Foreword, 1st Edition

This text was developed under the aegis of the American Society of Colon and Rectal Surgeons (ASCRS). It represents an attempt to cover the field of colon and rectal surgery with input from expert surgeons who have, in one way or another, shown special interest or expertise in specific areas of the specialty.

The book will hopefully serve as a source of useful information and perhaps even guidance to surgeons whose practice is confined to the specialty of colon and rectal surgery, and also to general surgeons, surgery residents, and medical students with an interest in surgery.

The finished product represents significant efforts from authors who have taken time from their busy schedules to set into writing their often unique perspectives. I know for certain that no author of any chapter in this book has a light schedule, but that fact validates each author's selection for authorship.

Special acknowledgment is due the editors, Bruce Wolff, David Beck, John Pemberton, and Steven Wexner. This project simply would not have come together without their efforts on many levels.

Finally, Jim Fleshman must be singled out for special recognition. The idea of an ASCRS-sponsored text began with Jim – an idea that he advocated, developed, nurtured, and forced until it became realized in the substance you now hold.

Foreword, 2nd Edition

The American Society of Colon and Rectal Surgeons (ASCRS) Textbook was originally conceived as a means of providing state of the art information to residents in training and fully trained surgeons seeking maintenance of certification and to support the mission of the ASCRS to continue to be the world's most established authority on colon and rectal disease. The second edition perpetuates these goals. This textbook has been significantly reorganized in response to the numerous important changes in our specialty. All chapters were rewritten and updated and new chapters have been added. While several authors from the first edition were retained, for the majority of chapters, new authors were selected. Most of these internationally acclaimed contributors are active members of the ASCRS who routinely contribute to our literature. These respected individuals have carefully crafted chapters which provide a comprehensive summary of the subject with an appropriate mixture of detailed personal experience and comprehensive literature review. This approach provides the reader with a very open-minded, evidence-based approach to all aspects of colorectal disease.

At the inception of the first edition, the editorial board was designed to be a rotating group of experts selected by the ASCRS Executive Council. As the two senior editors of this edition, it has been our distinct pleasure and honor to work with this edition's editorial board. They have sacrificed time and energy to achieve what we believe continues to be the standard in colon and rectal surgery. For the sake of ease of use and consistency, the Table of Contents correlates with the Core Curriculum established by the Association of Program Directors in Colon and Rectal Surgery and the key topics used by the American Board of Colon and Rectal Surgery. Furthermore, the Practice Parameters developed by the ASCRS Standards Committee have been incorporated into the text appendix. As occurred with the first edition, the proceeds from this textbook and any related publications will be utilized by the ASCRS Executive Council to sponsor the research and education efforts of the society.

The second edition continues to provide what the fellows and members of the ASCRS and trainees at all levels agree is the definitive source of knowledge in colon and rectal surgery. We are honored to have been a part of this ongoing monumental achievement and thank the leaders of the ASCRS for their continued support of the textbook. We thank our predecessors Bruce Wolf and Jim Fleshman, whose significant commitments as the co-senior editors of the first edition ensured the success of the textbook. We gratefully acknowledge our coeditors for their major contributions and rest comfortably as we leave the editorial board, knowing that future editions will continue to benefit from their dedication and expertise. We thank each chapter author and coauthor for their devotion to this task and to the mission of the ASCRS as without their individual and collective efforts the second edition would not be at such a tremendously high standard. We are grateful to the authors and coauthors of the first edition upon whose labors the foundation of this edition was easily laid. We also thank Sharon Beck for her support during this effort and our Developmental Editor Elektra McDermott for her extraordinary efforts which ensured the timely and professional completion of this second edition. Finally, we want to specially acknowledge the loss of our friend and colleague, W. Douglas Wong,

past president of the ASCRS. During the production of this edition, Doug passed away after a courageous battle with a terrible disease. He made numerous major contributions to our specialty and to this textbook. Although Doug will be missed, his innovations and teachings will endure and continue to benefit surgeons and patients throughout the world.

David E. Beck, MD, FASCRS
Steven D. Wexner, MD, FASCRS
April 2011

Preface

Drs. David Beck and Steven Wexner (Senior Editors) as well as the other members of the editorial board, Drs. Patricia Roberts, Theodore Saclarides, Michael Stamos, and Anthony Senagore, are to be congratulated on their successful completion of the second edition of the American Society of Colon and Rectal Surgeons (ASCRS) Textbook. The table of contents has been changed to reflect recent changes in the Core Curriculum for training Residents in colon and rectal surgery and format changes have been made to improve the presentation of the material. At least one third of the material has been completely renewed to reflect advances in the science of our specialty.

The ASCRS Textbook has rapidly become a major resource for training, read by almost all trainees interested in our specialty. The purpose of the text was originally to provide a standardized reference for evidence-based recommendations, referenced to ASCRS practice parameter guidelines were available. The first edition has been downloaded onto the Web-based Colon and Rectal Education System as the reference for all the educational efforts of the ASCRS Continuing Medical Education Committee. Our society, as owners and editors of the ASCRS Textbook, can be proud to be one of the few national organizations with its own comprehensive textbook from which certification and recertification materials can be drawn. Using an entire society as the pool of authors, allows the ASCRS Textbook, as much as possible, to avoid personal bias in the materials presented.

The ASCRS Manual for Residents in training at all levels has also been released this past year. The current Editorial Board has condensed the material from each chapter of the first Edition of the ASCRS Textbook to provide students and residents rapid access to a succinct, distilled version of the ASCRS Textbook. The production of these two educational resources adds evidence that the ASCRS is "the" authority on colorectal disease and has within its membership individuals who can claim the status of "expert." Their contribution has made the ASCRS Textbook a success and should be considered a major selfless contribution to our society and specialty.

As time passes, our specialty and the body of knowledge surrounding it certainly change. The existence of this ASCRS Textbook and the mechanism which perpetuates it guarantees that we always have the most up-to-date information available to our members and trainees. The proceeds from the sale of the ASCRS Textbook also flow into the Education Foundation of the ASCRS to bring independence from outside sponsorship to our national meeting. The Executive Council of the ASCRS is fully supportive of this effort by the Editorial Board of the ASCRS Textbook and gratefully recognizes their contribution and that of the group of experts who provide new and updated chapters for each successive edition.

Please remember the sacrifice of time and effort that made this publication possible. Strive to add to the knowledge which one day changes our practice and our specialty. Use this ASCRS Textbook to show the world that the ASCRS is THE authority on colorectal disease as we improve patient care.

James W. Fleshman, MD

1
Anatomy and Embryology

José Marcio Neves Jorge and Angelita Habr-Gama

Although much of our fundamental understanding of the anatomy of the colon, rectum, and anus comes from the efforts of researchers of the nineteenth and early twentieth centuries, comprehensive observations of this region had been made as early as 1543 by Andreas Vesalius through anatomic dissections.[1] However, anatomy of this region, especially that of the rectum and anal canal, is so intrinsically related to its physiology that much can be appreciated only in the living. Thus, it is a region in which the surgeon has an advantage over the anatomist through in vivo dissection, physiologic investigation, and endoscopic examination. However, anatomy of the pelvis is also challenging to the surgeon: the pelvis is a narrow space, packed with intestinal, urologic, gynecologic, vascular, and neural structures, all confined within a rigid and deep osseous–muscular cage. Therefore, detailed anatomy of this region is difficult to learn in the setting of an operating room and it demands not only observations in vivo, but historical reviews, anatomy laboratory studies, including dissections of humans and animals, with in-depth descriptions and drawings and sometimes associated with physiologic evaluation. Based on these studies, some controversial concepts of the anatomy, especially of the rectum and anal canal, have been actually changed.[2–8] In addition, virtual reality models have been designed to improve visualization of three-dimensional structures and more properly teach anatomy, pathology, and surgery of the anorectum and pelvic floor.[9]

Anatomy

Anus and Rectum

Anal Canal Structure, Anus, and Anal Verge

The anal canal is anatomically peculiar and has a complex physiology, which accounts for its crucial role in continence and, in addition, its susceptibility to a variety of diseases. The anus or anal orifice is an anteroposterior cutaneous slit that, along with the anal canal, remains virtually closed at rest, as a result of tonic circumferential contraction of the sphincters and the presence of anal cushions. The edge of the anal orifice, the anal verge or margin (anocutaneous line of Hilton), marks the lowermost edge of the anal canal and is sometimes the level of reference for measurements taken during sigmoidoscopy. Others favor the dentate line as a landmark because it is more precise. The difference between the anal verge and the dentate line is usually 1–2 cm. The epithelium distal to the anal verge acquires hair follicles, glands, including apocrine glands, and other features of normal skin, and is the source of perianal hidradenitis suppurativa, inflammation of the apocrine glands.

Anatomic Versus Surgical Anal Canal

Two definitions are found describing the anal canal (Figure 1-1). The "anatomic" or "embryologic" anal canal is only 2.0 cm long, extending from the anal verge to the dentate line, the level that corresponds to the proctodeal membrane. The "surgical" or "functional" anal canal is longer, extending for approximately 4.0 cm (in men) from the anal verge to the anorectal ring (levator ani). This "long anal canal" concept was first introduced by Milligan and Morgan[10] and has been considered, despite not being proximally marked by any apparent epithelial or developmental boundary, useful both as a physiologic and surgical parameter. The anorectal ring is at the level of the distal end of the ampullary part of the rectum and forms the anorectal angle, and the beginning of a region of higher intraluminal pressure. Therefore, this definition correlates with digital, manometric, and sonographic examinations.

Anatomic Relations of the Anal Canal

Posteriorly, the anal canal is related to the coccyx and anteriorly to the perineal body and the lowest part of the posterior vaginal wall in the female, and to the urethra in the male. The ischium and the ischiorectal fossa are situated on either side. The fossa ischiorectal contains fat and the inferior rectal
FIGURE 1-1. Anal canal.

vessels and nerves, which cross it to enter the wall of the anal canal.

Muscles of the Anal Canal

The muscular component of the mechanism of continence can be stratified into three functional groups: lateral compression from the pubococcygeus, circumferential closure from the internal and external anal sphincter, and angulation from the puborectalis (Figure 1-2). The internal and external anal sphincters, and the conjoined longitudinal are intrinsically related to the anal canal, and are addressed here.

Internal Anal Sphincter

The internal anal sphincter represents the distal 2.5- to 4.0-cm condensation of the circular muscle layer of the rectum. As a consequence of both intrinsic myogenic and extrinsic autonomic neurogenic properties, the internal anal sphincter is a smooth muscle in a state of continuous maximal contraction, and represents a natural barrier to the involuntary loss of stool and gas.

The lower rounded edge of the internal anal sphincter can be felt on physical examination, about 1.2 cm distal to the dentate line. The groove between the internal and external anal sphincter, the intersphincteric sulcus, can be visualized or easily palpated. Endosonographically, the internal anal sphincter is a 2- to 3-mm-thick circular band and shows a uniform hypoechogenicity.

External Anal Sphincter

The external anal sphincter is the elliptical cylinder of striated muscle that envelops the entire length of the inner tube of smooth muscle, but it ends slightly more distal than the internal anal sphincter. The external anal sphincter was initially described as encompassing three divisions: subcutaneous, superficial, and deep.[10] Goligher et al.[11] described the external anal sphincter as a simple, continuous sheet that forms, along with the puborectalis and levator ani, one funnel-shaped skeletal muscle. The deepest part of the external anal sphincter is intimately related to the puborectalis muscle, which can actually be considered a component of both the levator ani and the external anal sphincter muscle complexes. Others considered the external anal sphincter as being subdivided into two parts, deep (deep sphincter and puborectalis) and superficial (subcutaneous and superficial sphincter).[6,12,13] Shafik[14] proposed the three U-shaped loop system, but clinical experience has not supported this schema. The external anal sphincter is more likely to be one muscle unit, attached by the anococcygeal ligament posteriorly to the coccyx, and anteriorly to the perineal body, not divided into layers or laminae. Nevertheless, differences in

FIGURE 1-2. Muscles of the anal canal.
the arrangement of the external anal sphincter have been described between the genders.[15] In the male, the upper half of the external anal sphincter is enveloped anteriorly by the conjoined longitudinal muscle, whereas the lower half is crossed by it. In the female, the entire external anal sphincter is encapsulated by a mixture of fibers derived from both longitudinal and internal anal sphincter muscles.

Endosonographically, the puborectalis and the external anal sphincter, despite their mixed linear echogenicity, are both predominantly hyperechogenic, with a mean thickness of 6 mm (range, 5–8 mm). Distinction is made by position, shape, and topography. Recently, both anal endosonography and endocoil magnetic resonance imaging have been used to detail the anal sphincter complex in living, healthy subjects.[16–19] These tests provide a three-dimensional mapping of the anal sphincter; they help to study the differences in the arrangement of the external anal sphincter between the sexes and uncover sphincter disruption or defect during vaginal deliveries. In addition, there is some degree of "anatomical asymmetry" of the external anal sphincter, which accounts for both radial and longitudinal "functional asymmetry" observed during anal manometry.[20]

The automatic continence mechanism is formed by the resting tone, maintained by the internal anal sphincter, magnified by voluntary, reflex, and resting external anal sphincter contractile activities. In response to conditions of threatened incontinence, such as increased intraabdominal pressure and rectal distension, the external anal sphincter and puborectalis

reflexively and voluntarily contract further to prevent fecal leakage. Because of muscular fatigue, maximal voluntary contraction of the external anal sphincter can be sustained for only 30–60 s. However, the external anal sphincter and the pelvic floor muscles, unlike other skeletal muscles, which are usually inactive at rest, maintain unconscious resting electrical tone through a reflex arc at the cauda equina level. Histologic studies have shown that the external anal sphincter, puborectalis, and levator ani muscles have a predominance of type I fibers, which are a peculiarity of skeletal muscles connecting tonic contractile activity.[21]

Conjoined Longitudinal Muscle

Whereas the inner circular layer of the rectum gives rise to the internal anal sphincter, the outer longitudinal layer, at the level of the anorectal ring, mixes with fibers of the levator ani muscle to form the conjoined longitudinal muscle. This muscle descends between the internal and external anal sphincter, and ultimately some of its fibers, referred to as the *corrugator cutis ani muscle*, traverse the lowermost part of the external anal sphincter to insert into the perianal skin. Some of these fibers may enter the fat of the ischiorectal fossa.[22] Other sources for the striated component of the conjoined longitudinal muscle include the puborectalis and deep external anal sphincter, the pubococcygeus and top loop of the external anal sphincter, and the lower fibers of the puborectalis.[7,23,24] In its descending course, the

conjoined longitudinal muscle may give rise to medial extensions that cross the internal anal sphincter to contribute the smooth muscle of the submucosa (musculus canalis ani, sustentator tunicae mucosae, Treitz muscle, musculus submucosae ani).[25]

Possible functions of the conjoined longitudinal muscle include attaching the anorectum to the pelvis and acting as a skeleton that supports and binds the internal and external sphincter complex together.[22] Haas and Fox[26] consider that the meshwork formed by the conjoined longitudinal muscle may minimize functional deterioration of the sphincters after surgical division and act as a support to prevent hemorrhoidal and rectal prolapse. In addition, the conjoined longitudinal muscle and its extensions to the intersphincteric plane divide the adjacent tissues into subspaces and may actually have a role in the septation of thrombosed external hemorrhoids and containment of sepsis.[7] Finally, Shafik[23] ascribed to the conjoined longitudinal muscle the action of shortening and widening of the anal canal as well as eversion of the anal orifice, and proposed the controversial term evertor ani muscle. In addition to this primary function during defecation, a limited role in anal continence, specifically a potentialization effect in maintaining an anal seal, has also been proposed.[23]

Epithelium of the Anal Canal

The lining of the anal canal consists of an upper mucosal (endoderm) and a lower cutaneous (ectoderm) segment (Figure 1-1). The dentate (pectinate) line is the "saw-toothed" junction between these two distinct origins of venous and lymphatic drainage, nerve supply, and epithelial lining. Above this level, the intestine is innervated by the sympathetic and parasympathetic systems, with venous, arterial, and lymphatic drainage to and from the hypogastric vessels. Distal to the dentate line, the anal canal is innervated by the somatic nervous system, with blood supply and drainage from the inferior hemorrhoidal system. These differences are important when the classification and treatment of hemorrhoids are considered.

