way that practicing physicians' document and continue their education outside of the university setting.[10] As of 2006, 56 of 68 state and territorial licensing boards require certain levels of completion of CME for recertification of their medical licenses, including all allopathic and osteopathic licensure boards in the USA and the US territories.[11]

Even though CME is a major venue for education for the practicing physician and one of the primary means of demonstrating competence, there is little evidence to support the effectiveness of CME as it is currently structured to improve patient care or outcomes.[12,13] Partially in response to this shortcoming, the AMA commissioned a task force called the "initiative to Transform Medical Education" to consider reform of all medical education, including CME. The stated goal of the initiative was to "…promote excellence in patient care by implementing reform in the medical education and training system across the continuum, from premedical preparation and medical school admission through continuing physician professional development."[14] Despite the efforts of this task force, to date, there has been very little change in the CME field.

The American College of Chest Physicians obtained support form the Agency for Healthcare Research and Quality (AHRQ) to review the data for the effectiveness of CME. The AHRQ awarded this funding to the Johns Hopkins Evidence-Based Practice Center (EPC) to do a systematic review and attempt to answer several key questions.

CME Effectiveness on Practice Performance

This review identified 105 studies that evaluated the impact of CME on physician practice performance, both short-term and long-term. A wide range of objectives was studied, including prescribing, screening, guideline adherence, and others. Even though the majority of studies reported positive outcomes, slightly less than 30% did not. Nine studies reported mixed results.[15]

This same review attempted to review the question of which media was most effective for CME. Nine of 20 studies that evaluated single live media had positive long-term outcomes. Of the remaining studies, three had mixed results, three did not change behavior, and four studies lacked a control group.

Single print media did not seem to be effective; eight of the nine studies evaluated did not meet their objectives, whereas 40 of the 57 studies using multiple media met their objective.[15]

The effects of specific educational techniques were also evaluated. Multiple techniques were included in this review: academic detailing, audience response systems, case-based learning, clinical experiences, demonstrations, discussion groups, feedback, lectures, mentoring or precepting programs, point-of-care techniques, problem-based learning, team-based learning, programed learning, readings, role play, simulations with standardized patients, and writing. Review of the eleven studies that evaluated the use of single technique suggested that there was not a positive impact on practice behavior. A number of reports evaluated either multiple techniques (76 studies) or compared multiple techniques to single technique (18 studies). While the evidence was not overwhelming, the data suggested that multiple techniques were more useful that single techniques in achieving a positive impact on practice behavior.[15]

The effect of a single exposure to CME was evaluated as was multiple exposures. Of the studies with a single exposure, just under half of the studies demonstrated a positive effect. In comparison, almost two-thirds of the studies that used multiple exposures to CME met their objectives.[15]

CME Effectiveness for Knowledge Application and Psychomotor Skills

The number of studies that are related to CME and physician knowledge application are few in number. In the EPC review, only 15 studies evaluated either knowledge application or psychomotor skills training. Even in these 15 studies, it was felt that the overall quality of evidence was low.[16] The studies on knowledge application were evaluated only in primary care physicians. Most studies (11 of 12) demonstrated

effectiveness in improving knowledge application in the short term. As might be expected, multiple exposures and longer duration led to better results.

In the realm of psychomotor skills, there were only three studies to evaluate. In all three, the methods studied all improved psychomotor skills. However, the skills being taught were simple (knee injection, flexible sigmoidoscopy, and ankle/knee exam), and there was not enough information to make recommendations regarding the optimal methods.[16]

CME: Simulation Research

Included among possible forms of CME for a colon and rectal surgeon is simulation. Medical simulation is defined as "a person, device, or set of conditions which attempts to present [education and] evaluation problems authentically. The student or trainee is required to respond to the problems as he or she would under natural circumstances. Frequently the trainee receives performance feedback as if he or she were in the real situation."[17]

There is hope that simulation may give a practicing surgeon another alternative to develop the technical skills necessary to perform a new procedure before attempting this procedure on a patient. Simulation can be done in many ways: computer models, anatomical models, solitary or team performances. Although simulation can be valuable for certain aspects of medical education, the evidence for the effectiveness of simulation in the literature is relatively weak. AHRQ issued a report whose aim was to synthesize the results of nine literature reviews on simulation.[18] However, these reviews all evaluated simulation *outside* of CME.

While the authors of the AHRQ felt that simulation was an effective method of teaching, the overall strength of the evidence was weak due to there being only a small number of studies and not much quantitative data.[19] In addition, eight of the nine reviews had a narrow focus (single medical specialty, single simulation method) and the primary studies themselves were weak.[20]

One of the reviews cited by the AHRQ was the Best Evidence Medical Education (BEME) collaboration.[19] This review was broader in scope and evaluated all best educational practices in 670 journal articles. The studies were heterogeneous enough and weak methodologically so that rather than doing a quantitative meta-analysis instead a qualitative, narrative summary was done. The authors of the review stated that "the weight of the best available evidence suggests that high-fidelity medical simulations facilitate learning under the right conditions."[19] The conditions that facilitated learning are seen in Table 55-2.

There was a subset of 31 articles with enough data to allow a quantitative meta-analysis. These studies were designed to answer the question of whether or not there was an association between hours spent on simulation-based practice

TABLE 55-2. The 10 conditions to facilitate learning

1. Feedback is provided during learning experiences
2. Learners engage in repetitive practice
3. Simulation is integrated into an overall curriculum
4. Learners practice tasks with increasing levels of difficulty
5. Simulation is adaptable to multiple learning strategies
6. Clinical variation is built into simulation experiences
7. Simulation events occur in a controlled environment
8. Individualized learning is an option
9. Outcomes or benchmarks are clearly defined or measured
10. The simulation is a valid representation of clinical practice

Adapted from Issenberg SB, McGaghie WC, Petrusa ER et al. Features and uses of high-fidelity medical simulations that lead to effective learning: a BEME systematic review. Med Teach 2005;27:10–28.[19]

and learning outcomes. Perhaps not surprisingly, there was a highly significant "dose response" between practice time and achievement.[19]

CME: Best Educational Practices

In a review of best educational practices, McGaghie et al.[20] suggested that CME best practices would have the following three elements: mastery learning, deliberate practice, and recognition that cultural barriers in the medical profession that inhibit best educational practices.

Mastery Learning

Mastery learning has a number of key elements (Table 55-3). The objective in mastery learning is to assure that the final educational objectives are met by all learners with little or no variation in outcome. It is recognized that not all learners reach these objectives at the same time. Mastery learning can be applied to technical/physical skills as well as knowledge gains, features of medical professionalism, and affective qualities.[20]

Deliberate Practice

Deliberate practice has at least nine requirements (Table 55-4) that can be considered an educational variable associated with strong education as part of the mastery learning model. Although deliberate practice is demanding of learners, it is well grounded in theories of skill acquisition and maintenance. Deliberate practice should enable constant improvement of a skill or knowledge rather than simply maintaining a certain level of competence.[20]

Cultural Barriers

There are a number of barriers to the implementation of best educational practices. Despite a paucity of research to suggest its efficacy, the current system of CME is well established,

TABLE 55-3. Elements of mastery learning

1. Baseline or diagnostic testing
2. Clear learning objectives, sequenced as units in increasing difficulty
3. Engagement in educational activities (e.g., skills practice, data interpretation, reading, focused on reaching the objectives)
4. A set minimum passing standard (e.g., test score) for each educational unit
5. Formative testing to gauge unit completion at a preset minimum passing standard for mastery
6. Advancement to the next educational unit given measured achievement at or above the mastery standard
7. Continued practice or study on an educational unit until the mastery standard is reached.

Adapted from McGaghie WC, Siddall VJ, Mazmanian PE, Myers J. Lessons for continuing medical education from simulation research in undergraduate and graduate medical education: effectiveness of continuing medical education: American College Of Chest Physicians evidence-based educational guidelines. Chest 2009;135:62S–8.[20]

TABLE 55-4. Deliberate practice requirements

1. Highly motivated learners with good concentration
2. Engagement with a well-defined learning objective or task
3. Appropriate level of difficulty
4. Focused, repetitive practice
5. Rigorous, precise measurements
6. Informative feedback from educational sources (e.g., simulators or teachers)
7. Monitoring, correction of errors, and more deliberate practice
8. Evaluation to reach a mastery standard
9. Advancement to another task or unit.