The pectinate or dentate line corresponds to a line of anal valves that represent remnants of the proctodeal membrane. Above each valve, there is a little pocket known as an anal sinus or crypt. These crypts are connected to a variable number of glands, in average 6 (range, 3–12).[27,28] The anal glands first described by Chiari in 1878[29] are more concentrated in the posterior quadrants. More than one gland may open into the same crypt, whereas half the crypts have no communication. The anal gland ducts, in an outward and downward route, enter the submucosa; two-thirds enter the internal anal sphincter, and half of them terminate in the intersphincteric plane.[28] Obstruction of these ducts, presumably by accumulation of foreign material in the crypts, may lead to perianal abscesses and fistulas.[30] Cephalad to the dentate line, 8–14 longitudinal folds, known as the rectal columns (columns of Morgagni), have their bases connected in pairs to each valve at the dentate line. At the lower end of the columns are the anal papillae. The mucosa in the area of the columns consists of several layers of cuboidal cells and has a deep purple color because of the underlying internal hemorrhoidal plexus. This 0.5- to 1.0-cm strip of mucosa above the dentate line is known as the anal transition or cloacogenic zone. Cephalad to this area, the epithelium changes to a single layer of columnar cells and macroscopically acquires the characteristic pink color of the rectal mucosa.

The cutaneous part of the anal canal consists of modified squamous epithelium that is thin, smooth, pale, stretched, and devoid of hair and glands. The terms pecten and pecten band have been used to define this segment.[31] However, as pointed out by Goligher, the round band of fibrous tissue called pecten band, which is divided in the case of anal fissure (pectenotomy), probably represents the spastic internal anal sphincter.[11,32]

Rectum

Both proximal and distal limits of the rectum are controversial: the rectosigmoid junction is considered to be at the level of the third sacral vertebra by anatomists but at the sacral promontory by surgeons, and likewise, the distal limit is regarded to be the muscular anorectal ring by surgeons and the dentate line by anatomists. The rectum measures 12–15 cm in length and has three lateral curves: the upper and lower are convex to the right and the middle is convex to the left. These curves correspond intraluminally to the folds or valves of Houston. The two left-sided folds are usually noted at 7–8 cm and at 12–13 cm, respectively, and the one on the right is generally at 9–11 cm. The middle valve (Kohlrausch's plica) is the most consistent in presence and location and corresponds to the level of the anterior peritoneal reflection. Although the rectal valves do not contain all muscle wall layers from a clinical point of view, they are a good location for performing a rectal biopsies because they are readily accessible with minimal risk of perforation.[13,33] The valves of Houston must be negotiated during proctosigmoidoscopy; they are absent after mobilization of the rectum, and this is attributed to the 5-cm length gained after complete surgical dissection. The rectal mucosa is smooth, pink, and transparent, which allows visualization of small and large submucosal vessels. This characteristic "vascular pattern" disappears in inflammatory conditions and in melanosis coli.

The rectum is characterized by its wide, easily distensible lumen, and the absence of taeniae, epiploic appendices, haustra, or a well-defined mesentery. The prefix "meso," in gross anatomy, refers to two layers of peritoneum that suspend an organ. Normally, the rectum is not suspended but entirely extraperitoneal on its posterior aspect, and closely applied to the sacral hollow. Consequently, the term "mesorectum" is anatomically inaccurate. An exception, however, is that a peritonealized mesorectum may be noted in patients with procidentia. But, the word "mesorectum" has gained widespread popularity among surgeons to address the perirectal areolar tissue, which is thicker posteriorly, containing terminal

branches of the inferior mesenteric artery and enclosed by the fascia propria.[34,35] The "mesorectum" may be a metastatic site for a rectal cancer and is removed during surgery for rectal cancer without neurologic sequelae because no functionally significant nerves pass through it.

The upper third of the rectum is anteriorly and laterally invested by peritoneum; the middle third is covered by peritoneum on its anterior aspect only. Finally, the lower third of the rectum is entirely extraperitoneal because the anterior peritoneal reflection occurs at 9.0–7.0 cm from the anal verge in men and at 7.5–5.0 cm from the anal verge in women.

Anatomic Relations of the Rectum

The rectum occupies the sacral concavity and ends 2–3 cm anteroinferiorly from the tip of the coccyx. At this point, it angulates backward sharply to pass through the levators and becomes the anal canal. Anteriorly, in women, the rectum is closely related to the uterine cervix and posterior vaginal wall; in men, it lies behind the bladder, vas deferens, seminal vesicles, and prostate. Posterior to the rectum lie the median sacral vessels and the roots of the sacral nerve plexus.

Fascial Relationships of the Rectum

The parietal endopelvic fascia lines the walls and floor of the pelvis and continues on the internal organs as a visceral pelvic fascia (Figure 1-3A, B). Thus, the *fascia propria of the rectum* is an extension of the pelvic fascia, enclosing the rectum, fat, nerves, the blood, and lymphatic vessels. It is more evident in the posterior and lateral extraperitoneal aspects of the rectum.

The lateral ligaments or stalks of the rectum are distal condensations of the pelvic fascia that form a roughly triangular structure with a base on the lateral pelvic wall and an apex attached to the lateral aspect of the rectum.[32] Still a subject of misconception, the lateral stalks comprise essentially connective tissue and nerves, and the middle rectal artery does not traverse them. Branches, however, course through in approximately 25% of cases.[36] Consequently, division of the lateral stalks during rectal mobilization is associated with a 25% risk of bleeding. Although the lateral stalks do not contain important structures, the middle rectal artery and the pelvic plexus are both closely related, running, at different angles, underneath it.[37] One theoretical concern in ligation of the stalks is leaving behind lateral mesorectal tissue, which may limit adequate lateral or mesorectal margins during cancer surgery.[34,35,38]

The presacral fascia is a thickened part of the parietal endopelvic fascia that covers the concavity of the sacrum and coccyx, nerves, the middle sacral artery, and presacral veins. Operative dissection deep to the presacral fascia may cause troublesome bleeding from the underlying presacral veins. Presacral hemorrhage occurs as frequently as 4.6–7.0% of resections for rectal neoplasms, and despite its venous nature, can be life threatening.[39–41] This is a consequence of two factors: the difficulty in securing control because of retraction of the vascular stump into the sacral foramen and the high hydrostatic pressure of the presacral venous system. The presacral veins are avalvular and communicate via basivertebral veins with the internal vertebral venous system. The adventitia of the basivertebral veins adheres firmly to the sacral periosteum at the level of the ostia of the sacral foramina, mainly at the level of S3-4. With the patient in the lithotomy

FIGURE 1-3. Fascial relationships of the rectum: **A** male, **B** female.

position, the presacral veins can attain hydrostatic pressures of 17–23 cm H_2O, two to three times the normal pressure of the inferior vena cava.[40]

The rectosacral fascia is an anteroinferiorly directed thick fascial reflection from the presacral fascia at the S-4 level to the fascia propria of the rectum just above the anorectal ring.[42] The rectosacral fascia, classically known as the fascia of Waldeyer, is an important landmark during posterior rectal dissection.[2,42]

The visceral pelvic fascia of Denonvilliers is a tough fascial investment that separates the extraperitoneal rectum anteriorly from the prostate and seminal vesicles or vagina.[43] Therefore, three structures lie between the anterior rectal wall and the seminal vesicles and prostate: anterior mesorectum, fascia propria of the rectum, and Denonvilliers' fascia. A consensus has generally been reached about the anatomy of the plane of posterior and lateral rectal dissection, but anteriorly, the matter is more controversial. The anterior plane of rectal dissection may not necessarily follow the same plane of posterior and lateral dissection, and the use of the terms close rectal, mesorectal, and extramesorectal have been recently suggested to describe the available anterior planes.[44] The close rectal or perimuscular plane lies inside the fascia propria of the rectum, and therefore it is more difficult and bloody than the mesorectal plane. The mesorectal plane represents the continuation of the same plane of posterior and lateral dissection of the rectum. This is a natural anatomic plane and consequently more appropriate for most rectal cancers. Finally, the extramesorectal plane involves resection of the Denonvilliers' fascia, with the exposure of prostate and seminal vesicles, and is associated with high risk of mixed parasympathetic and sympathetic injury because of damage of the periprostatic plexus.

Urogenital Considerations

Identification of the ureters is advisable to avoid injury to their abdominal or pelvic portions during colorectal operations. On both sides, the ureters rest on the psoas muscle in their inferomedial course; they are crossed obliquely by the spermatic vessels anteriorly and the genitofemoral nerve posteriorly. In its pelvic portion, the ureter crosses the pelvic brim in front of or a little lateral to the bifurcation of the common iliac artery, and descends abruptly between the peritoneum and the internal iliac artery. Before entering the bladder in the male, the vas deferens crosses lateromedially on its superior aspect. In the female, as the ureter traverses the posterior layer of the broad ligament and the parametrium close to the side of the neck of the uterus and upper part of the vagina, it is enveloped by the vesical and vaginal venous plexuses and is crossed above and lateromedially by the uterine artery.

Arterial Supply of the Rectum and Anal Canal

The superior hemorrhoidal artery is the continuation of the inferior mesenteric artery, once it crosses the left iliac vessels. The artery descends in the sigmoid mesocolon to the level of S-3 and then to the posterior aspect of the rectum. In 80% of cases, it bifurcates into right, usually wider, and left terminal branches; multiple branches are present in 17%.[45] These divisions, once within the submucosa of the rectum, run straight downward to supply the lower rectum and the anal canal. Approximately five branches reach the level of the rectal columns, and condense in capillary plexuses, mostly at the right posterior, right anterior, and left lateral positions, corresponding to the location of the major internal hemorrhoidal groups.

The superior and inferior hemorrhoidal arteries represent the major blood supply to the anorectum. In addition, it is also supplied by the internal iliac arteries.

The contribution of the middle hemorrhoidal artery varies with the size of the superior hemorrhoidal artery; this may explain its controversial anatomy. Some authors report the absence of the middle hemorrhoidal artery in 40–88%[46,47], whereas others identify it in 94–100% of specimens.[45] It originates more frequently from the anterior division of the internal iliac or the pudendal arteries, and reaches the rectum. The middle hemorrhoidal artery reaches the lower third of the rectum anterolaterally, close to the level of the pelvic floor and deep to the levator fascia. It therefore does not run in the lateral ligaments, which are inclined posterolaterally.[2] The middle hemorrhoidal artery is more prone to be injured during low anterior resection, when anterolateral dissection of the rectum is performed close to the pelvic floor and the prostate and seminal vesicles or upper part of the vagina are being separated.[37] The anorectum has a profuse intramural anastomotic network, which probably accounts for the fact that division of both superior and middle hemorrhoidal arteries does not result in necrosis of the rectum.

The paired inferior hemorrhoidal arteries are branches of the internal pudendal artery, which in turn is a branch of the internal iliac artery. The inferior hemorrhoidal artery arises within the pudendal canal and is throughout its course entirely extrapelvic. It traverses the obturator fascia, the ischiorectal fossa, and the external anal sphincter to reach the submucosa of the anal canal, ultimately ascending in this plane. Klosterhalfen et al.[4] performed postmortem angiographic, manual, and histologic evaluations and demonstrated that in 85% of cases the posterior commissure was less well perfused than were the other sections of the anal canal. In addition, the blood supply could be jeopardized by contusion of the vessels passing vertically through the muscle fibers of the internal anal sphincter with increased sphincter tone. The resulting decreased blood supply could lead to ischemia at the posterior commissure, in a pathogenetic model of primary anal fissure.

Venous Drainage and Lymphatic Drainage of the Rectum and Anal Canal

The anorectum also drains, via middle and inferior hemorrhoidal veins, to the internal iliac vein and then to the inferior vena cava. Although it is still a controversial subject,

the presence of communications among these three venous systems may explain the lack of correlation between portal hypertension and hemorrhoids.[48] The paired inferior and middle hemorrhoidal veins and the single superior hemorrhoidal vein originate from three anorectal arteriovenous plexuses. The external hemorrhoidal plexus, situated subcutaneously around the anal canal below the dentate line, constitutes when dilated the external hemorrhoids. The internal hemorrhoidal plexus is situated submucosally, around the upper anal canal and above the dentate line. The internal hemorrhoids originate from this plexus. The perirectal or perimuscular rectal plexus drains to the middle and inferior hemorrhoidal veins.

Lymph from the upper two-thirds of the rectum drains exclusively upward to the inferior mesenteric nodes and then to the paraaortic nodes. Lymphatic drainage from the lower third of the rectum occurs not only cephalad, along the superior hemorrhoidal and inferior mesentery arteries, but also laterally, along the middle hemorrhoidal vessels to the internal iliac nodes. Studies using lymphoscintigraphy have failed to demonstrate communications between inferior mesenteric and internal iliac lymphatics.[49] In the anal canal, the dentate line is the landmark for two different systems of lymphatic drainage: above, to the inferior mesenteric and internal iliac nodes, and below, along the inferior rectal lymphatics to the superficial inguinal nodes, or less frequently along the inferior hemorrhoidal artery. In the female, drainage at 5 cm above the anal verge in the lymphatic may also spread to the posterior vaginal wall, uterus, cervix, broad ligament, fallopian tubes, ovaries, and cul-de-sac, and at 10 cm above the anal verge, spread seems to occur only to the broad ligament and cul-de-sac.[50]

Innervation of the Rectum and Anal Canal

Innervation of the Rectum

The sympathetic supply of the rectum and the left colon arises from L-1, L-2, and L-3 (Figure 1-4A, B). Preganglionic fibers, via lumbar sympathetic nerves, synapse in the preaortic plexus, and the postganglionic fibers follow the branches of the inferior mesenteric artery and superior rectal artery to the left colon and upper rectum. The lower rectum is innervated by the presacral nerves, which are formed by fusion of the aortic plexus and lumbar splanchnic nerves. Just below the sacral promontory, the presacral nerves form the hypogastric plexus (or superior hypogastric plexus). Two main hypogastric nerves, on either side of the rectum, carry sympathetic innervation from the hypogastric plexus to the pelvic plexus. The pelvic plexus lies on the lateral side of the pelvis at the level of the lower third of the rectum, adjacent to the lateral stalks.

The parasympathetic fibers to the rectum and anal canal emerge through the sacral foramen are called the nervi erigentes (S-2, S-3, and S-4). They pass laterally, forward, and upward to join the sympathetic hypogastric nerves at the pelvic plexus. From the pelvic plexus, combined postganglionic parasympathetic and sympathetic fibers are distributed to the left colon and upper rectum via the inferior mesenteric plexus, and directly to the lower rectum and upper anal canal. The periprostatic plexus, a subdivision of the pelvic plexus situated on Denonvilliers' fascia, supplies the prostate, seminal vesicles, corpora cavernosa, vas deferens, urethra, ejaculatory ducts, and bulbourethral glands. Sexual function is regulated by cerebrospinal, sympathetic, and parasympathetic components. Erection of the penis is mediated by both parasympathetic (arteriolar vasodilatation) and sympathetic inflow (inhibition of vasoconstriction).

All pelvic nerves lie in the plane between the peritoneum and the endopelvic fascia and are in danger of injury during rectal dissection. Permanent bladder paresis occurs in 7–59% of patients after abdominoperineal resection of the rectum[51]; the incidence of impotence is reported to range from 15 to 45%, and that of ejaculatory dysfunction from 32 to 42%.[52] The overall incidence of sexual dysfunction after proctectomy has been reported to reach 100% when wide dissection is performed for malignant disease[53–55]; however, this kind of procedure is unnecessary and these rates are much lower for benign conditions, such as inflammatory bowel disease (0–6%).[53,54,56,57] Dissections performed for benign conditions are undertaken closer to the bowel wall, thus reducing the possibility of nerve injury.[58]

Trauma to the autonomic nerves may occur at several points. During high ligation of the inferior mesenteric artery, close to the aorta, the sympathetic preaortic nerves may be injured. Division of both superior hypogastric plexus and hypogastric nerves may occur also during dissection at the level of the sacral promontory or in the presacral region. In such circumstances, sympathetic denervation with intact nervi erigentes results in retrograde ejaculation and bladder dysfunction. The nervi erigentes are located in the posterolateral aspect of the pelvis, and at the point of fusion with the sympathetic nerves are closely related to the middle hemorrhoidal artery. Injury to these nerves completely abolishes erectile function.[56] The pelvic plexus may be damaged either by excessive traction on the rectum, particularly laterally, or during division of the lateral stalks when this is performed close to the lateral pelvic wall. Finally, dissection near the seminal vesicles and prostate may damage the periprostatic plexus, leading to a mixed parasympathetic and sympathetic injury. This can result in erectile impotence as well as a flaccid, neurogenic bladder. Sexual complications after rectal surgery are readily evident in men but are probably underdiagnosed in women.[59]

Anal Canal

The internal anal sphincter is supplied by sympathetic (L-5) and parasympathetic nerves (S-2, S-3, and S-4) following the same route as the nerves to the rectum. The external anal sphincter is innervated on each side by the inferior rectal branch of the pudendal nerve (S-2 and S-3) and by the perineal branch of S-4. Despite the fact that the puborectalis

and external anal sphincter have somewhat different innervations, these muscles seem to act as an indivisible unit.[14] After unilateral transection of a pudendal nerve, external anal sphincter function is still preserved because of the crossover of the fibers at the spinal cord level.