Adapted from McGaghie WC, Siddall VJ, Mazmanian PE, Myers J. Lessons for continuing medical education from simulation research in undergraduate and graduate medical education: effectiveness of continuing medical education: American College Of Chest Physicians evidence-based educational guidelines. Chest 2009;135:62S–8.[20]

and it would take considerable time, effort, and resources to overcome inertia and make significant change. Much of education in the past has been patient centered so the notion of simulation and deliberate practice is a relatively foreign idea. The practicing physician has had very little in the way of outside motivators to require the use of more demanding ongoing education.[20]

CME and Maintenance of Certification

The American Board of Opthalmic Examinations was founded in 1916 and administered its first board certification exam in 1917. Other specialty boards followed and then in 1933 the American Board of Medical Specialties was formed to "act in an advisory capacity to these boards" and to "stimulate improvement in postgraduate medical education." There are now 24 member boards of the ABMS. Certification was considered life-long but the issue of recertification was raised as early as 1936. Eventually, the rapid advance of medical knowledge lead to the recognition of the need for

recertification although the first recertification examinations were not given until 1969.[11] The next evolution of this process is Maintenance of Certification (MOC), developed and introduced by the ABMS in 2000.[21] The implication is that the practitioner is *maintaining* competence and skills on a continuous basis rather than simply *recertifying* every 5–10 years. MOC has four elements (which are a distillation of the six elements of the competent physician):

Part I: Professional standing
Part II: Life-long learning and self-assessment
Part III: Cognitive expertise
Part IV: Practice performance assessment

In order to maintain certification, diplomats of the 24 member Boards (of which the American Board of Colon and Rectal Surgery is one) of the ABMS must satisfy all four parts of the MOC process. All member Boards require certain levels of CME to fulfill the requirements of lifelong learning (Part II). CME can also impact Part IV (practice performance assessment) helping physicians address their own practice performance by CME activities.

The Future of CME

It is clear that there is a need to improve the education system for practicing physicians. ACS has attempted to address this need in one way by accrediting Education Institutes. The stated goal of these Institutes is to "focus on competencies and to specifically address the teaching, learning, and assessment of technical skills using state-of-the-art educational methods and cutting-edge technology." The Institutes, to obtain certification, must plan to use a variety of methods, including bench models, simulation, simulators, and virtual reality to ensure that participants reach predetermined levels of skill by the completion of the course. There are also plans to do education research as well to better understand the science of acquisition and maintenance of surgical competence.[22]

The concept of mini-fellowships has also arisen as a way to fill the void for the practicing surgeon who desires to learn new skills or techniques. An internet search reveals that there are mini-fellowships for a vast array of technical skills. The sponsors can be industry, academic healthcare institutions, or in many cases a combination of both. The length of time commitment ranges from 3 days to 3 months. The experience almost always involves a combination of learning techniques, including didactics, simulation, cadaver labs, and video sessions. In some of these mini-fellowships, there is also opportunity to actually participate in surgery. These educational opportunities have not been studied but by using multiple techniques of teaching they are likely to be reasonably effective.

Parker and Parikh have recommended that CME in the future include the three following elements: assessment of learner needs, program design to meet those needs, and outcome assessment.[23] In the world of colon and rectal surgery,

there are several learner needs. The most obvious of these is the need to learn technical skills related to new technology and new procedures. Another powerful driver of needs assessment is performance measures. Performance measures are drawn from a number of sources, including the American Medical Association's Physician Consortium for Performance Improvement, the National Committee for Quality Assurance, the Agency for Healthcare Research and Quality, the National Quality Forum and Centers for Medicare and Medicaid Services. Performance measures are usually derived from evidence-based clinical guidelines. CME providers should be aware of the participants' baseline knowledge of the science behind these guidelines.

In an ideal CME program, the practitioner could have learning opportunities based on their own practice performance. This would allow the physicians to compare their own data to established benchmarks and guidelines. Ultimately, this could lead to the improvement in quality and safety in the physicians' practice.

Technology has an evolving role in CME. It has already changed the way CME is delivered by way of CD-ROMs to computers to Internet-based podcasts. This has clearly made CME more accessible to the practitioner who is not based at a university or teaching facility. The emerging use of electronic medical records and computerized order entry facilitates the physicians' ability to track their own practice performance. For surgeons, the increasing complexity and fidelity of simulation enhance the learning of new techniques.

Quality

Formosa Chen, Hiroko Kunitake, Elise Lawson, Joan Ryoo, and Clifford Y. Ko

Introduction

This topic is an interesting one, in that much research has been performed in this area and much policy has been enacted to improve quality of care. While an entire set of textbooks could be written on quality of care, the aims of this chapter are more focused on perhaps what would be interesting and important to a colon and rectal surgeon.

Thus, the specific aims of this chapter are to (1) familiarize the reader with the important principles and terminology in quality of care, (2) illustrate the application of these principles using colorectal surgery specific examples, and (3) provide a working knowledge to help today's surgeons navigate an environment where quality is increasingly being emphasized.

Background

The spotlight has been on health-care quality since the publication of the Institute of Medicine reports "*To Err is Human: Building a Safer Health System*" in 1999 and "*Crossing the Quality Chasm: A New Health System for the 21st Century*" in 2001. These reports brought to the public consciousness the issues of preventable medical errors and the gap between medical knowledge and medical practice.[1,2] What was surprising was not that errors occurred or that quality was suboptimal, but the frequency and degree to which they were found. The notion that in-hospital deaths due to preventable medical errors represented the eighth leading cause of death in the USA was alarming to providers and patients alike.

In the decade since the publication of these reports, the quality movement has intensified, and health-care quality measurement and assurance have become major topics at the forefront of health-care regulation and reform. Fueled by sensational stories in the popular media and the ready availability of information on the Internet, consumers are also learning to demand more from their health-care providers. Multiple stakeholders are involved in the quality movement, including the federal and state governments, insurance companies, employer groups, hospitals, physicians, and patients. Today, it is no longer possible to practice medicine without being confronted by the daily demands for higher quality care.

Defining "Quality" in Health Care

Defining quality of care is difficult because of the different viewpoints on what quality is and how it is defined. Avedis Donabedian wrote: "The definition of quality may be almost anything anyone wishes it to be, although it is, ordinarily, a reflection of values and goals current in the medical care system and in the larger society of which it is a part."[3] Currently, the most commonly cited definition of quality of care comes from the Institute of Medicine (IOM):

> Quality of care is the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge.[4]

Even with such a concisely worded definition, challenging issues arise. Whose desired outcomes? Do the patient's or provider's desires matter more? How do we measure these outcomes? What is and who determines the current professional knowledge? To focus the agenda on quality improvement, the IOM has proposed six key dimensions of quality as areas for emphasis and additional research. They propose that a health system should be safe, effective, patient-centered, timely, efficient, and equitable. Each of these dimensions is addressed to some extent in this chapter.

Regardless of how each stakeholder and organization defines and prioritizes "quality," it is perhaps more important to understand how quality is conceptualized, how it is measured, and how these concepts and measurements impact patients, providers/surgeons, and the practice of health care. These themes provide the structure for the following sections of this chapter.

The History of Quality in Surgery

Despite the recent acceleration of the quality movement, awareness of the significance of quality of care in surgery arose nearly a century ago with Dr. Ernest Codman, a surgeon who began his career in Boston at the Massachusetts General Hospital. Dr. Codman proposed the "end result system" in which doctors would follow up their patients to determine the results and complications of treatment and make these findings public. He lost his staff privileges in 1914 when he proposed that surgeon competence should be evaluated, and he eventually established his own hospital to pursue performance measurement and improvement objectives. Dr. Codman was one of the founders of the American College of Surgeons and later the Joint Commission on the Accreditation of Hospitals. Dr. Codman's pursuit of surgical outcomes and his endorsement of transparency in medical care are now part of the foundation upon which we strive to improve surgical quality in the USA.

Influenced by Dr. Codman's efforts to improve the quality of care through the self-examination of clinical practice, in 1935, the Philadelphia County Medical Society established the Anesthesia Mortality Committee, the antecedent to the now familiar Morbidity and Mortality Conference.[5] Later renamed the Anesthesia Study Commission, they published a report in 1947 stating that at least two thirds of fatalities reviewed were classified as preventable.[6] Morbidity and Mortality conferences are now a required educational activity mandated by the Accreditation Council for Graduate Medical Education (ACGME) for all residency programs, although conferences vary in their effectiveness in terms of quality evaluation and improvement.

One century ago, surgeons who championed the need for examining their own quality of care were shunned. Today health-care quality improvement and assurance are incentivized and increasingly regulated. The methodologies used to evaluate care have evolved from the examination of experiential case series to the ability to perform complex and sophisticated statistical models and comparisons. Thus, one

of the goals of this chapter is to try to simplify the state of the knowledge in health-care quality so that surgeons can apply it to their clinical practices. Instead of being driven by the external forces of change, surgeons should probably be drivers of quality improvement in their practices to benefit their patients.

A Conceptual Model of Quality of Care: The Donabedian Model of Quality of Care

Many have strived to develop means of understanding the multiple components of our complex and fragmented health-care system. One approach has been through the use of conceptual models. One of the most commonly used models for thinking about health-care quality is the Donabedian Model of Quality of Care, originally described by Avedis Donabedian as three *distinct* aspects of "outcome, process, and structure."[3] The model was later refined into a causal chain of the three interrelated components of (1) structure, (2) process, and (3) outcome (Figure 56-1). In this model, structure facilitates the processes of care, and both in turn impact outcomes. Each of these components is defined and discussed in further detail in the following sections.

The Donabedian Model (Part 1): Structure

"Structure" in the Donabedian model refers to the characteristics of the setting and providers in and through which health care takes place. Structural measures can describe entities as broad as the overall health care system or as specific as an individual physician.

Structural Measure at the Health System Level

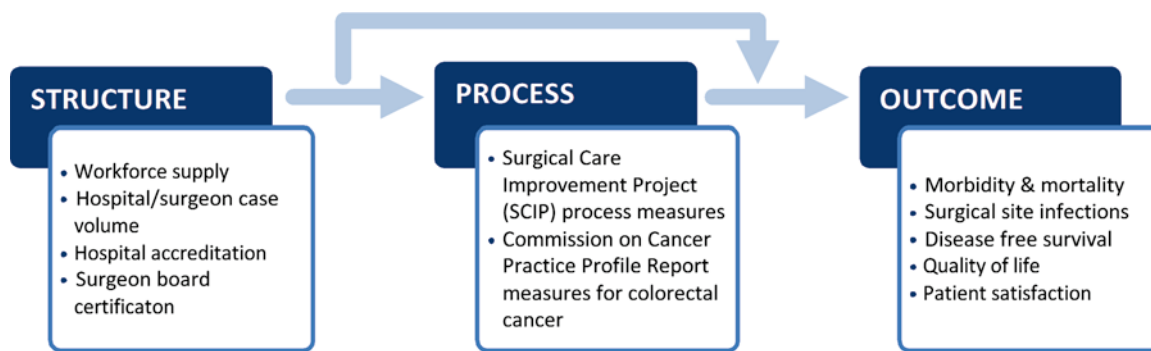
An example of a structural measure that assesses quality at the level of the overall health-care system is the adequacy of the health-care workforce to meet the needs and demands of the population that it serves. An inadequate physician


FIGURE 56-1. The Donabedian Model of Quality of Care: Interrelated components of structure, process, and outcome.

supply can lead to decreased access to appropriate specialists, delays in receipt of essential services, and worsened population health-related outcomes. The extremes of surgical workforce shortages are illustrated in developing countries such as Sierra Leone where there are four obstetricians in a country of 6 million (0.13 per 100,000 population)[7] or Uganda where there are 75 general surgeons serving a population of 30 million (0.25 per 100,000 population).[8] In contrast, on average there are 45 surgeons per 100,000 population in the USA. Despite this, surgical workforce shortages in the USA have been projected in multiple subspecialties by multiple studies.[9–14] A recent study by Williams et al.[11] has projected an imminent shortage of 1,300 general surgeons in the USA by 2010. The Association of American Medical Colleges (AAMC) also predicts a shortage of 124,000 physicians by 2025, with 33% of the shortage occurring in surgical specialties.[15] The AAMC has responded to the projected physician shortage by backing the Resident Physician Shortage Reduction Act of 2009, which proposes to increase the number of Medicare-supported residency positions by 15,000 slots, a 15% increase. However, this bill has stalled in Congress since its introduction in May 2009. While there are no studies specifically examining the projected workforce adequacy of colorectal surgeons, Etzioni et al.[10] projected a 47% increase in the number of oncologic colon and rectal resections between 2000 and 2020. Using different data sources, Etizioni et al.[16] also found that the demand for outpatient and inpatient colorectal procedures will increase by 21.3% and 40.6%, respectively, between 2005 and 2025.

Some researchers contend that overall there is no personnel shortage, but rather a misdistribution of surgeons between oversaturated and underserved areas.[17] Nevertheless, most studies agree that the growing elderly population will increase the demand for surgical services. Whether recent and upcoming policy changes to address the workforce shortage or whether market forces to affect the redistribution of surgeons can overcome the projected crisis is still to be seen. However, colorectal surgeons will certainly be faced with the challenge of providing more services to an expanding elderly population in an environment where surgeons will increasingly be held accountable for their outcomes. In the Donabedian model, the projected shortage of surgeons represents a potential structural flaw which will affect downstream processes and outcomes.

Structural Measure at the Institution Level

Examples of structural measures at the institution level include hospital accreditation status, nurse-to-patient ratios, availability of specialty services (e.g., interventional radiology, transplant services, etc.), teaching status or affiliation with academic institutions, and hospital volume.

Accreditation is a stamp of approval given to an institution, such as a hospital, or a cancer center by a respected authority, such as the Joint Commission on the Accreditation of Health Care Organizations or the Commission on Cancer of the American College of Surgeons, after a series of minimum qualifying criteria or benchmark standards have been met. Accredited institutions are believed to be of higher quality because they meet the stringent criteria of the accrediting body. From an institutional standpoint, accreditation activities are often integral to performance and quality improvement efforts. The pros of accreditation are as follows: (1) it provides a standardized evaluation of institutions that facilitates benchmarking and comparison; (2) preparing for and undergoing accreditation can promote organizational change and result in better cultures and systems for quality improvement; (3) being labeled "high quality" can lead to more patient referrals; and (4) some studies have found that accreditation is associated with higher quality care.[18] The cons of accreditation are as follows: (1) the process can be bureaucratic, administratively burdensome, and costly; and (2) some criticize accreditation as a superficial exercise with little bearing on actual quality. A systematic review of accreditation studies by Greenfield et al.[19] found no consistent relationship between accreditation status and quality indicators, with some studies showing a positive association and others showing no relationship between the two. In colorectal surgery, supporters of accreditation have proposed that accrediting programs for rectal cancer or inflammatory bowel disease may be beneficial in promoting higher quality and more standardized care for these patient populations. To date, potential programs such as these have remained solely in the "discussion" phase.

The topic of hospital volume, or the volume–outcome relationship, has also recently received increasing attention in the surgical literature. The volume–outcome relationship is the observed association between provider case volume and patient outcomes, usually with increasing provider volume (hospital or surgeon) associated with improved patient outcomes. This was first described in the surgical literature in 1979 by Luft et al.[20] who looked at mortality rates in 12 surgical procedures across 1,498 hospitals. The majority of studies examining the volume–outcome relationship have focused on short-term perioperative mortality, with fewer studies examining other outcomes such as long-term survival, cancer recurrence, length of stay, cost of care, and postoperative complications. A meta-analysis performed by Gruen et al.[21] examined the volume–outcome relationship between provider volume and mortality for six gastrointestinal cancers (esophagus, stomach, liver, pancreas, colon, and rectum). Using unadjusted mortality results from 101 publications, this group found a statistically significant inverse relationship between hospital volume and short-term perioperative mortality for all cancers except rectal cancer. However, they also noted that one-third of the reviewed studies found no association between hospital or surgeon volume and mortality. A systematic review performed by Killeen et al.[22] summarized the findings of 16 studies examining the

volume–outcome relationship in colorectal cancer resection and concluded that the evidence supported a significant inverse relationship between volume and the outcomes of in-hospital mortality, 30-day mortality, and 5-year survival. However, the magnitude of the volume effect on mortality was small.