Anal sensation is carried in the inferior rectal branch of the pudendal nerve and is thought to have a role in maintenance of anal continence. The upper anal canal contains a rich profusion of both free and organized sensory nerve endings, especially in the vicinity of the anal valves.[60] Organized nerve endings include Meissner's corpuscles (touch), Krause's bulbs (cold), Golgi-Mazzoni bodies (pressure), and genital corpuscles (friction).

Anorectal Spaces

The potential spaces of clinical significance in close relation to the anal canal and rectum include: ischiorectal, perianal, intersphincteric, submucosal, superficial postanal, deep postanal, supralevator, and retrorectal spaces (Figure 1-5A, B).

The ischiorectal fossa is subdivided by a thin horizontal fascia into two spaces: the perianal and ischiorectal. The ischiorectal space comprises the upper two-thirds of the ischiorectal fossa. It is pyramid-shaped, situated on both sides between the anal canal and the lower part of the rectum medially, and the side wall of the pelvis laterally.[61] The apex is at the origin of the levator ani muscle from the obturator fascia; the base is the perianal space. Anteriorly, the fossa is bounded by the urogenital diaphragm and transversus perinei muscle. Posterior to the ischiorectal fossa is the sacrotuberous ligament and the inferior border of the gluteus maximus. On the superolateral wall, the pudendal nerve and the internal pudendal vessels run in the pudendal canal (Alcock's canal). The ischiorectal fossa contains fat and the inferior rectal vessels and nerves.

The perianal space surrounds the lower part of the anal canal and contains the external hemorrhoidal plexus, the subcutaneous part of the external anal sphincter, the lowest part of the internal anal sphincter, and fibers of the longitudinal muscle. This space is the typical site of anal hematomas, perianal abscesses, and anal fistula tracts. The perianal space is continuous with the subcutaneous fat of the buttocks laterally and extends into the intersphincteric space medially. The intersphincteric space is a potential space between the internal and external anal sphincters. It is important in the genesis of perianal abscess because most of the anal glands end in this space. The submucous space is situated between the internal anal sphincter and the mucocutaneous lining of the anal canal. This space contains the internal hemorrhoidal plexus and the muscularis submucosae ani. Above, it is continuous with the submucous layer of the rectum, and, inferiorly, it ends at the level of the dentate line.

The superficial postanal space is interposed between the anococcygeal ligament and the skin. The deep postanal space, also known as the retro-sphincteric space of Courtney,

is situated between the anococcygeal ligament and the anococcygeal raphe. Both postanal spaces communicate posteriorly with the ischiorectal fossa and are the sites of horseshoe abscesses.

The supralevator spaces are situated between the peritoneum superiorly and the levator ani inferiorly. Medially, these bilateral spaces are limited by the rectum, and laterally by the obturator fascia. Supralevator abscesses may occur as a result of upward extension of a cryptoglandular infection or develop from a pelvic origin. The retrorectal space is located between the fascia propria of the rectum anteriorly and the presacral fascia posteriorly. Laterally are the lateral rectal ligaments and inferiorly the rectosacral ligament, and above the space is continuous with the retroperitoneum. The retrorectal space is a site for embryologic remnants and rare presacral tumors.

Pelvic floor Musculature

The muscles within the pelvis can be divided into three categories: (1) the anal sphincter complex; (2) pelvic floor muscles; and (3) muscles that line the sidewalls of the osseous pelvis.[61] Muscles in this last category form the external boundary of the pelvis and include the obturator internus and piriform. These muscles, compared with the other two groups, lack clinical relevance to anorectal diseases; however, they provide an open communication for pelvic infection to reach extrapelvic spaces. For example, infection from the deep postanal space, originated from posterior midline glands, can track along the obturator internus fascia and reach the ischiorectal fossa.

The anal sphincter and pelvic floor muscles, based on phylogenetic studies, derive from two embryonic cloaca groups, respectively, sphincteric and lateral compressor.[62] The sphincteric group is present in almost all animals. In mammals, this group is divided into ventral (urogenital) and dorsal (anal) components.[63] In primates, the latter components form the external anal sphincter. The lateral compressor or pelvicaudal group connects the rudimentary pelvis to the caudal end of the vertebral column. This group is more differentiated and subdivided into lateral and medial compartments only in reptiles and mammals. The homolog of the lateral compartment is the ischiococcygeus, and of the medial, pelvicaudal compartment, the pubococcygeus and ileococcygeus. In addition, most primates possess a variably sized group of muscle fibers close to the inner border of the medial pelvicaudal muscle, which attaches the rectum to the pubis. In humans, the fibers are more distinct and known as the puborectalis muscle.

Levator Ani

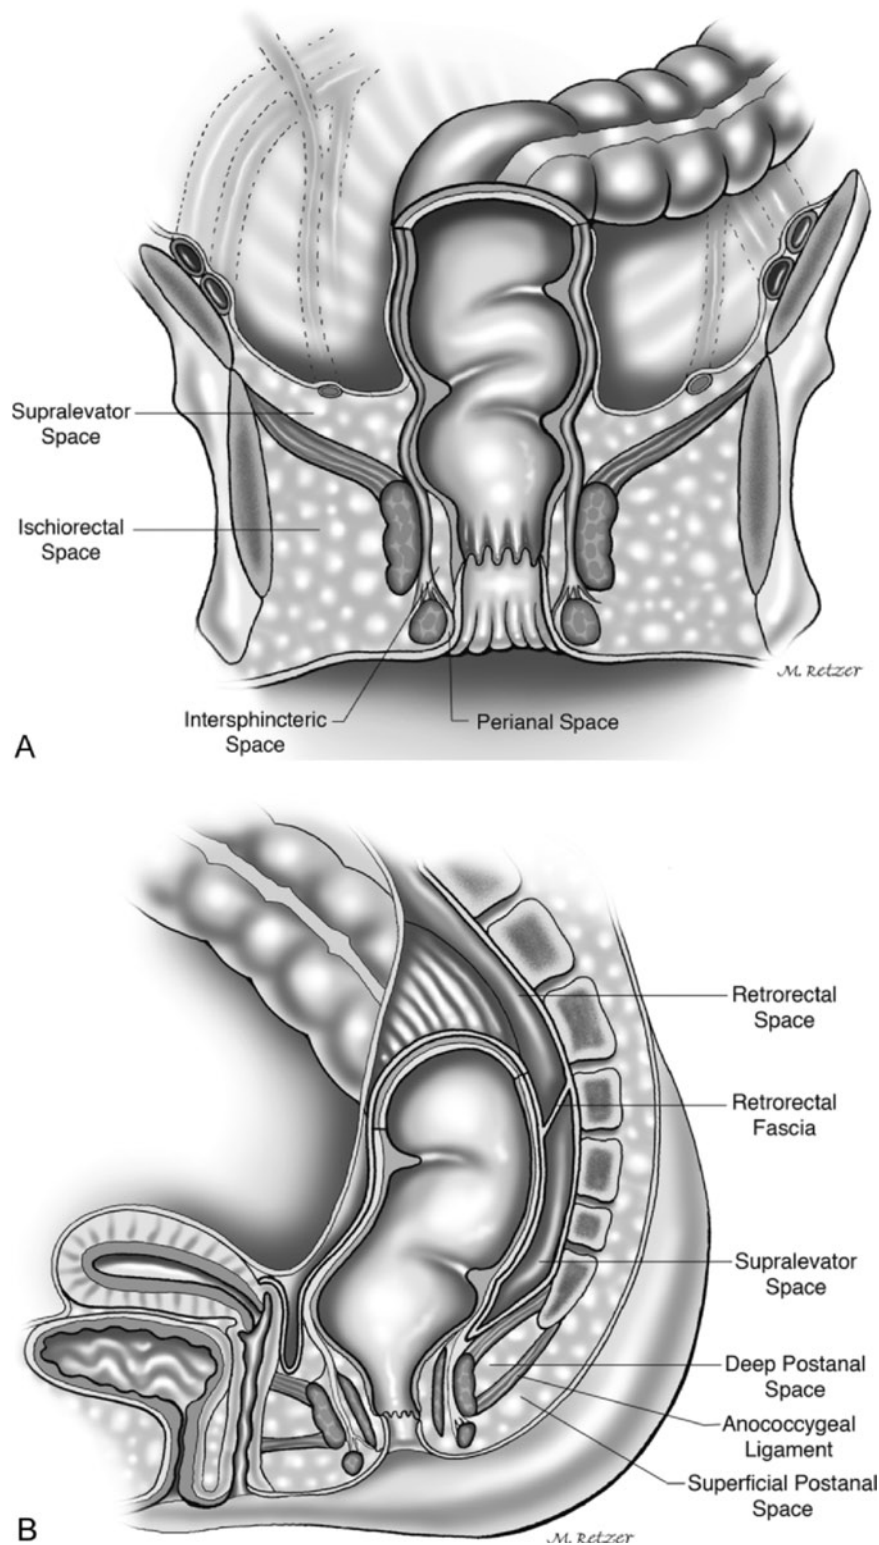
The levator ani muscle, or pelvic diaphragm, is the major component of the pelvic floor. It is a pair of broad, symmetric sheets composed of three striated muscles: ileococcygeus, pubococcygeus, and puborectalis (Figure 1-6A, B). A variable


FIGURE 1-5. Paraanal and pararectal spaces. **A** Frontal view. **B** Lateral view.
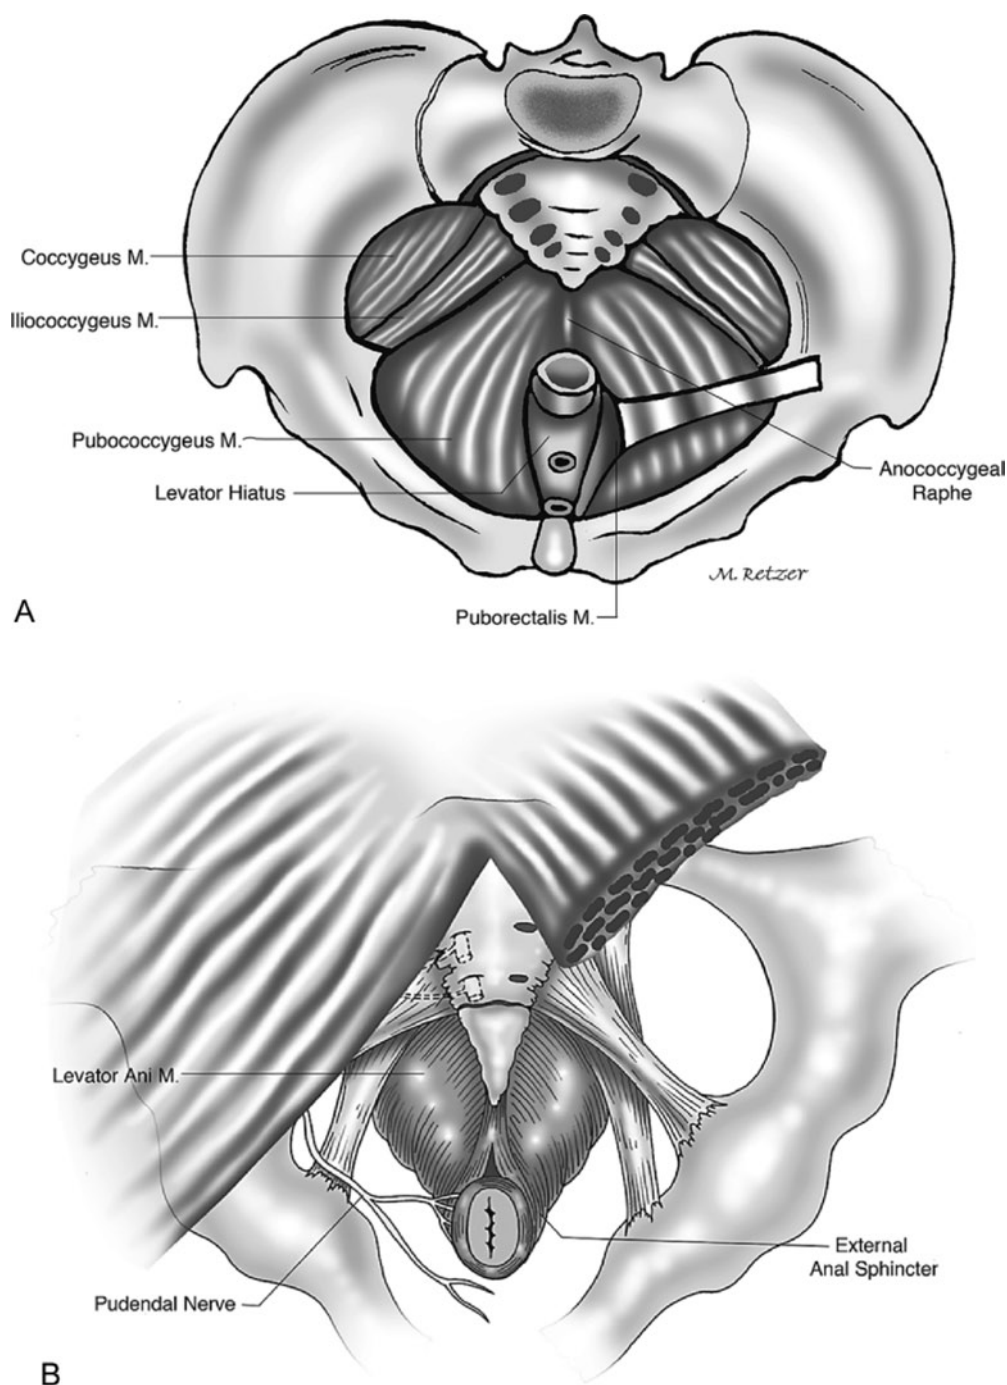

FIGURE 1-6. Levator ani muscle. **A** Superior. **B** Inferior surface.

fourth component, the ischiococcygeus or coccygeus, is rudimentary in humans and represented by only a few muscle fibers on the surface of the sacrospinous ligament. The levator ani is supplied by sacral roots on its pelvic surface (S-2, S-3, and S-4) and by the perineal branch of the pudendal nerve on its inferior surface. The puborectalis muscle receives additional innervation from the inferior rectal nerves.

The ileococcygeus muscles arise from the ischial spine and posterior part of the obturator fascia and course inferiorly and medially to insert into the lateral aspects of S-3 and S-4, the coccyx, and the anococcygeal raphe. The pubococcygeus arises from the posterior aspect of the pubis and the anterior part of the obturator fascia; it runs dorsally alongside the anorectal junction to decussate with fibers of the opposite

side at the anococcygeal raphe and insert into the anterior surface of the fourth sacral and first coccygeal segments.

The pelvic floor is "incomplete" in the midline where the lower rectum, urethra, and either the dorsal vein of the penis in men, or the vagina in women, pass through it. This defect is called the levator hiatus and consists of an elliptic space situated between the two pubococcygeus muscles. The hiatal ligament, originating from the pelvic fascia, keeps the intrahiatal viscera together and prevents their constriction during contraction of the levator ani. A possible (but controversial) dilator function has been attributed to the anococcygeal raphe because of its crisscross arrangement.[14]

The puborectalis muscle is a strong, U-shaped loop of striated muscle that slings the anorectal junction to the posterior aspect of the pubis (Figure 1-7). The puborectalis is the most medial portion of the levator ani muscle. It is situated immediately cephalad to the deep component of the external sphincter. Because the junction between the two muscles is indistinct and they have similar innervation (pudendal nerve), the puborectalis has been regarded by some authors as a part of the external anal sphincter and not of the levator ani complex.[14,15] Anatomic and phylogenetic studies suggest that the puborectalis may be a part of the levator ani[63] or of the external anal sphincter.[24,62] Embryologically, the puborectalis has a common primordium with the ileococcygeus and pubococcygeus muscles, and it is never connected with the external anal sphincter during the different stages of development.[6] In addition, neurophysiologic studies have implied that the innervation of these muscles may not be the same because stimulation of the sacral nerves results in electromyographic activity in the ipsilateral puborectalis muscle but not in the external anal sphincter.[64] Currently, because of this controversy, the puborectalis has been considered to belong to both muscular groups, the external anal sphincter and the levator ani.[65]

The Anorectal Ring and the Anorectal Angle

Two anatomic structures of the junction of the rectum and anal canal are related to the puborectalis muscle: the anorectal ring and the anorectal angle. The anorectal ring, a term coined by Milligan and Morgan[10] is a strong muscular ring that represents the upper end of the sphincter, more precisely the puborectalis, and the upper border of the internal anal sphincter, around the anorectal junction. Despite its lack of embryologic significance, it is an easily recognized boundary of the anal canal appreciated on physical examination, and it is of clinical relevance because division of this structure during surgery for abscesses or fistula inevitably results in fecal incontinence.