Other areas in colorectal surgery where a consistent volume–outcome relationship has been demonstrated include the increased use of laparoscopic and sphincter-sparing procedures by high-volume providers.[23–27] Most studies looking at the harvesting of lymph nodes in cancer procedures have found a significant volume–outcome relationship.[28–31] Studies examining postoperative complications have had mixed results.[29,31–37] With regard to benign colorectal diseases, two studies found that higher hospital volumes are associated with lower mortality following surgery for inflammatory bowel disease.[38,39] One study found that high-volume hospitals and surgeons were more likely to perform laparoscopic instead of open resections for diverticular disease. Studies examining cost of care have found that high-volume providers have shorter lengths of stay and in-hospital costs.[31,34,40,41]

Proponents of the volume–outcome relationship argue that regionalizing high-risk procedures to select high-volume providers can save patient lives. Critics argue that it is unclear whether increased volume leads to improved quality or whether high-quality care attracts more volume. They also argue that volume measures penalize low volume but high-quality providers. Regionalization policies may also adversely affect patient access to care and continuity of care if they are limited to select high-volume facilities that may be further away or outside of their list of usual providers. Given that the volume–outcome relationship is not consistently demonstrated across studies, some argue that volume is an imperfect proxy for quality.

Despite the ongoing controversy, health-care payers have incorporated structural measures into their criteria for "Centers of Excellence" to incentivize patients to utilize qualifying facilities or providers. A notable example is the Leapfrog Group's "Evidence-Based Hospital Referral" (EBHR) recommendations in which they establish a minimum annual hospital volume for seven higher-risk surgical procedures as a referral criteria and encourage purchasers, be they insurance companies or employer groups, to use their "leverage" to recognize and reward hospitals that meet EBHR standards.[1] Volume may solely be a proxy measure of quality, but it is increasingly being used by payers to determine referral patterns and may ultimately impact where surgeons choose to practice and the procedures they perform.

---

[1] The Leapfrog Group is a consortium of large employers that focuses on health-care quality. Their "Evidence-Based Hospital Referral" recommendations can be found at http://www.leapfrog-group.org/media/file/Leapfrog-Evidence-Based_Hospital_Referral_Fact_Sheet.pdf.

Structural Measure at the Practitioner Level

Examples of structural measures at the practitioner level include board certification and subspecialty training. Recently, there has been controversy surrounding the use of board certification as a colon and rectal surgeon as a marker for surgical quality in contrast to general surgeons. Board certification as a colon and rectal surgeon requires successful completion of an ACGME approved training program in general surgery and one additional year in an ACGME approved colon and rectal surgery residency. The candidate must then pass both the written (qualifying) and oral (certifying) examinations given by the American Board of Colon and Rectal Surgery. Overall, studies have generally shown improved outcomes for surgeons with specialty training.[42–45] A systematic review by Bilimoria et al.[43], which examined the effect of surgeon training and specialization on outcomes following colorectal cancer surgery, found lower recurrence rates in five out of the ten studies and improved long-term survival in seven of the ten studies for colorectal trained surgeons.[43] However, it was unclear if the additional training or having a specialized practice was responsible for the difference in outcomes. A study by Prystowsky et al.[46] found that American Board of Surgery (ABS) certification was associated with reduced mortality and morbidity but colorectal surgery training did not significantly affect outcomes. In this study, increasing years of experience was associated with reduced mortality. Board certification and specialty training are two examples of structural components which interact with structural components at the institutional and health-system level to influence process and outcome in the care of the colorectal surgery patient.

The Limitations of Structural Measures of Quality

There is a great deal of literature examining structural measures of quality and their association with patient outcomes. Evidence supporting the validity of these measures has prompted policy makers to adapt and apply these measures to influence health-care utilization patterns. However, the most significant downside to structural measures is their relative immutability, especially from the perspective of an individual surgeon. While structural measures may have an important role in policy discussions and population-based planning, there may be little that the surgeon can change in the structure of their practice to ultimately impact patient outcomes.

The Donabedian Model (Part 2): Process

Process refers to what providers do to the patient or do for the patient. Everything that occurs in the continuum of patient care constitutes a process of care. The literature contains numerous clinical practice guidelines that describe treatment processes and algorithms that comply with the standard of care or represent best practices. An example is the National Comprehensive Cancer Network

TABLE 56-1. An example of the distinction between a clinical guideline and a good measure

ASCRS practice parameter for the prevention of venous thrombosis [48]	Surgical care improvement project (SCIP) VTE prophylaxis process measure
Patients in the moderate-risk to high-risk categories for VTE undergoing abdominal surgery should receive prophylaxis with unfractionated (LDUH) or low-molecular-weight heparin (LMWH). Patients at risk for bleeding may receive mechanical prophylaxis instead.	*Numerator Statement*: Surgery patients who received appropriate venous thromboembolism (VTE) prophylaxis within 24 h prior to *Anesthesia Start Time* to 24 h after *Anesthesia End Time.* *Denominator Statement*: All selected surgery patients

TABLE 56-2. Examples of process measures in colorectal surgery

Name	Description and general application
Surgical Care Improvement Project (SCIP) process measures	Measures appropriate use of perioperative prophylactic antibiotics (selection, timing, and discontinuation), use of clippers for hair removal (instead of razors), immediate postoperative normothermia, use of venothromboembolism prophylaxis (selection and timing), continuation of perioperative beta-blockers, and removal of urinary catheters by postoperative day 2. Applicable to all surgical patients
National Quality Forum National Voluntary Consensus Standards for Quality of Cancer Care	Includes four colorectal cancer quality measures addressing the removal and examination of at least 12 lymph nodes in colon cancer resections, the completeness and quality of pathology reporting, and the timeliness of adjuvant chemotherapy in stage III colon cancer
National Initiative for Cancer Care Quality (NICCQ) quality indicators for colorectal cancer	Set of 25 indicators addressing multiple clinical domains. Measures cover diagnostic testing, pathology reporting, documentation, referrals to specialists, timing and receipt of treatment, technical quality of care, and respect for patient preferences. Applicable to stage II–III colorectal cancers

(NCCN) Practice Guidelines in Oncology.[2] Becoming more popular and commonplace are similar concepts – that being process measures or quality indicators. These are also processes that have been identified to be associated with high-quality care and have been developed into tools that can quantitatively measure how frequently these processes take place during patient care.

The difference between practice guidelines and process measures is that guidelines are often qualitative recommendations that often include gray areas of variable appropriateness, allowing for a physician's clinical judgment and patient preferences. In contrast, process measures are quantitative measurements, have simplistic measurement algorithms, and can be used to set standards of care.[47] Table 56-1 is an example of the distinction between a clinical guideline and a process measure.

The ASCRS practice parameter proposes the recommended care but uses words like "should" and "may," leaving the ultimate treatment decision up to the surgeon. The SCIP process measure on the other hand quantifies within a specific surgical population, the percentage of patients who actually received appropriate VTE prophylaxis within a defined 48 h window.

A good process measure has the following characteristics: (1) it is explicit in its inclusion and exclusion criteria (denominator); (2) it is rigid in its requirements for satisfying the process (numerator); and (3) it is linked to outcomes. Because good process measures are linked to quality of care, they are often called "quality indicators."

Examples of process measures or quality indicators include the Surgical Care Improvement Project (SCIP) process measures, the National Quality Forum National Consensus Standards for Quality of Cancer Care, and the National Initiative for Cancer Care Quality (NICCQ) quality indicators for colorectal cancers (Table 56-2).[48–50] These quality indicators establish the standard of care that patients should receive; they are explicit, quantitative, and evidence-based, and there is a growing trend by regulatory bodies and payers to use such quality indicators to set standards for appropriate care.

SCIP measures are reported to the Joint Commission and the Center for Medicare and Medicaid Services (CMS). These measures include the use of perioperative prophylactic antibiotics, the use of clippers for hair removal, immediate postoperative normothermia, the use of venothromboembolism prophylaxis, continuation of perioperative beta-blockers, and the removal of urinary catheters by postoperative day 2. Data collection on SCIP measures began in 2004 and has since become the focus of many institution-wide quality improvement (QI) efforts.

The utility of process measures or quality indicators lies in their ability to be measured and improved. As such, QI programs are often developed around indicators like the SCIP measures. Data collection and indicator measurement can be accomplished either prospectively or retrospectively and are often carried out by a nurse abstractor. Following baseline measurement of an organization's adherence to a set of quality indicators such as the SCIP measures, tailored

---

[2] The National Comprehensive Cancer Network (NCCN) Practice Guidelines in Oncology can be found at http://www.nccn.org/professionals/physician_gls/f_guidelines.asp.

interventions can then be designed and implemented to target areas of poor performance. The effectiveness of the QI program is demonstrated by improvement in adherence rates to the indicators. The ultimate goal of these QI programs is to improve patient outcomes by improving the delivery of specific processes of care.

The strength of the association between quality indicators and patient outcomes is based on the validity of the underlying scientific evidence. The development of process measures or quality indicators is often accomplished using Delphi methods that combine best evidence and expert opinion.[51] Follow-up studies examining the association between adherence to the quality indicators and patient outcomes are ultimately necessary to confirm the clinical validity of the measures. An example is a study by Pastor et al. examining the relationship between adherence to the SCIP measures and surgical site infections (SSI) in colorectal surgery patients. They found no significant reduction in the rate of SSI, despite significant improvements in compliance with the SCIP measures.[52] Studies like this raise the question of whether expending significant resources to improve performance in SCIP measures is actually improving patient outcomes. However, more studies are ultimately necessary to prove or disprove the validity of the SCIP measures.

One of the best ways to identify processes of care is through randomized controlled trials (RCTs). In point of fact, RCTs are considered the most reliable and impartial methods for determining which medical interventions work the best. Within colorectal surgery, the majority of clinical trials focus on new chemotherapy regimens or surgical techniques. Table 56-3 lists many of the colorectal-relevant randomized clinical trials published in the last 2 years. Although RCTs provide valuable information regarding specific treatment regimens, they are limited by the restricted selection of clinical trial participants, and therefore the results may not be absolutely generalizable to specific patients.

Limitations of Process Measures

One of the limitations of process measures is that it is often difficult to prove that performance of a process measure directly results in improved patient outcomes. Very few processes performed in clinical practice are substantiated by level I evidence (based on at least one well-designed randomized clinical trial). A second limitation is that there are no validated quality indicators for many areas in surgery where quality improvement may be warranted. The development of new and validated indicators can be an expensive, complex, and time-consuming process, making it prohibitive for some organizations wishing to develop their own tailored indicators. A third limitation is that data collection to measure adherence to process measures or quality indicators is often labor- and cost-intensive. Successful QI efforts require the buy-in of stakeholders at multiple levels within an organization, physician champions as well as adequate financial resources. Finally, outside of commonly used indicators such as the SCIP measures, there may be limited benchmarks against which an organization's performance can be compared. In the absence of benchmarks for comparison, QI programs often set an arbitrary goal of 85% or 90% compliance as their mark for success.

The Donabedian Model (Part 3): Outcomes

Outcomes are the end result of receiving health care. Traditionally, surgeons have examined their outcomes through morbidity and mortality conferences. In particular, these conferences focus on adverse outcomes of care. The objectives of outcome measurement are to evaluate and compare providers as a means to inform providers and patients, adjust financial compensation, and facilitate quality assurance and improvement.

In order to make valid comparisons between providers, appropriate patient risk adjustment must be performed. Risk-adjusted outcomes take into account the impact that patient characteristics and the context of care have on their outcomes. A simple way to think about risk adjustment is described by this equation by L.I. Iezzoni:

$$\text{Patient factors} + \text{Effectiveness of care} + \text{Random variation} = \text{Outcome}.$$

"Patient factors" represent the patient's variables, such as their diagnosis, age, gender, socioeconomic status, comorbidities, and illness severity. "Effectiveness of care" relates

to the nature of the intervention being studied. For example, surgical resection of a stage I cancer is more likely to result in a cure compared to surgical resection of stage IV cancer. The differential impact of the same treatment in different clinical contexts must also be considered when performing adequate risk adjustment. "Random variation" is perhaps best described by the saying: "You can do everything wrong and have a good outcome, and you can do everything right and have a bad outcome." The effect of random variation or "chance" is particularly significant when working with a small number of patients. An example where risk adjustment makes intuitive sense is when providers who care for older, sicker, and more complicated patients have higher mortality rates. Without appropriate risk adjustment to "level the playing field," it would be uninformative to compare outcomes across providers. The statistical methods for performing risk adjustment on outcomes data are sophisticated and complex and are beyond the scope of this chapter. For an in-depth examination of risk adjustment in measuring health-care outcomes, consider *Risk Adjustment for Measuring Healthcare Outcomes* edited by Lisa Iezzoni.[53]

Organizations often bypass the complexity of performing their own risk adjustment on outcomes data by relying on other organizations to do it for them. An example is the American College of Surgeons' National Surgical Quality Improvement Project (NSQIP). NSQIP first began as the National Veterans Administration Surgical Risk Study (NVASRS), which developed risk models for 30-day mortality and morbidity in nine surgical subspecialties to facilitate comparison of surgical outcomes at Veterans Administration (VA) hospitals to the national average. NVASRS allowed for the first time a comparison of surgical quality across surgical subspecialties and VA hospitals across the country. With its success, NVASRS then evolved into an ongoing quality improvement program known as the National Surgical Quality Improvement Project. In 1999, NSQIP was piloted in three non-VA hospitals, demonstrating that it was feasible to collect and analyze data using NSQIP risk-adjusted models in non-VA settings. Since 2001, with funding from the Agency for Healthcare Research and Quality (AHRQ), the American College of Surgeons has expanded NSQIP data collection to include over 250 private sector hospitals. NSQIP allows hospitals to submit their own data, compare their risk-adjusted outcomes to a national average, and identify areas in surgical care where their rates of mortality or complications are higher than expected based on their patient population.

In addition to objective or "hard" patient outcomes such as mortality or complications, there are also subjective patient-reported outcomes such as patient satisfaction, functional status, and quality of life. These areas of outcome measurement have received increasing attention in the era of patient-centered health care.

In the colorectal surgery literature, there are increasing numbers of studies focused on patient-reported sexual function, general health, quality of life, and satisfaction following colorectal surgery, given that many patients will favor quality of life over quantity of life. [54–62]

Using a multitude of survey instruments which address physical function, clinical symptoms, quality of life, and patient satisfaction, patient-reported outcomes aim to define the critical component of health care which is not captured in administrative or clinical data – the patient's perspective. Now, as we strive to improve quality, particularly in the context of pay-for-performance and patient-centered care, patient-reported outcomes have been recognized as a key component in the measurement of health-care quality. For the practicing surgeon, quality-of-life instruments and the results of quality of life studies highlight areas of importance to the patient which may need to be addressed during the provision of care.

There are many validated instruments available to evaluate physical function, clinical symptoms, and quality of life, and there are increasing numbers of instruments being developed for colorectal patients (Table 56-4).[63–79] Patient-reported outcomes survey instruments. For example, colorectal cancer-specific instruments include the European Organization for Research and Treatment of Cancer (EORTC) CR-38 and Functional Assessment of Cancer Therapy-Colorectal (FACT-C). To give a flavor of the content of these two instruments, they both are briefly discussed below.

The EORTC is one of the largest clinical trial groups in Europe which has focused on developing cancer-specific questionnaires and site-specific questionnaires to evaluate quality of life in cancer patients. The EORTC CR-38 was designed as a supplement to the core questionnaire, EORTC QLQ-C30, for use in colorectal cancer patients participating in international clinical trials. The EORTC CR-38 consists of 38 items covering symptoms and side effects related to different treatment modalities, body image, sexuality, and future perspective.[78,79] Nineteen questions are completed by all patients, and the remaining 19 questions are specific to certain subsamples of patients such as male or female gender or presence of a stoma. The CR-38 consists of two functional scales, body image and sexuality, and seven symptom scales: micturition, gastrointestinal, chemotherapy, defecation, stoma, male and female sexual problems. Together with the EORTC QLQ-C30, the CR-38 provides a comprehensive assessment of quality of life in colorectal cancer patients over a wide variety of stages and treatments.