The anorectal angle is thought to be the result of the anatomic configuration of the U-shaped sling of puborectalis muscle around the anorectal junction. Whereas the anal sphincters are responsible for the closure of the anal canal to retain gas and liquid stool, the puborectalis muscle and the anorectal angle are designed to maintain gross fecal continence. Different theories have been postulated to explain the importance of the puborectalis and the anorectal angle in the maintenance of fecal continence. Parks et al.[66] opined that increasing intraabdominal pressure forces the anterior rectal wall down into the upper anal canal, occluding it by

FIGURE 1-7. The anteriorly directed pull of the puborectalis contributes to the angulation between the rectum and anal canal, the anorectal angle.

a type of flap valve mechanism that creates an effective seal. Subsequently, it has been demonstrated that the flap mechanism does not occur. Instead, a continuous sphincteric occlusion-like activity that is attributed to the puborectalis is noted.[67,68]

Colon

General Considerations

The colon is a capacious tube that roughly surrounds the loops of small intestine as an arch. Named from the Greek *koluein* ("to retard"), the colon is variable in length, averaging approximately 150 cm, which corresponds to one-quarter the length of the small intestine. Its diameter can be substantially augmented by distension – it gradually decreases from 7.5 cm at the cecum to 2.5 cm at the sigmoid. In humans, the colon is described to be somewhere between the short, straight type with a rudimentary cecum, such as that of the carnivores, and a long sacculated colon with a capacious cecum, such as that of the herbivores.

Anatomic differences between the small and large intestines include position, caliber, degree of fixation, and, in the colon, the presence of three distinct characteristics: the taeniae coli, the haustra, and the appendices epiploicae. The three taeniae coli, anterior (taenia libera), posteromedial (taenia mesocolica), and posterolateral (taenia omentalis), represent bands of the outer longitudinal coat of muscle that traverse the colon from the base of the appendix to the rectosigmoid junction, where they merge. The muscular longitudinal layer is actually a complete coat around the colon, although it is considerably thicker at the taeniae.[69] The haustra or haustral sacculations are outpouchings of bowel wall between the taeniae; they are caused by the relative shortness of the taeniae, about one-sixth shorter than the length of the bowel wall.[13] The haustra are separated by the plicae semilunares or crescentic folds of the bowel wall, which give the colon its characteristic radiographic appearance when filled with air or barium. The appendices epiploicae are small appendages of fat that protrude from the serosal aspect of the colon.

Cecum

The cecum is the sacculated segment (Latin *caecus*, "blind") of the large bowel that projects downward as a 6- to 8-cm blind pouch below the entrance of the ileum. Usually situated in the right iliac fossa, the cecum is almost entirely or at least in its lower half, invested with peritoneum. However, its mobility is usually limited by a small mesocecum. The ileum terminates in the posteromedial aspect of the cecum; the angulation between these two structures is maintained by the superior and inferior ileocecal ligaments. These ligaments, along with the mesentery of the appendix, form three pericecal recesses or fossae: superior ileocecal, inferior ileocecal, and retrocecal. Viewed from the cecal lumen, the ileocecal junction is represented by a narrow, transversely situated,

slit-like opening known as the ileocecal valve or the valve de Bauhin. At either end, the two prominent semilunar lips of the valve fuse and continue as a single frenulum of mucosa. A circular sphincter, the ileocecal sphincter, originates from a slight thickening of the muscular layer of the terminal ileum. A competent ileocecal valve is related to the critical closed-loop type of colonic obstruction. However, ileocecal competence is not always demonstrated on barium enema studies. Instead of preventing reflux of colonic contents into the ileum, the ileocecal valve regulates ileal emptying. The ileocecal sphincter seems to relax in response to the entrance of food into the stomach.[70] As in the gastroesophageal junction, extrasphincteric factors such as the ileocecal angulation apparently have a role in the prevention of reflux from the colon to the ileum.[71]

Appendix

The vermiform appendix is an elongated diverticulum that arises from the posteromedial aspect of the cecum about 3.0 cm below the ileocecal junction. Its length varies from 2 to 20 cm (mean, 8–10 cm), and it is approximately 5 mm in diameter. The appendix, because of its great mobility, may occupy a variety of positions, possibly at different times in the same individual. It has been estimated that in 85–95% of cases, the appendix lies posteromedial on the cecum toward the ileum, but other positions include retrocecal, pelvic, subcecal, preileal and retroileal.[72–74] The confluence of the three taeniae is a useful guide in locating the base of the appendix. The mesoappendix, a triangular fold attached to the posterior leaf of the mesentery of the terminal ileum, usually contains the appendicular vessels close to its free edge.

Ascending Colon

The ascending colon is approximately 15 cm long. It ascends, from the level of the ileocecal junction to the right colic or hepatic flexure, laterally to the psoas muscle and anteriorly to the iliacus, the quadratus lumborum, and the lower pole of the right kidney. The ascending colon is covered with peritoneum anteriorly and on both sides. In addition, fragile adhesions between the right abdominal wall and its anterior aspect, known as Jackson's membrane, may be present. Like the descending colon on its posterior surface, the ascending colon is devoid of peritoneum, which is instead replaced by an areolar tissue (fascia of Toldt) resulting from an embryologic process of fusion or coalescence of the mesentery to the posterior parietal peritoneum. In the lateral peritoneal reflection, this process is represented by the white line of Toldt, which is more evident at the descending-sigmoid junction. This line serves as a guide for the surgeon when the ascending, descending, or sigmoid colon is mobilized. At the visceral surface of the right lobe of the liver and lateral to the gallbladder, the ascending colon turns sharply medially and slightly caudad and ventrally to form the right colic (hepatic) flexure. This flexure is supported by the nephrocolic

ligament and lies immediately ventral to the lower part of the right kidney and over the descending duodenum.

Transverse Colon

The transverse colon is approximately 45 cm long, the longest segment of the large bowel. It crosses the abdomen, with an inferior curve immediately caudad to the greater curvature of the stomach. The transverse colon is relatively fixed at each flexure, and, in between, it is suspended by a 10- to 15-cm-wide area which provides variable mobility; the nadir of the transverse colon may reach the hypogastrium. The transverse colon is completely invested with peritoneum, but the greater omentum is fused on its anterosuperior aspect. The left colic or splenic flexure is situated beneath the lower angle of the spleen and firmly attached to the diaphragm by the phreno-colic ligament, which also forms a shelf to support the spleen. Because of the risk of hemorrhage, mobilization of the splenic flexure should be approached with great care, preceded by dissection upward along the descending colon and medially to laterally along the transverse colon toward the splenic flexure. This flexure, when compared with the hepatic flexure, is more acute, higher, and more deeply situated.

Descending Colon

The descending colon courses downward from the splenic flexure to the brim of the true pelvis, a distance of approximately 25 cm.[32] Similarly to the ascending colon, the descending colon is covered by peritoneum only on its anterior and lateral aspects. Posteriorly, it rests directly against the left kidney and the quadratus lumborum and transversus abdominis muscles. However, the descending colon is narrower and more dorsally situated than the ascending colon.

Sigmoid Colon

The sigmoid colon is commonly a 35- to 40-cm-long, mobile, omega-shaped loop completely invested by peritoneum; however, it varies greatly in length and configuration. The mesosigmoid is attached to the pelvic walls in an inverted V shape, resting in a recess known as the intersigmoid fossa. The left ureter lies immediately underneath this fossa and is crossed on its anterior surface by the spermatic, left colic, and sigmoid vessels. Both the anatomy and function of the rectosigmoid junction have been matters of substantial controversy. As early as 1833, it was postulated that the sigmoid could have a role in continence as the fecal reservoir, based on the observation that the rectum is usually emptied and contracted.[74] Since then, a thickening of the circular muscular layer between the rectum and sigmoid has been described and diversely termed the sphincter ani tertius, rectosigmoid sphincter, and pylorus sigmoidorectalis, and it has probably been mistaken for one of the transverse folds of the rectum.[75–79] The rectosigmoid junction has been frequently regarded by surgeons as an indistinct zone, a region

comprising the last 5–8 cm of sigmoid and the uppermost 5 cm of the rectum.[32,80] However, others have considered it a clearly defined segment because it is the narrowest portion of the large intestine; in fact, it is usually characterized endoscopically as a narrow and sharply angulated segment.[81] According to a study in human cadavers, the rectosigmoid junction, macroscopically identified as the point where the taenia libera and the taenia omentalis fuse to form a single anterior taenia and where both haustra and mesocolon terminate, is situated 6–7 cm below the sacral promontory.[5] With microdissection, this segment is characterized by conspicuous strands of longitudinal muscle fibers and the presence of curved interconnecting fibers between the longitudinal and circular muscle layers, resulting in a delicate syncytium of smooth muscle that allows synergistic interplay between the two layers. The rectosigmoid does not fit the anatomic definition of a sphincter as "a band of thickened circular muscle that closes the lumen by contraction and of a longitudinal muscle that dilates it"; however, this segment may be regarded as a functional sphincter because mechanisms of active dilation and passive "kinking" occlusion do exist.[81]

Blood Supply

The superior and inferior mesenteric arteries nourish the entire large intestine, and the limit between the two territories is the junction between the proximal two-thirds and the distal third of the transverse colon. This represents the embryologic division between the midgut and the hindgut. The superior mesenteric artery originates from the aorta behind the superior border of the pancreas at L-1 and supplies the cecum, appendix, ascending colon, and most of the transverse colon. After passing behind the neck of the pancreas and anteromedial to the uncinate process, the superior mesenteric artery crosses the third part of the duodenum and continues downward and to the right along the base of the mesentery. From its left side arises a series of 12–20 jejunal and ileal branches. From its right side arise the colic branches: middle, right, and ileocolic arteries. The ileocolic, the most constant of these vessels, bifurcates into a superior or ascending branch, which communicates with the descending branch of the right colic artery, and an inferior or descending branch, which gives off the anterior cecal, posterior cecal, and appendicular and ileal divisions.[82] The right colic artery may also arise from the ileocolic or middle colic arteries and is absent in 2–18% of specimens.[45,82,83] It supplies the ascending colon and hepatic flexure through its ascending and descending branches, both of them joining with neighboring vessels to contribute to the marginal artery. The middle colic artery is the highest of the three colic branches of the superior mesenteric artery, arising close to the inferior border of the pancreas. Its right branch supplies the right transverse colon and hepatic flexure, anastomosing with the ascending branch of the right colic artery. Its left branch supplies the distal half of the transverse colon. Anatomic variations of this artery include the absence in

4–20% of cases and the presence of an accessory middle colic artery in 10%; the middle colic artery can be the main supply to the splenic flexure in about 33% of cases.[82,84]

The inferior mesenteric artery originates from the left anterior surface of the aorta, 3–4 cm above its bifurcation at the level of L2-3, and runs downward and to the left to enter the pelvis. Within the abdomen, the inferior mesenteric artery branches into the left colic artery and two to six sigmoidal arteries. After crossing the left common iliac artery, it acquires the name superior hemorrhoidal artery (superior rectal artery). The left colic artery, the highest branch of the inferior mesenteric artery, bifurcates into an ascending branch, which runs upward to the splenic flexure to contribute to the arcade of Riolan, and a descending branch, which supplies most of the descending colon. The sigmoidal arteries form arcades within the sigmoid mesocolon, resembling the small-bowel vasculature, and anastomose with branches of the left colic artery proximally, and with the superior hemorrhoidal artery distally. The marginal artery terminates within the arcade of sigmoidal arteries. The superior hemorrhoidal artery is the continuation of the inferior mesenteric artery, once it crosses the left iliac vessels. The artery descends in the sigmoid mesocolon to the level of S-3 and then to the posterior aspect of the rectum. In 80% of cases, it bifurcates into right and left terminal branches; multiple branches are present in 17%.[45] These divisions, once within the submucosa of the rectum, run straight downward to supply the lower rectum and the anal canal.

The venous drainage of the large intestine basically follows its arterial supply. Blood from the right colon, via the superior mesenteric vein, and from left colon and rectum, via the inferior mesenteric vein, reaches the intrahepatic capillary bed through the portal vein.

Collateral Circulation

The anatomy of the mesenteric circulation is still a matter of controversy, and this may in part be related to the inherent confusion of the use of eponyms. The central anastomotic artery connecting all colonic mesenteric branches, first described by Haller[85] in 1786, later became known as the marginal artery of Drummond because this author was the first to demonstrate its surgical significance (1913).[86,87] Subsequently, discontinuity of the marginal artery has been shown at the lower ascending colon, and especially at the left colic flexure and the sigmoid colon. This potential hypovascularity is a source of concern during colonic resection. The splenic flexure comprises the watershed between midgut and hindgut supplies (Griffiths' critical point); this anastomosis is of variable magnitude, and it may be absent in about 50% of cases.[88] For this reason, ischemic colitis usually affects or is most severe near the splenic flexure.[89,90] Another potential area of discontinuity of the marginal artery is the Sudeck's critical point, situated between the lowest sigmoid and the superior hemorrhoidal arteries; however, surgical experience

and radiological studies have both demonstrated adequate communications between these vessels.[91] There is also a collateral network involving middle hemorrhoidal, internal iliac, and external iliac arteries which could potentially prevent gangrene of the pelvis and even the lower extremities in case of occlusion of the distal aorta.[92,93]

The term arc of Riolan was vaguely defined as the communication between superior and inferior mesenteric arteries in the author's original work. Later, the eponym marginal artery of Drummond confused the subject.[94] In 1964, Moskowitz et al.[95] proposed another term, meandering mesenteric artery, and differentiated it from the marginal artery of Drummond. The meandering mesenteric artery is a thick and tortuous vessel that makes a crucial communication between the middle colic artery and the ascending branch of the left colic artery, especially in advanced atherosclerotic disease.[94] The presence of the meandering mesenteric artery indicates severe stenosis of either the superior mesenteric artery (retrograde flow) or inferior mesenteric artery (antegrade flow).

Lymphatic Drainage

The submucous and subserous layers of the colon and rectum have a rich network of lymphatic plexuses, which drain into an extramural system of lymph channels and follow their vascular supply.[50] Colorectal lymph nodes are classically divided into four groups: epiploic, paracolic, intermediate, and principal.[96] The epiploic group lies on the bowel wall under the peritoneum and in the appendices epiploicae; they are more numerous in the sigmoid and are known in the rectum as the nodules of Gerota. The lymphatic drainage from all parts of the colon follows its vascular supply. The paracolic nodes are situated along the marginal artery and on the arcades; they are considered to have the most numerous filters. The intermediate nodes are situated on the primary colic vessels, and the main or principal nodes on the superior and inferior mesenteric vessels. The lymph then drains to the cisterna chyli via the paraaortic chain of nodes. Colorectal carcinoma staging systems are based on the neoplastic involvement of these various lymph node groups.

Innervation

The sympathetic and parasympathetic components of the autonomic innervation of the large intestine closely follow the blood supply. The sympathetic supply of the right colon originates from the lower six thoracic segments. These thoracic splanchnic nerves reach the celiac, preaortic, and superior mesenteric ganglia, where they synapse. The postganglionic fibers then course along the superior mesenteric artery to the small bowel and right colon. The parasympathetic supply comes from the right (posterior) vagus nerve and celiac plexus. The fibers travel along the superior mesenteric artery, and finally synapse with cells in the autonomic plexuses within the bowel wall. The sympathetic supply of the left colon and rectum arises from L-1, L-2, and L-3.

Preganglionic fibers, via lumbar sympathetic nerves, synapse in the preaortic plexus, and the postganglionic fibers follow the branches of the inferior mesenteric artery and superior rectal artery to the left colon and upper rectum.

Embryology

Anus and Rectum

The distal colon, rectum, and the anal canal above the dentate line are all derived from the hindgut. Therefore, this segment is supplied by the hindgut (inferior mesenteric) artery, with corresponding venous and lymphatic drainage. Its parasympathetic outflow comes from S-2, S-3, and S-4 via splanchnic nerves.

The dentate line marks the fusion between endodermal and ectodermal tubes, where the terminal portion of the hindgut or cloaca fuses with the proctodeum, an ingrowth from the anal pit. The cloaca originates at the portion of the rectum below the pubococcygeal line, whereas the hindgut originates above it.

Before the fifth week of development, the intestinal and urogenital tracts terminate in conjunction with the cloaca. During the sixth to eighth weeks of fetal life, the urorectal septum or fold of Tourneux migrates caudally and divides the cloacal closing plate into an anterior urogenital plate and a posterior anal plate (Figure 1-8). Any slight posterior shift in the position of the septum during its descent reduces the size of the anal opening, giving rise to anorectal defects.

The cloacal part of the anal canal, which has both endodermal and ectodermal elements, forms the anal transitional zone after breakdown of the anal membrane.[73] During the tenth week, the anal tubercles, a pair of ectodermal swellings around the proctodeal pit, fuse dorsally to form a horseshoe-shaped structure and anteriorly to create the perineal body. The cloacal sphincter is separated by the perineal body into urogenital and anal portions (external anal sphincter). The internal anal sphincter is formed later (6th to 12th week) from enlarging fibers of the circular layer of the rectum.[6,97]

In the female, the fused Müllerian ducts that form the uterus and vagina move downward to reach the urogenital sinus about the sixteenth week. In the male, the site of the urogenital membrane is obliterated by fusion of the genital folds and the sinus becomes incorporated into the urethra. The sphincters apparently migrate during their development; the external sphincter grows cephalad and the internal sphincter moves caudally. Concomitantly, the longitudinal muscle descends into the intersphincteric plane.[6]

Anorectal Malformations

The anorectal malformations can be traced to developmental arrest at various stages of normal maturation. The Duhamel's theory of "syndrome of caudal regression" is supported by the high incidence of spinal, sacral, and lower limb
FIGURE 1-8. **A** Embryology of the large intestine. I. Sagittal section of early embryo with the primitive tube at the third week of development. II. Normal development of intestine. defects associated with these anomalies.[98] In fact, associated anomalies, most frequently skeleton and urinary defects, may occur in up to 70%.[99] Digestive tract, particularly

tracheoesophageal fistula or esophageal stenosis, cardiac, and abdominal wall defects may also occur in patients with anorectal anomalies. There is evidence for familial occurrence of anorectal defects; the estimated risk in a family of a second occurrence of some form of imperforate anus is up to 50 times the normal chance.[100]

The proposed classification systems for the congenital malformations of the anorectal region are usually either incomplete or complex. The most comprehensive system has been proposed by Gough[101] and Santulli[102] and takes into consideration whether the rectum terminates above (anorectal defects) or below (anal defects) the puborectalis sling (Table 1-1).

Anal Defects

Anal Stenosis

Some degree of stricture of the rectum is present in 25–39% of infants, and only about 25% of these shows some degree of disordered evacuation, but spontaneous dilation occurs between 3 and 6 months of age in the vast majority of patients.[103] Although stenosis has been attributed to excessive fusion of the anal tubercles, probably the cause is a posterior shift in the position of the urorectal septum during its descent at the sixth week of fetal life.[101]

Membranous Atresia

This defect, also known as "covered anus," is very rare. It is characterized by the presence of a thin membrane of skin between the blind end of the anal canal and the surface. Most cases occur in males and probably represent excessive posterior closure of the urogenital folds.[101]

Anal Agenesis

The rectum extends below the puborectalis and ends, either blindly, or more often, in an ectopic opening or fistula to the perineum anteriorly, to the vulva, or urethra. Regardless of the location of the ectopic orifice, the sphincter is present at the normal site.

Anorectal Defects

Anorectal Agenesis

Anorectal agenesis more often affects males and represents the most common type of "imperforate anus." The rectum ends well above the surface, the anus is represented by a dimple, and the anal sphincter is usually normal. This malformation is the result of excessive obliteration of the embryonic tailgut and the adjacent dorsal portion of the cloaca. The descending urorectal septum reaches the dorsal wall of the diminished cloaca, leaving a blindly ending colon above and an isolated rectal membrane below.

In most cases, there is a fistula or fibrous remnant connecting the rectal ending to the urethra or vagina. Fistulae represent areas in the septum where the lateral ridges have joined but failed to unite, although the more caudal union is complete. High fistulae, vaginal and urethral, with anorectal agenesis originate as early as the sixth or seventh week, whereas low fistulae (perineal) of anal ectopia originate in the eighth or ninth week of fetal life.

Rectal Atresia or "High Atresia"

Although considered clinically as an anorectal defect, embryologically this is the most caudal type of atresia of the large intestine. The rectum and anal canal are separated from each other by an atretic portion.

Persistent Cloaca

This is a rare condition that occurs only in female infants. It results from the total failure of the urorectal septum to descend, and therefore occurs at a very early stage of development (10-mm stage).

Colon and Small Bowel

The primitive gut tube develops from the endodermal roof of the yolk sac. At first, the primitive intestine is a straight tube suspended in a sagittal plane on a common mesentery. At the beginning of the third week of development, it can be divided into three regions: the foregut in the head fold, the hindgut with its ventral allantoic outgrowth in the smaller tail fold, and, between these two portions, the midgut, which at this stage opens ventrally into the yolk sac (Figure 1-8). The normal embryologic process of rotation of the intestinal tract includes three stages, as outlined below.

First Stage: Physiologic Herniation of the Primitive Digestive Tube

The first stage of rotation begins between the sixth and eighth weeks of intrauterine life, when the primitive intestinal tube elongates on its mesenteric around the superior mesenteric artery and bulges through the umbilical cord as a temporary physiologic herniation. This intraumbilical loop moves, at the eighth week of embryologic development, counterclockwise

90° from the sagittal to the horizontal plane. The anomalies of this stage are rare and include situs inversus, inverted duodenum, and extroversion of the cloaca.

Second Stage: Return of the Midgut to the Abdomen

The second stage of gut rotation occurs at the tenth week of intrauterine life. During this stage, the midgut loop returns to the peritoneal cavity from the umbilical herniation, and simultaneously rotates 180° counterclockwise around the pedicle formed by the mesenteric root. The prearterial segment of the midgut or duodenojejunal loop returns first to the abdomen, as the gut rotates counterclockwise. The duodenum comes to lie behind the superior mesenteric artery. The postarterial segment or cecocolic loop also reduces and comes to lie in front of the superior mesenteric artery. Anomalies of the second stage are relatively more common than the ones originated from the first stage and include nonrotation, malrotation, reversed rotation, internal hernia, and omphalocele.

Third Stage: Fixation of the Midgut

The third stage of gut rotation starts after return of the gut to the peritoneal cavity and ends at birth. The cecum, initially in the upper abdomen, descends, migrating to the right lower quadrant, as counterclockwise rotation continues to 270°. After completion of the sequential rotation of the gastrointestinal tract, in the latter weeks of the first trimester, the process of fixation initiates. Gradually, fusion of parts of the primitive mesentery occurs, with fixation of the duodenum, and the ascending and descending parts of the colon to the posterior abdominal wall in their final position. Anomalies of this stage are common and include mobile cecum, subhepatic or undescended cecum, hyperdescent of the cecum, and persistent colonic mesentery.

The midgut progresses below the major pancreatic papilla to form the small intestine, the ascending colon, and the proximal two-thirds of the transverse colon. This segment is supplied by the midgut (superior mesenteric) artery, with corresponding venous and lymphatic drainage.

The neuroenteric ganglion cells migrate from the neural crest to the upper end of the alimentary tract and then follow vagal fibers caudad. The sympathetic innervation of the midgut and likewise the hindgut originates from T-8 to L-2, via splanchnic nerves and the autonomic abdominopelvic plexuses. The parasympathetic outflow to the midgut is derived from the tenth cranial nerve (vagus) with preganglionic cell bodies in the brain stem.

The distal colon (distal third of the transverse colon), the rectum, and the anal canal above the dentate line are all derived from the hindgut. Therefore, this segment is supplied by the hindgut (inferior mesenteric) artery, with corresponding venous and lymphatic drainage. Its parasympathetic outflow comes from S-2, S-3, and S-4 via splanchnic nerves.

Abnormalities of Rotation

Nonrotation

In this condition, the midgut loop returns to the peritoneal cavity without the process of rotation, and, consequently, the entire small bowel locates on the right side of the abdomen, and the left colon is on the left side. This condition may be entirely asymptomatic and constitute a finding at laparotomies. However, it may complicate with volvulus affecting the entire small bowel. The twist of the entire midgut loop on its pedicle can occur, usually at the level of the duodenojejunal junction and the midtransverse colon because of the defective fixation of the mesenteric root.

Malrotation

In malrotation, the cecum fails to complete the 360° rotation around the superior mesenteric, and does not complete the migration process. As a result of this failure in the migration process, the malrotated cecum locates in the right upper quadrant and is fixed by lateral bands or adhesions. These bands can overlie the distal part of the duodenum and cause extrinsic compression.

Reversed Rotation

In this condition, the midgut rotates clockwise instead of counterclockwise; consequently, the transverse colon locates posteriorly and the duodenum anteriorly, in relation to the mesenteric artery.

Omphalocele

Omphalocele is the retention of the midgut in the umbilical sac as a result of failure of the gut to return to the peritoneal cavity.

Incomplete Attachment of Cecum and Mesentery

Under normal conditions, the cecum is almost entirely or at least in its lower half invested with peritoneum. However, its mobility is usually limited by a small mesocecum. In approximately 5% of individuals, the peritoneal covering is absent posteriorly; it then rests directly on the iliacus and psoas major muscles.[32] Alternatively, an abnormally mobile cecum-ascending colon, resulting from an anomaly of fixation, can be found in 10–22% of individuals.[104] In this case, a long mesentery is present, and the cecum may assume varied positions. This lack of fixation may predispose to the development of volvulus.

Internal Hernias Around the Ligament of Treitz

Both internal hernias and congenital obstructive bands or adhesions are causes of congenital bowel obstruction, and result from an anomaly during the process of fixation. This failure may occur when the fusion of mesothelial layers is incomplete or if it occurs between structures that are

abnormally rotated. Retroperitoneal hernias can occur in any intraperitoneal fossae, particularly paraduodenal, paracecal, and intersigmoid. The most common internal hernias resulting from abnormal fixation of the colon are right and left paraduodenal hernias.[103]

Other Congenital Malformations of the Colon and Small Intestine

Proximal Colon Duplications

Duplication of the colon comprises three general groups of congenital abnormalities: mesenteric cysts, diverticula, and long colon duplication.[105]

Mesenteric cysts, similarly to the duplication cysts found at the retroperitoneum and the mediastinum, are lined by intestinal epithelium and a variable amount of smooth muscle. These cysts lie in the mesentery of the colon or behind the rectum, may be separable or inseparable from the bowel wall, and usually present, as the size increases, either as a palpable mass or intestinal obstruction. Diverticula are blind ending pouches of variable lengths and arise either from the mesenteric or the antimesenteric border of the bowel. They may have heterotopic gastric mucosa or pancreatic-type tissue. Long colon duplication or tubular duplication of the colon is the rarest form of duplication. Almost invariably, the two parts lie parallel, sharing a common wall throughout most of their length; frequently, it involves the entire colon and rectum. Often, there is an association of pelvic genitourinary anomalies.

Meckel's Diverticulum

Meckel's diverticulum is a remnant of the vitelline or omphalomesenteric duct, arising from the antimesenteric border of the terminal ileum, usually within 50 cm of the ileocecal valve.[73] Associated abnormalities include persistence of a fibrous band connecting the diverticulum to the umbilicus or a patent omphalomesenteric duct, the presence of ectopic mucosa or aberrant pancreatic tissue (in more than half of asymptomatic diverticula), and herniation of the diverticulum in an indirect inguinal hernia (Littré's hernia).

In most people, Meckel's diverticulum is asymptomatic, and according to autopsy series, it exists in 1–3% of the general population.[106] Surgical complications are more frequent in infants and children and include hemorrhage from ectopic gastric mucosa, intestinal obstruction resulting from associated congenital bands or ileocolic intussusception, diverticulitis, perforation, and umbilical discharge from a patent omphalomesenteric duct.

Atresia of the Colon

Colonic atresia is a rare cause of intestinal obstruction; it represents only 5% of all forms of gastrointestinal atresia. It is probably caused by a vascular accident occurring during intrauterine life.[104] Colonic atresia can be classified in three basic types: (1) incomplete occlusion of the lumen by a membranous diaphragm; (2) proximal end distal colonic segments that end blindly and are joined by a cord-like remnant of the bowel; and (3) complete separation of the proximal anal distal blind segments with the absence of a segment of megacolon.[107] Colonic atresia may be variable in length and can occur at any site in the colon, and its association with Hirschsprung's disease has been reported.[104]

Hirschsprung's Disease

Congenital megacolon is one of the most distressing of nonlethal anomalies, and was promptly attached to Hirschsprung's name after his description of autopsies of two infants who died from this condition in 1888.[108] However, it was recognized as early as 1825 in adults, and, in 1829, in infants.[109] This disease results from the absence of ganglion cells in the myenteric plexus of the colon caused by the interruption of migration of neuroenteric cells from the neural crest before they reach the rectum. The physiologic obstruction, more insidious than an anatomic atresia, results in proximal dilation and hypertrophy of the colon above. The extent of the aganglionosis is variable. The internal anal sphincter is involved in all cases, and the entire rectum in most cases. The disease is more common in males and its severity is related to the length of the aganglionic segment. Although most patients reach surgery before they are a year old, many are older, and a few reach adulthood. This topic is further discussed in Chap. 50.

Colonic Physiology

Ursula M. Szmulowicz and Tracy L. Hull

The human colon is a dynamic organ, involved in a vast array of functions, including the absorption of water and electrolytes, the salvage of unabsorbed nutrients, and the transport of luminal contents as feces. While not an organ essential for life, the colon still plays a major role in maintaining the overall health of the human body. Understanding these physiologic principles is integral to the successful treatment – both medical and surgical – of colonic disease.

Embryology

The embryology of the colon informs its anatomy. In the third and fourth weeks of gestation, the primitive intestine arises from the cephalocaudal and lateral folding of the dorsal surface of the endoderm-lined yolk sac, forming a straight tube situated posteriorly in the embryo.[1–3] Although the mucosa originates from the endoderm of the yolk sac, the muscular wall, connective tissue, and serosa have a mesodermal etiology.[4] By the fourth week of gestation, the gut tube develops into three distinct regions: the foregut, midgut, and hindgut.[4] The midgut begins immediately distal to the confluence of the common bile duct and the duodenum, extending to include the proximal two-thirds of the transverse colon. At the midgut, the primitive intestine maintains its connection to the yolk sac via the vitelline duct; failure of the vitelline duct to obliterate ultimately results in a Meckel's diverticulum or a vitelline cyst or fistula.[2,5] The hindgut reaches from the distal third of the transverse colon to the anal canal proximal to the dentate line. The midgut receives its vascular supply from the superior mesenteric artery and the hindgut from the inferior mesenteric artery.[6]

The colon gains its ultimate position by means of a series of rotations of the embryonic gut. During the fifth week of gestation, the midgut, particularly the future ileum, rapidly enlarges beyond the capacity of the abdominal cavity, culminating in its physiologic herniation through the umbilicus in the sixth week.[1] While exteriorized, this hairpin-shaped primary intestinal loop rotates 90° counterclockwise around an axis comprised of the superior mesenteric artery, as viewed from the front. Although the cranial limb of the herniated primary intestinal loop – the future small intestine – continues to elongate and organize into loops, the caudal limb – the proximal colon – remains mainly unaltered, its only adjustment involving the development of a cecal bud, a bulge from its antimesenteric border.[3] In the tenth week of gestation, the herniated intestine commences its return to the abdominal cavity, in the process completing an additional 180° counterclockwise rotation to finalize the disposition of the embryonic proximal jejunum on the left and the primitive colon on the right.[2] The cecum – the last component to reenter the abdomen – initially is located in the right upper quadrant but then migrates inferiorly to the right iliac fossa as the dorsal mesentery suspending the ascending colon shortens and then recedes.[4] As the cecal bud descends, the appendix appears as a narrow diverticulum.[2–7] The loss of the dorsal mesentery of the ascending and descending colon produces their retroperitoneal fixation, absent in the cecum, transverse colon, and sigmoid colon.[2]

Innervation

Colonic innervation emanates from two sources: the extrinsic and the intrinsic nerves. Extrinsic innervation involves the sympathetic and parasympathetic nerves of the autonomic nervous system, which are responsible for colonic motility and sensation. Intrinsic innervation arises from the poorly understood enteric nervous system.