The FACT-C combines the Functional Assessment of Cancer Therapy-General (FACT-G), a 27-item general questionnaire of health-related quality of life in patients with cancer or other chronic illness, with a nine-item Colorectal Cancer Subscale (CCS). The FACT-C contains five subscales, namely, EWB (Emotional Well-Being), SWB (Social Well-Being), FWB (Functional Well-Being), PWB (Physical Well-Being), and CCS (Colorectal Cancer Subscale), and assesses quality-of-life concerns pertinent to colorectal cancer patients.[72]

TABLE 56-4. Patient-reported outcomes survey instruments

Area	Survey instrument	Description	Specific for cancer patients?
Clinical symptoms	Fatigue Symptom Inventory [63,64]	Measurement of fatigue intensity, duration, and interference with daily functioning	Yes
Clinical symptoms	Brief Pain Inventory [65,66]	Assessment of pain severity, location, and impact on function	Yes
Clinical symptoms	Neurotoxicity Scale (NTX-12) [67]	Evaluate sensory and motor symptoms, auditory problems	Yes
Physical function	Instrumental Activities of Daily Living (IADL) [68]	Assessment of independent living skills (e.g., using the telephone, shopping, paying bills)	No
Quality of life	Impact of Cancer [69,70]	Measurement of positive and negative impacts of cancer	Yes
Quality of life	Life Orientation Test [71]	Measurement of optimism and pessimism	No
Quality of life	Functional Assessment of Cancer Therapy-Colorectal (FACT-C) [72]	Assessment of physical, mental, social well-being	Colorectal cancer specific
Quality of life Clinical symptoms Physical function	SF-36/SF-12 [73–77]	Summary physical health and summary mental health scores	No
Quality of life Physical function	European Organization for Research and Treatment of Cancer (EORTC) CR-38 [78,79]	Evaluate quality of life and function of colorectal cancer patients Y	Colorectal cancer specific

Overall, as quality of life becomes an increasingly evaluated outcome metric of quality of care, it is important that providers understand the instruments and their content.

Limitations to Outcome Measures

Ultimately, the goal of quality-of-care research, measurement, and improvement efforts is to improve patient outcomes. To this end, health-care researchers and providers often look directly to outcome measures which inform us only of the end result of care. The limitation of this is that when there are poor outcomes, outcome measures alone do not identify a specific structure or process that can be changed to alter the result of care. A thorough assessment of outcome measures must be performed in the context of structure and process to be completely understood. A second limitation of outcome measures, some argue, is that the overemphasis on adverse outcomes may encourage providers to "cherry pick" their patients. Proponents of risk-adjusted outcomes maintain that appropriately applied risk models can overcome the bias of patient selection. However, appropriate risk adjustment can be complex, costly, and prohibitively expensive for smaller organizations without the resources to obtain the necessary expertise or services.

Summarizing Structure, Process, and Outcome

Beauty lies in the eyes of the beholder. What is considered important or valid in quality depends on one's viewpoint. What health-policy planners or hospital administrators care about may be vastly different from what the surgeon or patient focuses on. Each component of the Donabedian model – structure, process, and outcome – describes and evaluates distinct aspects of quality within the overall health-care system. Quality measures have been developed, applied, and validated by different stakeholders in all three components for different purposes, each with its proponents and critics. Some would argue that the ultimate endpoint is patient outcomes. But others would counter that if doing the "wrong thing for the wrong patient at the wrong time in the wrong way" results in a good outcome, then that should not be considered good quality care. There is, unfortunately, no single perfect quality metric that serves as an adequate proxy for overall quality. Therefore, we will continue to utilize these imperfect measures of quality, with a full understanding of their strengths and limitations, even as we continue to develop and validate new ways of understanding and measuring quality of care.

Quality of the Data

Evaluating, measuring, and improving quality of care is important. Yet, one of the main difficulties with measuring and improving quality in all of health care, including colorectal surgery is the quality and availability of data. It remains important that all providers understand some of the intricacies of data – including the source of data, who collects the data, and what data are collected in the context of analysis. As all providers rely on data to define quality and to guide them in delivering better care, it is paramount that the data are of high quality. In point of fact, the well-known phrase, *Garbage In*, *Garbage Out*, reminds us that we absolutely need high-quality data to make valid

conclusions and achieve high-quality care. Ideally, to evaluate the quality of colorectal surgery care, a database would capture comprehensive detailed information about the patient, their disease, the procedure and treatments they received, the provider, all outcomes from wound infection to disease recurrence and reoperation, patient's quality of life and function, mortality, and cost. However, creating such a database would be prohibitively expensive both in terms of manpower and cost. Instead, colorectal surgeons must depend on a large number of existing databases which capture different aspects of structure, process, and outcome, and assimilate the results from each to gauge what is quality care.

Currently available *sources* of data may be divided into two main types: administrative databases and clinical databases. Administrative databases such as the Medicare claims database, the National Hospital Discharge Database, and statewide hospital discharge databases (e.g., the California inpatient file, managed by the Office of Statewide Health Planning and Development, and the Statewide Planning and Research Cooperative System (SPARCS), managed by the New York Department of Health) record admissions, diagnoses, and procedures from administrative/billing claims. Clinical databases such as the Society of Thoracic Surgeons Registry, Surveillance Epidemiology End Result (SEER) of the National Cancer Institute, and National Surgical Quality Improvement Program (NSQIP) of the American College of Surgeons use chart abstractors and hospital registrars to record patient-level clinical data such as comorbidities and search for evidence of wound infections, urinary tract infections, cancer recurrence, and other clinical outcomes. There are also research-focused databases relevant to colorectal surgery such as the Cancer Care Outcomes Research and Surveillance Consortium (CanCORS) which combines medical record abstraction, patient surveys, and provider surveys in an attempt to provide a more complete assessment of the experience and outcomes of the colorectal surgery patient.

Advantages of administrative databases include access to large amounts of demographic and procedural data on large population-based samples which is easily compiled. However, administrative databases are limited by the lack of clinically meaningful data. Clinical databases provide clinical findings such as wound infections and patient outcomes. However, intensive resource expenditures are usually necessary to collect this data by chart abstraction and individual patient assessment.

An important issue to recognize in terms of data quality is identifying who is *collecting the data*. A number of databases or clinical registries have relied upon surgeons or other providers to collect the data. Other databases, such as cancer registries, rely upon a third party such as a trained and audited cancer registrar to collect the data. A number of studies have demonstrated that "third party"

data collectors tend to have higher clinical accuracy. As increasingly more "clinical" data are being used to evaluate and improve quality, knowing the source of data, who collected the data, and what variables will be collected will be important.

Appropriateness and Appropriateness Criteria

Background

An appropriate procedure has been defined as one in which "the expected health benefit (e.g., increased life expectancy, relief of pain, reduction in anxiety, improved functional capacity) exceeds the expected negative consequences (e.g., mortality, morbidity, anxiety, pain, time lost from work) by a sufficiently wide margin that the procedure is worth doing, exclusive of cost."[80] Appropriateness criteria are a method of explicitly delineating and weighing these benefits and harms, based on evidence in the literature and the clinical judgment of a multidisciplinary panel of physicians. Once developed, the criteria can be retrospectively or prospectively applied to systematically assess the appropriateness or overuse and underuse of a procedure. They can also be used as clinical decision aides to guide shared decision making between the surgeon and patient. Numerous studies have shown that patients have better outcomes when they are treated according to appropriateness criteria.

Currently, a systematic review of the literature has identified a gap in the availability of appropriateness criteria in surgery, with criteria being formally developed for only 18 procedures including coronary artery bypass grafting, colonoscopy, cataract surgery, and carotid endarterectomy (unpublished data). Targets for appropriateness criteria development are typically procedures that are commonly performed, have elevated risk of morbidity and mortality, and/or utilize significant resources. Procedures with documented variation in use among different geographic areas have also been prioritized in the past. The amount and quality of scientific literature describing the procedure are also important considerations.

Development of Appropriateness Criteria

The gold standard for decision making in health care is the randomized controlled trial. Unfortunately, for most procedures, these trials have not been attempted, and if performed, they cannot be generalized to a wider patient population. Appropriateness criteria compensate for these gaps in the literature by combining available scientific evidence with expert clinical judgment. The RAND/UCLA Appropriateness Method (RAM) is a commonly used technique for the development of appropriateness criteria.[81]

Use of Appropriateness Criteria

Numerous studies have documented significant variations in health-care delivery across different patient populations. The Dartmouth Atlas, for example, reports geographic differences in rates of procedures performed that cannot be explained by differences in the patient population alone. It has been hypothesized that this variation may be due to the inappropriate overuse and underuse of procedures in different regions of the country. Appropriateness criteria have been applied retrospectively to systematically investigate this hypothesis. Although few studies have been performed in colorectal surgery, it is important to discuss and understand some of the seminal work that has been performed in other areas to inform this topic. Many future studies will likely be performed in colorectal surgery.