The parasympathetic nerves primarily exert an excitatory affect upon colonic motility. The main parasympathetic neurotransmitters include acetylcholine and tachykinins such as substance P. The parasympathetic supply to the proximal colon originates from the posterior division of the vagus nerve – the tenth cranial nerve.[8,9] These parasympathetic fibers reach the colon by following the branches of the superior mesenteric artery: the ileocolic and middle colic arteries. The distal colon, however, receives its parasympathetic

input from the second to fourth sacral nerves, with the third sacral nerve the most dominant.[8,9] These pelvic splanchnic nerves – the nervi erigentes – emerge from the lateral horns of S2–4.[8,9] After exiting the spinal column, the preganglionic parasympathetic fibers travel superiorly and laterally, deep to the peritoneum, to join the inferior hypogastric plexus, located on the anterolateral pelvic wall, adjacent to the lateral ligaments at the level of the lower third of the rectum.[10] From the inferior hypogastric plexus, these parasympathetic fibers are distributed to the pelvic organs and to the distal colon as far proximal as the splenic flexure.[11] The preganglionic parasympathetic fibers ultimately synapse in the bowel wall at the ganglia within the myenteric plexus of Auerbach and Meissner's plexus.[12]

Unlike the parasympathetic nerves, the sympathetic system effects a tonic inhibition of the nonsphincteric colonic muscle and, thus, of colonic peristalsis.[11] Additionally, sympathetic fibers prevent epithelial secretion and reduce splanchnic blood flow.[9] However, the sympathetic supply is excitatory to sphincter muscles, particularly to the ileocecal junction and the internal anal sphincter.[9,11,13] The primary sympathetic neurotransmitter is norepinephrine.[8,11] The inhibition of colonic tone, although not fully understood, is believed to be mediated via α_2 adrenergic receptors.[14] In one study in humans, the α_2 agonist clonidine was determined to decrease fasting colonic tone, while the α_2 antagonist yohimbine increased it.[15] Stimulation of the α_2 adrenoreceptor also blocked the release of acetylcholine from the hyperpolarized parasympathetic neurons in the myenteric and pelvic plexi, thus arresting parasympathetic function.[11,15] In contrast, the in vivo administration of the α_1 agonist phenylephrine and the β_2 agonist ritodrine at the highest acceptable dosages had no impact upon colonic tone.[15] Yet, in an in vitro study, agonists of the β_1, β_2, and β_3 colonic adrenoceptors relaxed the human taenia coli; the circular muscular tone maximally diminished after treatment with the β_1 agonist.[16]

The preganglionic sympathetic effector cells are derived from the intermediolateral cell column (lateral horns) of the thoracic (T1–12) and, in particular, the lumbar spine (L1–2 or 3–4). The sympathetic nerve fibers leave the spinal column via the ventral spinal nerve roots (rami). These myelinated preganglionic fibers then exit from the ventral spinal nerve root a white ramus communicans ("communicating branches") to merge with the paired sympathetic trunks (paravertebral ganglia), found along the entire length of the vertebral column. Once it has joined a sympathetic trunk, the preganglionic sympathetic nerve fiber either immediately synapses at that ganglion or it ascends or descends along the trunk before synapsing at another vertebral level, from the first cervical vertebra to the first coccygeal vertebra, along the sympathetic trunk.[17] A single preganglionic fiber synapses with 30 or more postganglionic fibers.[8] After synapsing, the unmyelinated postganglionic fibers depart the sympathetic trunk as a gray ramus communicans, reuniting

with the ventral spinal ramus, after which it is distributed to the sweat glands and arrector pili muscles of the body wall and to the smooth muscle of the blood vessels throughout the body.[18] Yet, most preganglionic fibers – those innervating the abdominopelvic viscera – pass through the sympathetic trunk without synapsing, instead proceeding to the interconnected collateral (preaortic or prevertebral) ganglia that lie anterior to the aorta at its junction with its main vascular branches as part of a specific splanchnic ("visceral") nerve: the greater (T5–T9 or 10), lesser (T10–T11), least (T12), or lumbar (L1–2) splanchnic nerves.[12,17,19] While the midgut receives its sympathetic input from the lesser splanchnic nerve, the hindgut is supplied by the lumbar splanchnic nerve.[18] Once these preganglionic fibers synapse at a collateral ganglion, the postganglionic fibers follow the vasculature to the intestine, concluding in the enteric ganglia.[20] Some of the postganglionic fibers terminate instead on intestinal epithelial cells, whereby intestinal secretion is inhibited.[20] The midgut derivatives are primarily innervated by postganglionic fibers from the superior mesenteric ganglion and the hindgut structures, from the inferior mesenteric ganglion, although commingling between the ganglia is common.[8]

The intrinsic innervation of the colon – the enteric nervous system – is uniquely able to mediate reflex behavior independent of input from the brain or spinal cord.[21] This intrinsic network regulates the majority of colonic motility.[9] However, the activity of the enteric nervous system is impacted by the extrinsic nerves: the sympathetic, parasympathetic, and visceral afferent nerves.[8,11] This "little brain" employs the same modulators and neuro transmitters present in the central nervous system, including the excitatory acetylcholine, substance P, and neurokinin A and the inhibitory nitric oxide, adenosine triphosphate (ATP), vasoactive intestinal polypeptide (VIP), and pituitary adenyl cyclase-activating peptide.[9,13,21,22] The enteric nervous system acts through many different types of neurons, with their cell bodies amassed within neuronal plexi positioned either between the circular and longitudinal muscles (the myenteric plexus of Auerbach) or in the submucosal layer.[9] The submucosal plexi are comprised of Meissner's plexus, situated adjacent to the mucosa, and Schabadasch's plexus, which lies near the circular muscle.[9] Notably, the number of neurons in the enteric nervous system greatly exceeds that of the entire autonomic nervous system.[9] The myenteric plexus directs smooth muscle function while the submucosal plexus modulates mucosal ion transport and absorptive functions.[11] Moreover, the enteric network influences blood flow to the colon.[20] Control of colonic motor function via the enteric nervous system remains poorly understood at this time. However, a reflex arc is initiated by a mechanical (e.g., stretch), chemical, or other noxious stimulus, which activates an enteric primary afferent neuron; the impulse is carried to an enteric motor neuron – the effector cell – via an enteric interneuron, producing an excitatory or inhibitory effect.[9,20]

Colonic Function

Salvage, Metabolism, and Storage

Although digestion and absorption primarily take place in the stomach and small intestine, the colon still plays a major role in these operations. The colon processes various complex carbohydrates and, to a lesser extent, proteins that prove resistant to digestion and absorption in the more proximal intestine.[23,24] Unlike the small intestine, the colon salvages nutrients from these products via fermentation. Fermentation occurs by means of the saccarolytic and proteolytic members of the over 400 species of bacteria, the majority of which are obligate anaerobes, present within the colon.[25] Approximately 10% of ingested carbohydrates enter the cecum as undigested material.[11] Among the diverse end products of the bacterial fermentation of complex carbohydrates – mainly the soluble plant residues (fiber) – are the short-chain fatty acids, represented principally by butyrate (15%), propionate (25%), and acetate (60%).[26] Ingestion of a diet higher in complex carbohydrates, beans, resistant starches, and soluble fiber leads to a greater output of short-chain fatty acids than that of insoluble fibers. The composition of the bacterial microenvironment also influences the amount of synthesized short-chain fatty acids.[11,27] The nondigestible carbohydrate inulin – an extract of chicory – has been studied as a prebiotic, a food that selectively alters the admixture of the colonic bacterial flora; although its addition to the diet increased the proportion of beneficial bifidobacteria in the feces in various studies, its impact – whether healthful or harmful – upon other bacterial species could not be well gauged.[28] Bacterial fermentation of the complex carbohydrates primarily transpires in the ascending and proximal transverse colon. In contrast, the undigested dietary proteins that reach the colon, as well as proteins from mucous and sloughed epithelial cells, are fermented in the distal colon, primarily because the carbohydrates – the preferred nutrient of most bacteria – were previously exhausted in the proximal colon; the concentration of the short-chain fatty acids produced in the distal colon is 30% less than in the proximal colon.[27,29,30] However, a diet that includes prebiotics such as inulin results in a greater degree of saccarolytic fermentation in the distal colon due to the greater availability of these slowly fermentable, highly polymerized carbohydrates.[27] The fermented proteins are converted into short-chain fatty acids, branched chain fatty acids, and amines. In addition, the bacterial fermentation of undigested proteins generates ammonia, phenols, indoles, and sulfurs; these possibly toxic substances are considered potential etiologic agents for such diseases as colon cancer and ulcerative colitis.[27] Some of these proteolytic metabolites become a nitrogen source for bacterial growth.[29,31] The residual products of the bacterial fermentation of complex carbohydrates and proteins are absorbed or, like carbon dioxide, hydrogen, and methane, passed with the feces.[28] The dietary fats that reach the colon likely are not recovered in the colon but are expelled with the stool.[25]

The short-chain fatty acids occupy an integral position in colonic health. More than 95% of the short-chain fatty acids are created in and are immediately appropriated by the colon, with very little excreted in the feces.[25,27,32] An average of 400 mmol/day, with a range of 150–600 mmol/day, of short-chain fatty acids are produced in the colon.[33,34] This reclamation of undigested matter in the colon as short-chain fatty acids provides 5–15% of the total caloric needs of an individual.[27] These weak acids – the preeminent colonic anions – mainly remain dissociated in the colonic lumen until absorbed either in exchange for bicarbonate via a SCFA/HCO_3^- transport channel; by an active transport mechanism such as the sodium-coupled monocarboxylate transporter (SMCT1) or the monocarboxylate transporter isoform 1 (MCT1); or by diffusion in their lipid soluble form.[27] The sodium-coupled monocarboxylate transporter facilitates the conservation of sodium, chloride, and water in the colon.[27] Furthermore, the short-chain fatty acids are incorporated as the basic elements for mucin synthesis, lipogenesis, gluconeogenesis, and protein production. In particular, propionate combines with other three-carbon compounds in the liver to participate in gluconeogenesis. Acetate is used by the liver as a component to fashion longer-chain fatty acids and by the muscle as sustenance.[23,24]

Although the least abundant of the short-chain fatty acids, butyrate has the greatest import in colonic homeostasis. This short-chain fatty acid acts as the primary energy source for the colonocyte, supplying 70–90% of its energy requirements; these epithelial cells receive their nourishment solely from luminal substrates, not from the bloodstream.[20,23,24] Of the short-chain fatty acids, butyrate best promotes the absorption of water, sodium, and chloride from the colon, acting as an antidiarrheal agent.[27] This short-chain fatty acid also advances colonic cell proliferation and differentiation, repair, and immune function.[11,27,35] Butyrate has been shown to influence colon carcinogenesis: studies have revealed that fewer butyrate transporters were present in human colonic adenocarcinomas, resulting in a decrease in the utilization of the trophic butyrate in the malignant cells.[27] Moreover, in vitro studies of cancer cell lines identified apoptosis, nonproliferation, and differentiation after the administration of butyrate.[27] One method by which butyrate modulates gene expression and, thus, cancer growth likely arises from its ability to suppress histone deacetylase, thus encouraging the union of various transcription factors with nuclear DNA; to modify intracellular kinase signaling; and to inhibit nuclear factor-κB.[27]

In the colon, many metabolic processes are influenced by functional food components. These foods – the pre- and probiotics – alter the colonic microenvironment, adding to the impact of environmental factors and genetics.[33] As previously discussed, prebiotics – primarily nondigestable oligosaccharides (NDOs) – are slowly fermentable foods that selectively propagate microbial proliferation and/or activity.[36] These products are completely metabolized in the

colon into short-chain fatty acids, energy, and lactic acid, leaving no nondigestable oligosaccharides in the stool.[33] In contrast, probiotics represent active bacterial cultures that benefit the host by replenishing the colonic microenvironment.[37] Synbiotics combine the action of pre- and probiotics.[33] Investigations of these functional foods have focused on the lactobacilli and bifidobacteria, the growth of which transforms the colonic milieu, augmenting the immune function of the gut-associated lymphoid tissue (GALT).[31,33] The effect of these supplements is thought to be attributable to an increased production of butyrate, changes in mucin production, or interference in the binding of pathogenic bacteria to the colonic mucosa.[27,38] Prebiotics are particularly associated with an elevation of the concentration of short-chain fatty acids.[33] To combat the rising incidence of antibiotic-resistant bacteria in hospitals, the World Health Organization has recommended the use of microbial interference therapies – nonpathogenic bacteria that eradicate pathogens – such as probiotics.[34] Currently, probiotics are prescribed in cases of disturbed microbial balance, such as antibiotic-associated diarrhea. In the future, pre- and probiotics may become important supplements regularly administered to patients to promote health and to prevent illness. These functional foods further present the possibility of reducing the potential of carcinogens to form cancers.[31,38]

While the colon is one organ, it demonstrates regional differences. As noted, the proximal and distal colon have different embryological origins, derived from the mid- and hindgut, respectively. In appearance, the proximal colon is more saccular and the distal colon, more tubular.[39] The short-chain fatty acids are principally synthesized in the more acidic environment of the proximal colon. The proximal colon serves as a reservoir, in contrast to the distal colon, which mainly performs as a conduit.[40] Yet, this truism is disputed by studies in which radiopaque markers were determined to have the same dwell time of approximately 11 h in the proximal, distal, and middle colonic segments, suggesting that the proximal colon does not preferentially operate as a receptacle for stool.[9] Also, the character of the luminal contents impacts transit times. Large volumes of liquid quickly pass through the ascending colon but remain within the transverse colon for as long as 20–40 h; in contrast, a solid meal is retained by the cecum and ascending colon for longer periods than a liquid diet.[9,41,42] The salvage of water and electrolytes is primarily accorded to the proximal colon, although the distal colon and rectum contribute to this task, albeit to a lesser extent.[43,44] In the event that a large amount of chyme is delivered to the colon, the distal colon and rectum may assist in the absorption of enough fluid to produce a solid stool.[41] The regional heterogeneity of the colon exhibits adaptability. After a right hemicolectomy, the transverse colon adjusts to become a neo-proximal colon; 6 months after the surgery, the progress of an ingested isotope from the small intestine through the shortened colon returns to the preoperative baseline.[45] The assumption of this role may

ensue due to the greater concentrations of short-chain fatty acids to which the transverse colon is exposed following a right hemicolectomy, producing such changes as an increase in water and sodium retention.[30]

Transport of Water and Electrolytes

Among its roles in preserving intestinal homeostasis, the colon is also integral to water and electrolyte transport. The colon maintains an appropriate hydration and electrolyte balance by means of the absorption and secretion of intestinal water and electrolytes. The mucosal surface area available for these processes amounts to approximately 2,000 cm^2.[30] While the surface epithelial cells in the colon are primarily responsible for absorption, the crypt cells are involved in fluid secretion; however, crypt cells have been found to some degree to contribute to absorption.[11,30,46] After the liquid effluent from the small intestine has traversed the colon, fluid and electrolyte absorption and secretion as well as bacterial activity produce about 200 g of solid feces per day.[20]

The colon is extremely efficient at conserving intestinal water.[13] Water is passively absorbed along an osmotic gradient, enabled by a luminal sodium concentration lower than that of the epithelial cells; as such, the salvage of intestinal water relies upon sodium conservation.[11,30] Normally, the colon is presented with 1.5–2 L of water daily, as compared to the 9–10 L that pass through the small intestine; of this amount, 1.5–2 L are ingested, with the remainder originating from salivary, biliary, pancreatic, and intestinal secretions.[24,30] Approximately 90% of this water is reclaimed by the colon, leaving 100–150 mL in the feces.[20] The absorption of water primarily follows a paracellular pathway, although a transcellular route involves various protein channels: aquaporins 3, 4, 5, 8, and 9.[20] The ascending colon demonstrates the greatest absorptive capability, as the chyme resides within this segment the longest, thus maximizing its contact with the mucosa. As a consequence, diarrhea more consistently ensues after a right, as opposed to a left, hemicolectomy. Fluid retention is promoted by the antidiuretic hormone.[43] When challenged, the proximal colon, with the additional contribution of the sigmoid colon and rectosigmoid, is able to save a further 5–6 L of intestinal water daily.[47–49] Yet this facility is contingent upon the composition, rate of flow (less than 1–2 mL/min), and amount of the effluent. In the case that the absorptive capacity of the colon is exceeded, diarrhea results. Fluid secretion in the colon only transpires in the presence of diverse secretagogues, such as laxatives, bacterial endotoxins, hormones (e.g., VIP), and endogenous substances (e.g., bile acids).[43]

The colon is essential to the recovery of sodium. Under normal conditions, the colon principally absorbs sodium and chloride but secretes bicarbonate and potassium. The liquid chyme delivered to the colon contains 130–140 mmol/L of sodium whereas the concentration in stool is 40 mmol/L;

approximately 95% of the sodium transported into the colon is conserved.[29,43] If required, the colon is able to increase its salvage of sodium to 800 mmol/L/day.[43] The normal colon can prevent hyponatremia even despite a diet containing as little as 1 mEq of sodium daily; in contrast, the absence of a colon encourages dehydration and hyponatremia.[43] The transport mechanisms for sodium absorption, located on the luminal surface of the epithelial cells, vary throughout the colon: a Na^+/H^+ exchange channel in the proximal colon and an electrogenic sodium-specific channel (ENaC) in the distal colon and rectum.[20] The Na^+/H^+ exchange channels (NHE 2 and 3) are coupled to the Cl^--HCO_3^- exchange channels.[20] The activity of the electrogenic sodium-specific channel in the distal colon and rectum is requisite for the desiccation of stool.[20] These two types of transport channel allow for the passive diffusion of sodium into the colonic epithelial cells along an electrochemical gradient, consisting of a low intracellular sodium concentration (<15 mM) and a negative intracellular electrical potential difference as compared to the lumen.[30] This favorable electrochemical gradient is created by the active extrusion of sodium via the Na^+/K^+ ATPase pump on the basolateral membrane of the epithelial cell: three sodium ions are expelled in exchange for two potassium ions.[20,30] Aldosterone, a mineralocorticoid secreted by the adrenal gland in response to sodium depletion and dehydration, enhances fluid and sodium absorption in the colon.[46,50] The absorption of sodium is further promoted by somatostatin, α_2-adrenergic agents (e.g., clonidine), and the short-chain fatty acids.[11,24]

Like sodium, chloride is recovered from the colonic lumen. In the proximal colon, chloride is traded for bicarbonate via the Cl^--HCO_3^- exchange channel found on the luminal surface of the epithelial cells; the activity of this channel is linked to the Na^+/H^+ exchange protein.[20,29] However, chloride also is absorbed through a Cl^--HCO_3^- exchange channel that is not associated with sodium.[20] Chloride absorption is supported by an acidic luminal milieu; consequentially, the concomitant secretion of bicarbonate neutralizes organic acids within the colonic lumen.[24,43] The transport mechanism for bicarbonate secretion is poorly understood. Yet, bicarbonate, responsible for the alkalinity of the feces, is the primary electrolyte wasted in diarrhea.[20]

Potassium transport is primarily a passive process, following the movement of sodium across cell membranes. However, active potassium secretion occurs in the proximal colon and active absorption in the distal colon.[11,20] The H^+/K^+ ATPase actively conveys potassium into the epithelial cells of the distal colon and rectum.[20] A potassium channel is believed to facilitate active secretion in the proximal colon.[20] Potassium secretion, combined with potassium derived from bacteria and colonic mucous, may explain the relatively high concentration of this electrolyte – 50–90 mmol/L – in stool.[51,52]

The colon contributes to the metabolism of urea. Approximately 0.4–1 g of urea enters the colon in the small bowel effluent daily.[43] The urea is converted by the colonic

microorganisms into ammonia, which is then passively absorbed by the surface epithelial cells.[29,43] Ammonia is also derived from dietary nitrogen, the sloughed mucosal lining, and bacterial waste. Only 1–3 mmol of ammonia is excreted with the feces. The majority of the ammonia that reaches the colon is returned via the enterohepatic circulation to the liver, where it is refashioned into urea.[30]

Colonic Motility

Methodology to Measure Colonic Transit

Although altered motility is thought to play a major role in various gastrointestinal disorders, surprisingly little is known about the subject. This lack of understanding arises in part from the inaccessibility of the colon, particularly the proximal colon, for direct study. Bowel questionnaires have been used to gain insight into colonic motility; however, interestingly, stool frequency – or the recollection of the patient of their stool frequency – and colorectal transit time, which represents 75% of total intestinal transit time, are poorly related.[41,53,54] Early evaluations using barium were also unable to achieve a precise measurement of colonic motility.[55] The initial techniques to determine colonic motility began with the calculation of colonic transit time.

Radiopaque Markers

One of the first methods to gauge colonic transit time involves radiopaque markers. This study, proposed by Hinton and colleagues in 1969 to assess severe constipation, follows the passage of the markers over sequential abdominal radiographs.[11,56] Total and regional colonic transit times are reflected by the number and the location of the markers.[11] For men, the average total colonic transit is 30.7 h (SD 3.0) and for women, 38.3 h (SD 2.9).[55] Currently, the commercially available Sitzmarks™ (Konsyl Pharmaceuticals, Easton, MD) are composed of a gelatin capsule containing 24 radioopaque PVC O-rings. Various protocols for the examination exist, all of which require the cessation of all laxatives 48 h prior to swallowing the markers. In one approach that focuses on total colonic transit, 5 days after taking the capsule, an abdominal radiograph is obtained. A normal study demonstrates evacuation of 80% of the markers. The retention of more than 20% of the markers suggests slow transit constipation. Some physicians give a single capsule on Sunday evening and obtain abdominal X-rays on days 1, 3, and 5. The film on the first day provides evidence that gastric and small motility are grossly normal if all the markers are in the colon.

In order to localize the markers to specific segments of the colon – right, left, and pelvis – another technique requires that the patient consume one capsule, after which abdominal radiographs are performed every other day until all 24 markers have been expelled. As an alternative, patients

ingest single capsules on three successive days, with only one abdominal radiograph done on day 4 of the study so as to minimize radiation exposure.[57] The number of markers present equals the colonic transit time in hours. To better determine the distribution of the markers, some centers use capsules holding markers of different shape on each of the 3 days. An accumulation of the markers in the rectosigmoid indicates a dyssynergic defecation pattern.[58] The reliability of the technique is affected by patient compliance as well as by differences in the interpretation of the results.[59]

Scintigraphy

Some centers favor the more expensive colonic scintigraphy over the radiopaque marker method to measure colonic transit. As with the marker study, the protocols are not standardized among institutions. Although patients refrain from taking laxatives or opiates 24 h before the test, a normal diet is maintained throughout the study. The isotope is positioned in the cecum by the ingestion of a delayed release capsule or by orocecal intubation.[11] The delayed release capsule, coated with the pH-sensitive polymer methacrylate, is comprised of activated charcoal or polystyrene pellets labeled with either ^{111}In or ^{99m}Tc. The coating dissolves at the pH of 7.2–7.4 found in the distal ileum, after which the radioactive material is delivered into the colon.[40,60] Images are taken with a gamma camera at specified intervals, usually at 4, 24, and 48 h after consumption of the isotope, although this can be performed as frequently as twice daily.[11,61] Segmental transit is usually determined for the ascending, transverse, descending, and rectosigmoid regions of the colon. The proportion of the counts is calculated in each section and then multiplied by a weighing factor: 0 for the cecum, 1 for the ascending colon, 2 for the transverse colon, 3 for the descending colon, 4 for the rectosigmoid colon, and 5 for stool.[60] The results are expressed as the geometric center of the isotope mass at any given time point, with a low count indicating that the isotope is close to the cecum and a higher count that it has progressed more distally.[11,61] For clinical use, the total percentage of retained isotope as compared to normal data appears to be the most convenient reporting system. Scintigraphy correlates well with the radiopaque technique in assessing colonic transit, with a similar sensitivity in diagnosing patients with slow transit constipation.[60] The total exposure to radiation is also equivalent.[11] Due to its greater costs, in most cases scintigraphy serves as a research instrument.

Wireless Motility Capsule

The wireless motility capsule has been proposed as an alternative method to determine colonic transit time. This technique, already proven for the study of gastroparesis, uses a capsule containing miniature pressure, temperature, and pH measurement devices. The capsule is ingested, after which continuous recordings are obtained in an ambulatory setting, with the data captured over 5 days via a wireless instrument.[59]

In one trial, the results from the capsule approach correlated well with those acquired from the radiopaque markers, with a similar sensitivity and specificity in detecting abnormal transit in those patients with constipation.[59] The capsule is able to gauge phasic colonic contractions but not colonic motor patterns.[62] This costly procedure is not widely employed but is attractive in that radiation exposure is avoided and patient compliance is facilitated.[59]

Techniques to Record Colonic Motility

Colonic motility remains a constantly evolving field of study. The techniques by which colonic motility are gauged rely upon the monitoring of electrical activity or of intraluminal pressure, using surface electrodes or a manometry or barostat apparatus, respectively.[11] This indirect assessment of colonic motility has been hindered by the instruments available for its measurement, the colonic anatomy, and the need for prolonged readings. Recordings are usually obtained over 6 h in the laboratory and over 24 h in an ambulatory setting due to the long colonic transit time, especially as compared to the small intestine.[62] Also, the methods suffer from an absence of standardization. Although evaluations of colonic motility had initially focused upon the easily accessed distal colon, subsequent trials have indicated that this segment is not representative of the proximal colon. Yet, placement of the intraluminal devices is difficult, requiring either oral or nasal intubation or colonoscopy; furthermore, application of the surface electrodes demands surgery. Additionally, the necessity to purge the colon of stool may impact the results, producing an increase in the number of high amplitude propagated contractions, although these findings are conflicting.[63,64] Determinations of colonic pressure are further influenced by artifact from extrinsic forces such as cough, straining, and sneezing.[62] Thus, most of these approaches rest in the researchers' domain and have not been assimilated into the standard clinical armamentarium. However, significant progress is being gained with these tools to understand the physiology and pathophysiology of colonic motility.

Manometry

Colonic manometry has been the more frequently employed method to measure phasic (brief) colonic contractions. However, few centers utilize this technique in regular practice. In this procedure, a flexible catheter – either a solid-state or a water-perfused catheter system – is inserted into the colon. It is argued that the water-perfused system increases the amount of fluid in the colon, thus altering the results. However, the solid-state catheters are fragile, expensive, and sensitive to corrosive damage from colonic irritants.[65] However, this nonperfused system is more convenient and portable, allowing for long-term and ambulatory recordings.[66] The validity of the readings depends upon the proper placement of the catheter. As noted, the introduction of the catheter occurs

via an oral or nasal route, confirmed with fluoroscopy, or by colonoscopy. With endoscopy, the catheter is either carried along with the colonoscope in a piggyback fashion, grasped by biopsy forceps, or is threaded over a guidewire, deposited via the colonoscope, under fluoroscopic guidance. The tip of the catheter is stationed as far proximal as the transverse colon; with direct colonoscopic deployment, the proximal transverse colon is reached in all subjects, with the probe remaining in position in greater than 80% of cases.[65,67–69] To adhere to more physiologic conditions, unprepared colons are currently advocated, despite the impediment presented by the retained stool to the retrograde placement of the catheters; in some cases, enemas are instead used. Also, to prevent data artifact, minimal air is insufflated via the colonoscope and as much aspirated as possible during its withdrawal. The patients are often asked to maintain a diary to mark events such as bowel movements, flatus, and meals. Manometry is well able to detect the changes in intraluminal pressure after eating or the administration of a colonic stimulant (e.g., bisacodyl). However, these variations in pressure do not consistently correspond to contractions: in a study of colonic motility, the simultaneous use of manometry and colonoscopy indicated that a majority of pressure fluctuations perceived by the catheter reflected colonic relaxation, not contraction.[70] Furthermore, manometry does not reliably identify all contractions, some of which are not associated with an appreciable pressure deflection.[9,70] An investigation comparing the barostat with manometry suggested that the measurements obtained from manometry are also affected by the luminal diameter in which the tip of the device lies.[70] However, unlike the barostat, manometry recognizes patterns of motor activity due to the multiple recording sites along the catheter.[62]

Barometry

The colonic barostat device addresses the inability of manometry to record colonic tone, i.e., sustained contractions. As with manometry, it is utilized clinically in few centers. The instrument includes a compressible polyethylene balloon, placed within the colonic lumen, that is attached via tubing to a barostat – a cylinder containing a piston.[11] The balloon is maintained at a low constant pressure such that it is continuously in close contact with the colon wall in a single location.[71] Contraction of the colon constricts the balloon, reducing its volume by forcing air into the barostat; in contrast, colonic relaxation produces an increase in the volume of the balloon so as to sustain a constant pressure.[11] Changes in the volume of the balloon reflect colonic tone, although phasic contractions are also assessed.[72,73] However, patterns of colonic activity cannot be distinguished as measurements are obtained in only one site.[62] Unlike the manometry technique, the barostat system is capable of detecting contractions that do not produce a significant pressure change, even in colonic segments wider than 5.6 cm.[11]

Electrodes

Electrodes have also been applied for the study of colonic motility. These devices record the myoelectrical signals from the colon that result in muscular activity.[74,75] The electrodes are placed on the serosal surface via surgery or on the mucosa by colonoscopy. The technique is seldom used due to ethical concerns.

Peristalsis

Peristalsis represents the alternating waves of contraction and relaxation of the circular muscles of the colon wall. Fecal material is propelled antegrade through the colon by the contraction of the circular muscle proximal but the relaxation of the muscle distal to it, i.e., descending inhibition.[11] During peristaltic activity, the saccular haustra – the product of circular muscle contraction – recede and then reform, first proximal to and subsequently at the level of the transferred material, again giving rise to colonic segmentation.[9,41,76] The contribution of the longitudinal smooth muscle to colonic activity is unknown.[9] The average rate of antegrade colonic transit is approximately 1 cm/h.[9] The peristaltic reflex is thought to be initiated by luminal distention and, possibly, by chemical stimuli, which stimulate the enteric sensory neurons; ultimately, the enteric motor neurons – the effector cells – are activated via the intermediary of the enteric interneurons.[11] The interneurons may also directly detect changes in smooth muscle length.[77] The primary neurotransmitters involved in the peristaltic reflex include the excitatory acetylcholine and the inhibitory nitric oxide and adenosine triphosphate (ATP).[11] Although the enteric nervous network primarily controls peristalsis, the extrinsic nervous system modifies the reflex, with the sympathetic nerves suppressing and the parasympathetic nerves promoting motility, especially during defecation. Interestingly, the parasympathetic nerves also assist in the synchronization of descending inhibition. The antegrade movement of the fecal bolus is further dependent upon the radius of the colonic segment, the consistency of the feces, and the pressure differential between segments.

Colonic motility adheres to several patterns. Generally, contractions vary between tonic and phasic. The poorly understood tonic contractions are sustained events of slow onset, not necessarily inciting an elevation of the intraluminal pressure.[76] Bassotti et al. further classify the briefer phasic contractile episodes as high and low amplitude propagated contractions and as segmental contractions.[71,78]

High amplitude propagated contractions – also known as migrating long spike bursts, large bowel peristalsis, and giant migrating contractions – function to transport large volumes of feces over long distances.[71,78,79] These contractions are believed to be the manometric equivalent of mass movement – first identified on radiographic studies of the colon – whereby colonic contents are projected

distally in seconds.[40,67,80,81] The high amplitude propagated contractions transpire between 2 and 24 times a day, with an average of approximately five to six times a day.[62,71] These contractions, with an amplitude of 100–200 mmHg (average of 100 mmHg), persist for 20–30 s.[62,71] The contraction usually begins in the proximal colon and is transmitted distally for 15 cm or longer, with the velocity gradually increasing to as fast as 1 cm/s as the impulse moves caudad.[11] A contraction that starts in the proximal colon is conveyed farther than that commencing in the distal colon: 50 cm from the cecum and 20 cm from the sigmoid colon.[9] More than 95% of these contractions proceed antegrade; however, only one-third of these contractions result in the transit of fecal material.[11,71,78] Moreover, not all instances of defecation, particularly those involving liquid stool, are incited by a high amplitude propagated contraction.[78] High amplitude propagated contractions are considered the probable origin of the pressure spikes that occur upon morning waking (35%) and after meals (50%).[71] The urge to defecate is likely attributable to these contractions.[71] Borborigmy is thought also to arise from high amplitude propagated contractions.[78] The impetus for these contractions is incompletely comprehended. These contractions are elicited by cholinergic medications (e.g., neostigmine), eating, colonic distention, short-chain fatty acids, and laxatives (e.g., bisacodyl).[11] However, only in 50% of cases does colonic distention produce propagating activity.[78] In patients with constipation, high amplitude propagated contractions are decreased in number, amplitude, extent, and speed.

The low amplitude propagated contractions are still less understood. These contractions (5–40 mmHg) – also referred to as long spike bursts – last for 3 s.[71] As with the high amplitude propagated contractions, these contractions are strongly related to meals and the sleep-wake cycle. There may be an association with the passage of flatus and, in particular, liquid stool.[82,83] Similar to the high amplitude propagated contractions, these contractions are likely provoked by colonic distention.[71] The mechanisms by which these two propagated contractions are regulated remain unclear. However, propulsive activity depends upon a functional enteric nervous system.[71]

Segmental contractions, presenting singly or in rhythmic or arrhythmic bursts, account for the majority of colonic activity, particularly at rest.[78] These contractions appear with an amplitude of 5–50 mmHg.[71] Found primarily in the ascending and transverse colon, this activity produces localized contractions of the circular and longitudinal muscles, in effect segregating the haustrae.[71] These segmental contractions, the correlate of myoelectrical short spike bursts, result in the slow, sequential antegrade or retrograde movement of colonic contents among the haustra, allowing for mixing of the material.[13] Additionally, contact with the mucosal surface is maximized, which permits the absorption of intestinal water and electrolytes.[71] Only 6% of segmental contractions are rhythmic, with a frequency of 2–8 cycles per minute;

however, in the rectosigmoid region, a slower interval of 3 cycles per minute is preeminent, possibly giving rise to a physiologic sphincter to aid in continence.[9,78,83]

Unlike other mammals, humans possess a colon in which cyclic motility is absent.[78] The human rectum, however, does display such cyclic activity, the rectal motor complex. The rectal motor complex is comprised of phasic contractions with amplitude of more than 5 mmHg. These phasic contractions appear at a cycle of 2–3 per minute, with each persisting for approximately 3 min. Yet, the interlude between these contractions ranges from 10 to 260 min. This phasic activity in the rectum and, potentially, the rectosigmoid may contribute to fecal continence, as it is correlated with an elevated anal canal pressure; this role is further suggested by the greater prominence of this activity at night.