One of the earliest studies to use appropriateness criteria to study variations in procedure use was published in 1987 by Chassin et al.[82] who analyzed the use of coronary angiography, carotid endarterectomy, and upper gastrointestinal endoscopy in hospitals that were preidentified as being high, average, or low users of these procedures. By applying appropriateness criteria, the researchers found significant rates of inappropriate use for each procedure: 17% of cases for angiography, 32% for carotid endarterectomy, and 17% for endoscopy. Statistically significant differences in the rates of appropriate procedure performance were found for coronary angiography and endoscopy between high- and low-use hospitals, but the differences were small. Of note, the authors suggested that the variation between high- and low-use hospitals may be the result of both underuse and overuse.[82]

Studies have also been performed to determine if the use of appropriateness criteria affects clinical outcomes. Hemingway et al.[83] followed a cohort of consecutive patients undergoing coronary angiography at three London hospitals. Appropriateness criteria for percutaneous transluminal coronary angioplasty (PTCA) and coronary artery bypass grafting (CABG) were applied to these patients, and their treating physicians were blinded to the results. These patients were then followed for a median of 30 months, and their clinical outcomes were recorded. The researchers found that 34% of patients for whom PTCA was rated appropriate were treated medically instead. These patients were significantly more likely to experience angina compared to the patients treated with PTCA. Twenty-six percent of the patients for whom CABG was considered appropriate were treated medically. These patients were significantly more likely to die or have a nonfatal myocardial infarction compared to patients who underwent CABG. The researchers concluded that underuse was associated with adverse clinical outcomes.[83] Finally, a graded relationship between appropriateness rating and outcome was observed, meaning that patients who underwent a procedure and had received a high appropriateness score had better outcomes than those who underwent the procedure and had a lower score.

Apart from research and setting standards, appropriateness criteria are also developed for use as clinical decision aids. The American College of Cardiology Foundation, along with several partner societies, has published appropriateness criteria for coronary revascularization. These criteria are meant to provide guidance for patients and clinicians in discussions regarding revascularization and are also used for reviewing utilization patterns. They are explicitly not meant to replace clinical judgment and practice experience.

The American College of Radiology (ACR) has developed appropriateness criteria for a broad range of therapeutic and diagnostic topics to reduce inappropriate utilization of radiologic services. Radport is a decision support system that uses the ACR appropriateness criteria to guide the ordering of diagnostic imaging. A "utility score" is determined based on clinical information provided by the clinician and is meant to reduce the use of low-utility examinations.

Limitations of Appropriateness Criteria

A frequent criticism of appropriateness criteria is the reliance on expert opinion, which is inherently subjective. There will always be a role for clinical judgment in the consideration of appropriateness because it is not feasible to perform randomized controlled trials for every indication for every procedure. However, studies have shown that the results of appropriateness panels using the RAM are reproducible with new, independent panels. Furthermore, there is less variability in the development of appropriateness criteria than among the individual judgments of physicians.[84]

The utility and validity of appropriateness criteria are dependent upon the quality of the criteria, which in turn is dependent on both the available evidence base for the procedure as well as the judgment of the panel. The reliability of the RAM panel process will thus likely be lower when the scientific evidence base is minimal or weak. The panel itself is typically created by requesting nominations for panelists from various stakeholder societies. This ensures that panelists are well respected within their field for their clinical judgment and knowledge base and also provides face validity for the appropriateness criteria created through professional society endorsement.

Finally, concern is often raised regarding the clinical validity of appropriateness criteria. Despite efforts to create an exhaustive list of clinical indications for a procedure, there may still be patients for whom the criteria do not apply. Appropriateness criteria should thus be thought of as an aid in clinical decision making and should not replace a clinician's judgment. For utilization purposes, it may be helpful to continually review why patients rated inappropriate by the criteria are operated on (or vice versa) to ensure that the criteria are clinically valid.

Appropriateness Criteria and Guidelines in Colorectal Surgery

Appropriateness criteria have not been developed specifically for colorectal surgical procedures, although they do exist for colonoscopy. The American College of Radiology (ACR) has also developed appropriateness criteria to guide imaging decisions for screening and pretreatment staging of colorectal cancer as well as criteria to guide the treatment of rectal cancer (resectable, metastatic, or recurrent), anal cancer, and mesenteric ischemia. The ACR criteria are available online on their Web site.[3]

To date, what are generally available to colorectal surgeons are practice guidelines or practice parameters. The National Guideline Clearinghouse is an initiative of the Agency for Healthcare Research and Quality (AHRQ) and is a publicly available database of evidence-based clinical practice guidelines. The database includes practice parameters developed by the American Society of Colon and Rectal Surgeons (ASCRS) for topics including colon cancer, rectal cancer, anal squamous neoplasms, ulcerative colitis, Crohn's disease, sigmoid diverticulitis, constipation, fecal incontinence, anal fissures, hemorrhoids, perianal abscess, and fistula-in-ano. Though not formal appropriateness criteria, the ASCRS has developed guidelines for laparoscopic resection of colon and rectal cancer, a consensus document on bowel preparation before colonoscopy (in association with multiple other profession societies), and practice parameters for the prevention of venous thromboembolism. These guidelines contain elements of appropriateness but are not explicit enough to qualify as appropriateness criteria. This gap in the availability of appropriateness criteria, especially for surgical procedures, represents an opportunity for future research and development.

Comparative Effectiveness and Cost-Effectiveness

Background

If good quality care can be understood as "doing the right thing for the right patient at the right time the right way," part of evaluating and improving quality should include systematic and valid ways to define what is "right." Quality indicators and appropriateness criteria are two methods that have been presented in this chapter. Another method is comparative effectiveness. The focus of comparative effectiveness research (CER) is the *practical* comparison of different treatments or procedures to determine what works best for whom. Distinct from the traditional clinical trials that seek to determine efficacy (whether a treatment works or not), CER is geared toward delineating effectiveness – the relative benefits of treatment options in *routine* clinical practice.

The IOM has described six defining characteristics of CER: (1) it directly informs clinical decisions from the patient perspective or policy decisions from the population perspective; (2) it compares at least two treatment options, both of which could be considered "best practice"; (3) it describes results at the population and subgroup levels to inform more individualized decisions; (4) the outcomes measured are important to patients; (5) a variety of methods and data may be used, from observational studies and RCTs to meta-analyses or systematic literature reviews; and (6) the setting of CER should be similar to routine practice environments.[85]

CER has gained considerable interest at the national policy level as a means for maintaining quality while simultaneously addressing the "runaway" cost of health care, as spending is projected to reach 20% of the gross domestic product by 2016.[86] At the federal level, the American Recovery and Reinvestment Act of 2009 appropriated $1.1 billion dollars to CER.[87] In light of the emphasis placed on CER by the US government, CER is likely to affect clinical practice to a greater degree than in the past, regardless of misgivings raised by critics of this approach. Although cost-cutting is not the main focus of CER, a consequent benefit according to its proponents is cost reduction by the elimination of less effective, ineffective, or even harmful services. Extreme opponents have viewed CER as a means to limit treatment options and effect health-care rationing.[88] The reality is that the current expansion of health-care cost is not sustainable and we routinely lack sufficient information to make informed decisions about the risks and benefits of treatment options.[89] To this end, CER will help clinicians and patients make individualized and informed decisions based on sound clinical evidence.

Cost-Effectiveness

Cost-effectiveness is a specific subset of comparative effectiveness research that provides explicit comparisons of "the relative value of different interventions in creating better health and/or longer life."[89] What distinguishes cost-effectiveness from other types of comparative effectiveness studies is the explicit comparison of cost or values. For example, a study may compare laparoscopic to open colectomy for colon cancer. The comparison of postoperative complications, recurrence, and survival across the two modalities would constitute a comparative effectiveness study. The comparison of the associated cost or resource utilization, such as operating time, length of hospital stay, hospital charges, or time to return to work would constitute a cost-effectiveness study. There is often a considerable overlap between the two study types.

A reluctance to place a monetary value on health outcomes has lead to the widespread use of the cost-effectiveness ratio,

---

[3]The ACR appropriateness criteria can be found at http://www.acr.org/SecondaryMainMenuCategories/quality_safety/app_criteria.aspx.

which often takes the form of "incremental cost per quality-adjusted life year (QALY) gained." QALY is a measure of disease burden that takes into account both the quantity and quality of life lived. QALY values range from zero to one, with zero being death and one being 1 year of life lived in perfect health. But what "incremental cost" is one QALY worth and how much is considered cost-effective? While these values are somewhat arbitrary, researchers have often accepted a range of $50,000 to $100,000 per QALY gained as cost-effective. The value of $50,000 in US studies stems from the "dialysis standard," the approximate cost of taking care of a dialysis patient for one year. Using these definitions and standards, an intervention or treatment that costs less than $50,000 per QALY gained may be deemed cost-effective.

In theory, cost-effectiveness methodology provides the advantage of combining the best scientific evidence, available clinical outcomes, and cost data. Cost-effectiveness studies, however, are limited by their reliance on the use of appropriate assumptions in creating a model of care and accurate value and cost estimates. Predictably, the cost of providing surgical care is difficult to quantify, whether it be the direct or the indirect component. Direct cost involve near-term spending related to delivery of care, including that incurred secondary to complications of receiving that care. Indirect cost generally refer to economic and societal cost due to loss of productivity from health-care receipt, often estimated by measuring time to return to work following a surgical procedure. Studies assessing direct cost of care often use administrative billing or claims data as a proxy for cost. Such data is easy to obtain and can include large numbers of patients for population-based studies. However, hospital charges and claims data are "operator-dependent" and influenced by the person who bills or codes, thus not necessarily representing accurate or actual resources used in providing care. Studies that explicitly measure the cost of care by taking into account equipment, supplies, and labor, on the other hand, are usually limited to single institutions where medical charts and thorough accounting data are available for review. Despite these limitations, cost-effectiveness studies are a major component of CER and will play a role in determining appropriate cost-saving measures.

Comparative Effectiveness and Cost-Effectiveness in Colorectal Surgery

The impact of comparative effectiveness and cost-effectiveness studies on colorectal surgical practice has already been felt and will only increase over time, with the greatest effect anticipated on procedure choice and disease management. For example, debates on laparoscopic vs. open colectomy and "fast-track pathways" compared to traditional postoperative care in colorectal procedures have been informed by comparative effectiveness analyses and cost-effectiveness studies.

Laparoscopic surgery has been touted as equivalent in effectiveness and potentially superior to open colorectal surgery in both benign and malignant disease for its associated shorter postoperative recovery time, decreased pain associated with smaller incisions, and decreased length of hospitalization. Overall, the available literature suggests that short-term and long-term outcomes may be similar between the procedures but the heterogeneity of studies and the paucity of randomized controlled trials make comparing the two difficult, particularly when additionally attempting to assess cost.[90–92]

In a systematic review commissioned by the National Institute of Clinical Effectiveness (NICE) in the UK, laparoscopic surgery for nonmetastatic colorectal cancer was associated with a shorter recovery period and shorter length of hospital stay and no significant difference in 3-year disease-free survival or mortality compared with open resection. However, the authors noted longer operative times among laparoscopic cases as well as a fair number of laparoscopic to open conversions.[90] A Cochrane Database systematic review of 12 eligible randomized controlled trials involving nonmetastatic colorectal cancer patients found no differences in cancer-related mortality, port-site or wound recurrences, or recurrence rate at the site of the primary tumor, suggesting that laparoscopic and open resection of colon carcinoma are equivalent with regard to these long-term outcomes. The authors recommend further studies to adequately evaluate incisional hernia rates, postoperative adhesion rates, and upper rectal surgery long-term outcomes.[91]

Studies on the economic impact of laparoscopic vs. open colectomy have generally been few in number and plagued by the complexity of accurately determining cost. A systematic review by Dowson et al.[92] found that only two of 29 eligible randomized controlled trials between 1991 and 2005 had accounted for the indirect cost involved with both types of procedures. Thus, across all studies, operating room costs was higher, but there was no significant difference in total hospital cost. Length of hospital stay was uniformly shorter for laparoscopic surgery cases (median difference 2.8 days; $p < 0.001$). The authors speculated that the "societal benefits" derived from the decreased indirect cost could potentially outweigh the greater up-front procedural cost, making laparoscopic surgery a viable alternative, particularly given the equivalence of short-term and long-term outcomes.[92]

On the basis of their systematic review, researchers from the NICE-commissioned study proceeded to a formal cost-effectiveness analysis of laparoscopic vs. open colon resection. Though the cost of laparoscopic surgery was £250–300 (approximately $390–470 USD) more than open colon resection, the analysis resulted in a 40% likelihood that laparoscopic surgery was more cost-effective than open surgery at the threshold of £30,000 ($46,800) per QALY gained in light of decreased length of hospitalization, faster recovery, and reduced pain. Given the "modest additional cost" of laparoscopy, the findings lead the authors to conclude that

"a judgment [*sic*] is required as to whether the benefits associated with earlier recovery are worth this extra cost."[90]

A dearth of cost-effectiveness studies is noted in the evaluation of "fast-track" or "enhanced recovery" postoperative management following colorectal surgery. Several comparative effectiveness studies have been performed in which outcomes such as length of hospital stay, morbidity, mortality, and readmission rates were examined. Recent systematic reviews have suggested that enhanced recovery programs are safe and effective following colorectal surgery when compared with conventional postoperative care. Wind et al. found a significantly shorter index hospital stay, significantly less morbidity but no significant difference in readmission rates or mortality for fast-track patients compared with conventional postoperative care.[93] Similarly, a review by Walter et al.[94] showed decreased length of stay, decreased 30-day morbidity, and no increase in 30-day mortality between the two management modalities following colorectal resection. Thirty-day readmission rates were higher among fast-track patients compared with conventional management patients in the clinical controlled trials, although not in the randomized controlled trials. This last finding highlights an important caveat with regard to comparative effectiveness research and reviews of the evidence for fast-track care: some caution is warranted in adopting enhanced recovery measures outside of the study context given the limited number of studies available at this time (six studies with a total of 512 patients were eligible and analyzed in the former systematic review, and four studies with a total of 376 patients were eligible for analysis in the latter).

The opportunity for further research in the realm of comparative effectiveness and cost-effectiveness of colorectal surgical disease management is immense. All practitioners need awareness and some fluency with this type of evidence-based research. Inevitably, clinicians will encounter difficulty in decision making when confronted with the individual patient where population-based evidence provides a certain recommendation, but this intervention proves ineffective for the given person compared to the more costly alternative. From this perspective, the results of comparative effectiveness studies may prove a challenge to the practitioner, especially when such population-based data become matters of organizational or national policy. However, if we can take the best available evidence and make decisions rationally using an algorithm that at least begins with the most cost-effective option before moving to others, ultimately, we as a nation may see reduced cost and improvement in health outcomes.[88]

Attribution of Quality

There are a number of issues that have yet to be resolved, but remain important to recognize. One is attribution. It is a given that the evaluation of quality of surgical care may be measured at different levels. As an example, the rate of anastomotic leak or the rate of giving prophylactic antibiotics may be measured at the surgeon level, the facility level, the system level, or some other level altogether. There are a number of issues related to this topic that deserve discussion, but one of the more important aspects is the idea of accountability or attribution. In other words, who should be responsible for the performance/quality metric and who should be rewarded? Should it be an individual, a facility, or some sort of "team or service"? This is not such an easy determination because it is likely different for different metrics, and as the unit of measurement becomes smaller and smaller, the appropriateness of the measure becomes increasingly debatable. For example, there has been much discussion regarding the appropriateness of the number of nodes retrieved in a node negative colectomy. Whether one believes in the scientific merits of the measure or not, it provides an example of attribution, since attaining a sufficient number of lymph nodes in a colectomy specimen relies on both the surgeon and pathologist. Thus, if we were to have a metric that measures an individual, who should be rewarded for attaining a sufficient number of nodes – surgeon or pathologist? There are many metrics that are similar in nature, where it remains difficult to attribute a quality process or outcome to an individual provider.

Most of the common surgical metrics at the time of this writing are at the hospital level (e.g., surgical care improvement program); however, many "regulatory" groups are investigating how we might develop individual surgeon-based metrics.

Summary

It is difficult to say exactly what all of this quality-related information means for the practicing colorectal surgeon. It is fair to say, however, that quality evaluation is probably here to stay and that in an iterative fashion, quality measurement will likely continue to increase. Already, structural measures are being used for various surgical procedures, process measures are being measured at the hospital level with the Surgical Care Improvement Program (SCIP) and also at the individual surgeon level with the Patient Quality Reporting Initiative (PQRI). Outcomes are being measured in various programs (e.g., Hospital-Acquired Conditions). The American Board of Colon and Rectal Surgery has the Maintenance of Certification program, where the aim is to effect continuous professional development with ongoing education, assessment, and improvement. As the field of performance evaluation and quality improvement progresses, it will remain important for providers to be involved in the ongoing discussions and decisions. By being active stakeholders, providers can influence the development of quality improvement so that it continues to be fair, useful, applicable, and meaningful to surgeons and their patients.