Cellular Basis of Motility

Colonic motor activity is driven and coordinated by the interstitial cells of Cajal, the intestinal pacemaker cells.[84] In the absence of these cells, the intestinal smooth muscle is inactive.[85] The interstitial cells of Cajal arise from smooth muscle precursor cells; that is, the cells are of mesenchymal, not neuronal, origin.[86] These cells are classified by their location as ICC_{MY} – in the myenteric plexus, between the muscular layers; ICC_{SM} – in the submucosal surface of the circular muscle; and ICC_{IM} – within the circular and longitudinal muscles.[87] The interstitial cells of Cajal are linked to the individual smooth muscle cells via intracellular gap junctions; the similarly coupled smooth muscle cells function as a single unit, a syncytium.[9] The gap junctions allow for the passage of current – predominantly slow waves – from the interstitial cells of Cajal to the smooth muscle syncytium, leading to its depolarization.[86] The interstitial cells of Cajal are believed to be mechanosensitive, able to transduce stretch stimulus from the distended colonic lumen into electrical activity.[88] The ICC_{SM} – the primary pacemaker cells – continuously generate high amplitude slow waves, at a frequency of 2–4 per minute, within the circular muscle layer.[9] Unlike the other types of interstitial cells of Cajal, the ICC_{SM} are present only within the colon, solely in its proximal portion.[86] A slow wave of sufficient charge produces a smooth muscle action potential, allowing for an influx of calcium into the smooth muscle cells via the L-type calcium channels and, thus, a brief contraction.[76] The amplitude of the slow waves is greatest at the submucosal surface of the circular muscle, diminishing while traveling through the muscular wall.[89] Slow waves migrate antegrade and retrograde along short segments of the colon, rapidly in the circumferential and slowly in the longitudinal axis; as waves of different inception meet, their propagation ceases, giving rise to non-propulsive mixing activity.[9,85] A second pacemaker site may involve the ICC_{MY}. In addition to the slow waves, the ICC_{MY} may initiate low amplitude myenteric potential oscillations (MPOs) at a frequency of 12–20 per minute, which are

conveyed to the circular and longitudinal smooth muscle.[9] The MPOs possibly are the source of propagating contractions.[9] Moreover, the ICC_{MY} synchronize the activity of the circular and longitudinal layers of the smooth muscle.[86] As opposed to the ICC_{SM}, the ICC_{MY} are widespread throughout the colon.[86] The etiology of the intrinsic electrical activity of the ICC_{MY} and ICC_{SM} is uncertain but may involve calcium regulated nonselective cation channels or large-conductance chloride channels; the oscillations from the interstitial cells of Cajal remain even the absence of extrinsic neural input.[9] The ICC_{IM} are thought to mediate such extrinsic input – from the enteric and autonomic neural networks – upon smooth muscle function; the release of acetylcholine and nitric oxide from excitatory and inhibitory neurons, respectively, results in alterations in the activity of the ICC_{IM}.[9,88] Furthermore, the ICC_{IM} appear to augment the slow waves and MPOs from the ICC_{SM} and ICC_{MY}, respectively, as they are transmitted along the smooth muscle syncytium.[9] Much still remains to be elucidated about the cellular basis of colonic motility.

Characteristics of Colonic Motility in Health

Manometry studies have demonstrated a noncyclical pattern of colonic activity.[11] The variations in colonic activity are mirrored by changes in colonic tone.[83] The human colon follows a circadian rhythm in which sleep is associated with its relaxation and, thus, with a marked diminution of its pressure activity.[65,90] However, as previously noted, the rectum and rectosigmoid display continued phasic activity during the night. Immediately after morning waking, a two- to three-fold increase in colonic pressure activity – likely due to high amplitude propagated contractions – occurs, inciting an urge to defecate in some cases. A similar rise in colonic activity transpires during brief night-time arousals or during REM sleep.[71] The mechanism by which the colon rapidly responds to these alterations in wakefulness is unknown. During the day, the transverse and descending colon reveal more pressure activity than the rectosigmoid colon. Moreover, less activity is seen in the transverse and descending colon of women, as compared to men.[65]

Oral intake also impacts colonic activity. Within 1–3 min of the initial bites of a meal, long before the food reaches the colon, segmental contractions begin in the proximal and distal colon, persisting for 2–3 h.[65,91] This colonic motor response to eating, or gastrocolic reflex, also features a concomitant increase in the colonic smooth muscle tone, especially in the proximal colon, often affiliated with high amplitude propagated contractions.[39,41,71] The colon exhibits regional differences in its response to a meal: the proximal colon evinces a swifter but briefer duration of contractile activity than the distal colon.[71] Although infrequently identified during scintigraphic studies, retrograde propulsion most commonly appears after meals as well as during morning waking.[65] Colonic motility is instigated by a higher calorie meal (more than 500 kcal), fat, and, to a lesser degree,

carbohydrates; in contrast, proteins inhibit motor function.[71] The colonic response to eating includes two phases: an initial stimulation of the gastro-duodenal wall mechano- and chemoreceptors and a subsequent activation of receptors in the colonic wall.[71] The means by which the gastrocolic reflex arises is unclear but may involve cholecystokinin, gastrin, serotoninergic input, or cholinergic stimuli. However, cholecystokinin antagonists do not block the reflex; also, infusions of high dose cholecystokinin have no effect upon colonic activity although pancreatic exocrine secretion and gallbladder contraction are maximally stimulated.[92] Interestingly, the colonic motor response to eating persists following a gastrectomy or spinal injury; yet, the colon must be in continuity for the reflex to take place.[71]

Stress, both physical and emotional, also influences colonic function. One study found that psychological stress induced a significant increase in propagating contractions, both in their frequency and amplitude, throughout the colon, even in the absence of an appreciable autonomic response.[93] Despite the withdrawal of the stressor, the augmented motor activity endured.[93] In contrast, physical stress, consisting of exposures to extremes of temperature, precipitated a significant elevation in the frequency and amplitude of simultaneous contractions, which ceased immediately after the activity stopped.[93] In some trials, low and high amplitude propagated contractions are stimulated by acute physical exercise.[71,94]

Defecation

The process of defecation involves the entire colon, not solely the anus and rectum. As already described, the majority of colonic activity – the segmental contractions – serve to retain fecal material so as to promote the salvage of intestinal water and electrolytes. However, periodically, colonic activity shifts in order to foster the expulsion of stool. Approximately 1 h prior to the act of defecation, an involuntary preexpulsive phase is initiated, in which the frequency and amplitude of antegrade nonpropagating and, particularly, propagating contractions steadily increase throughout the whole colon.[95] The early component of the preexpulsive phase – the first 15–60 min – is characterized by propagating contractions that initially arise from the proximal colon but subsequently from the distal colon; this initial sequence is thought to transport stool into the distal colon, thus stimulating distal colonic afferent nerves, which in turn provoke further propagating sequences.[9,95] During the late phase, consisting of the last 15 min, the point of origin of these contractions reverses from the distal to the proximal colon.[9,95] Scintigraphic studies reveal that, in one bowel movement, 20% of the ascending colon can be emptied; other evaluations indicate that nearly the entire colon may be evacuated of stool in a single defecatory action.[9,96] A number of investigations identified antegrade high amplitude propagated contractions in close temporal relation to

defecation; yet, not all of these contractions necessarily precede or end in defecation.[78,97,98] However, at least one high amplitude propagated contraction of very high amplitude usually coincides with the urge to defecate.[95] While the early activity is unnoticed, the late phase is often associated with the urge to defecate that occurs prior to the voluntary act of fecal evacuation.[95]

Colonic Sensation

Colonic sensation has proved a complicated, poorly understood topic. The normal physiologic processes of the healthy colon are largely unnoticed, with only fullness and an urge to defecate consciously perceptible.[11] The colon itself contains no specialized sensory end organs.[41] However, naked nerve endings lie within the serosa, muscularis propria, and mucosa of the colon while Pacinian corpuscles are found in the mesentery.[9] Afferent nerve fibers reach the central nervous system via parasympathetic pathways and spinal afferent nerves, both of which display mechano- and chemosensitivity.[99] The parasympathetic fibers convey sensory information from the proximal colon via the vagus nerve to cell bodies in the nodose and jugular ganglia and, from the distal colon, by the pelvic splanchnic nerves.[13,41,99] The precise role of the parasympathetic afferent fibers remains unknown but likely involves unconscious reflex sensation, not painful stimuli.[9] Sensory input from the colon is chiefly detected by spinal afferent neurons, primarily by those with their cell bodies within the lumbar dorsal root ganglia.[8,9,99] These lumbar spinal afferent nerves travel with the sympathetic fibers within the lumbar splanchnic nerves from the colon by way of the inferior mesenteric ganglia.[9] The lumbar spinal afferent fibers conclude in sensory endings throughout the entire large intestine, whereby pain, colorectal distention, mesenteric traction, and noxious mucosal stimuli are discerned.[9] In contrast, the sacral spinal afferents, with their cell bodies in the sacral dorsal root ganglia of S2–4, are thought to be concerned with a sensation of rectal fullness and an urge to defecate.[9] These sacral spinal afferent fibers are borne along with the parasympathetic pelvic splanchnic nerves.[8]

Visceral pain sensation is carried by rapidly conducting Aδ fibers or by unmyelinated C fibers.[11] The Aδ fibers are associated with the more localized "discriminative" pain, which persists for as long as the stimulus, and the C fibers in the diffuse "affective-motivational" pain, which continues beyond the duration of the catalyst.[11] Sensory information is transported to the brain along the spinothalamic and spinoreticular tracts as well as by the dorsal column of the spinal cord.[11] The spinothalamic tracts specifically transmit sensation from the Aδ and C fibers to the somatosensory cortex via the lateral thalamic nuclei or to the frontal, parietal, and limbic regions by means of the medial thalamic nuclei, respectively.[11]

The modulation of visceral sensation occurs through several methods. Enteroenteric reflexes mediated by the spinal cord produce variations in the smooth muscle tone, leading to changes in the activation of the nerve endings in the intestine or mesentery.[100] The perception of visceral pain is influenced by descending noradrenergic and serotonergic pathways that emanate from the reticular formation, hypothalamus, and frontal cortex. These fibers project to the dorsal horn of the spinal cord, where they modify noxious input from the visceral afferent nerves.[13] This mechanism likely explains the experience of wounded soldiers who feel no pain in the midst of battle.[101] The intersection of visceral spinal afferent nerves with somatic afferent nerves in the dorsal horn of the spinal cord produces the phenomenon of referred pain, in which visceral sensation is consciously recognized as somatic pain, located in a dermatome of the same embryologic origin as the visceral structure: T8–T12 for the midgut and T12–L2 for the hindgut.[8,13,101] In addition, visceral afferent nerves from the colon relay information via collaterals to the reticular formation and thalamus, which induce alterations in affect, appetite, pulse, and blood pressure through autonomic, hypothalamic, and limbic system connections.[13,102]

Disturbances in Colonic Physiology

Physiology of Constipation

Constipation is a common complaint, with a prevalence of 2–28% among Western populations.[103] This disorder refers to infrequent bowel movements (fewer than three per week); hard or lumpy stools; incomplete evacuation; a sensation of anorectal obstruction; the need for manual maneuvers to facilitate defecation; and/or excessive straining.[104] Individuals with constipation are an incredibly heterogeneous group. Distinct subtypes of constipation exist, each requiring different treatment modalities; however, even within these subtypes, there may be wide variability in the clinical presentation and pathophysiologic etiology. The causes for constipation range from dietary, pharmacologic, structural, to systemic.

Many people become constipated due to dietary and lifestyle neglect. In the USA, fiber intake is overall low. Two primary roles of the colon, solidifying liquid chyme into stool and defecation, are dependent upon adequate dietary fiber: dietary fiber "normalizes" large bowel function.[105,106] In particular, the bulkier stool produced by fiber supplementation stimulates propulsive activity, thus decreasing colonic transit time.[103] The recommendation for adequate fiber intake ranges from 20 to 35 g/day for adults.[107] For an individual on a 1,500–2,000 kcal/day diet, in order to include 15 g of fiber, 11 servings of refined grains and 5 servings of fruits and vegetables must be consumed.[105] Fiber is classified as either soluble or insoluble, acting by differing mechanisms to

increase stool weight. Soluble fibers such as oat bran provide rapidly fermentable material to the proximal colon, which allows for sustained bacterial growth.[108] The consequent higher bacterial content of the stool results in the greater fecal mass.[108] In an average bowel movement, 50% of the stool weight consists of bacteria.[103] Also, soluble fibers cause a rise in the excretion of lipid and fat, further boosting stool weight.[108] In contrast, poorly fermentable insoluble fibers such as wheat bran, cellulose, and lignin augment stool weight by providing more undigested plant material for evacuation.[108] One gram of wheat bran generates 2.7 g of stool.[103] Wheat bran also promotes fat excretion, but not to the extent of oat bran.[108] The outcomes of fiber supplementation as a treatment for constipation have yielded conflicting data.

Constipation may be seen more commonly in sedentary individuals. The Nurses Health Study suggested that those women who engaged in daily strenuous activity were 44% less likely to experience constipation than those who exercised less than once a week.[109] During exercise, phasic and propagating motor activity is diminished in the colon, with the effect more pronounced with more vigorous effort; however, after the physical exertion is completed, an increase in the frequency and amplitude of the propagating pressure waves is demonstrated, possibly due to the restoration of parasympathetic input.[68] This postexercise pattern may precipitate the propulsion of feces.[68] During or after exercise, individuals often report an urge to defecate or defecation itself.[109] In fact, abdominal cramps and diarrhea are frequently related by runners.[110,111] However, in a small study of the impact of regular exercise – 1 h a day, 5 days a week – upon chronic idiopathic constipation, there was no symptomatic improvement in the eight subjects after 4 weeks of increased activity.[112] Moreover, a small study examining colonic transit in otherwise sedentary men after mild exercise, consisting of 1 h of walking on a treadmill for 3 days/week, showed no significant difference in the passage of radiopaque markers as compared to baseline.[113]

Idiopathic slow transit constipation involves ineffectual colonic propulsion, resulting in a measurable delay in the movement of fecal material through the colon. The severity of the presentation is variable, with the most intractable cases referred to as colonic inertia. These patients with slow transit constipation, usually women, have fewer than one bowel movement per week, often in association with abdominal pain, a lack of an urge to defecate, malaise, fatigue, or bloating.[103] Little benefit is gained from dietary fiber supplementation, which, conversely, may cause worsened constipation, or from laxatives.[103] The symptoms often arise during puberty and steadily deteriorate over time.[103] Retarded colonic transit in these individuals is either pan-colonic or segmental.[60] Slow transit constipation is consistently affiliated with a blunted colonic motor response to eating (i.e., gastrocolic reflex), including both propulsive and segmental contractions.[60,64,83] In contrast, in patients with colonic inertia, there is *no* colonic response to a meal.[103] A significant decrease in the frequency as well as the amplitude of high amplitude propagated contractions is demonstrated in slow transit constipation, leading to reduced colonic propulsive activity.[41,64,71,114,115] Furthermore, the preexpulsive phase of the defecatory process is depressed.[103] Conflicting results have been obtained from investigations into excessive, disorganized rectosigmoid phasic activity – a "brake" to antegrade propulsion – as a factor in slow transit constipation.[60,64] Histological evaluations reveal a marked decrease in the population of myenteric plexus neurons; however, of the neurons present in the myenteric plexus, those that produce the potent inhibitory neurotransmitter nitric oxide are vastly predominant, especially as compared to controls.[116] Slow transit constipation also features a significant reduction in the interstitial cells of Cajal either throughout the colon or solely in the sigmoid colon.[84,117,118] Moreover, the morphology of the existing cells is seen to be strikingly abnormal, demonstrating few dendrites and an irregular surface.[103] Colonic transit studies of slow transit constipation reveal retention of more than 20% of the radiopaque markers 5 days after their ingestion.[103]

Obstructed Defecation

Obstructed defecation usually results from abnormalities in pelvic as opposed to colonic function. Typically, this disorder is associated with failure of the puborectalis muscle to relax during defecation, producing a functional – not a physical – obstruction.[11] Anatomic abnormalities also causing obstructed defecation include rectocele, enterocele, excessive perineal descent, and rectal intussusception. These patients report inordinate straining, incomplete evacuation, painful defecation, infrequent bowel movements, and digital anal disimpaction.[103] Among the diagnostic tests for obstructed defecation are anorectal manometry or electromyelography, balloon expulsion, barium defecography, and dynamic MRI. A defecogram may identify retention of 50–100% of the instilled barium in the rectum of patients with obstructive defecation.[58] Colonic transit studies in these patients demonstrate collection of six or more radiopaque markers in the distal colon, indicating partial evacuation of the rectum.[58,119] Two-thirds of patients with obstructive defecation may display a concurrent pattern of slow transit constipation.[58]

Obstructed defecation rarely arises from a colonic source – a sigmoidocele. In this variant, a redundant sigmoid colon descends into the rectovaginal pouch (of Douglas) during defecation, impinging upon the rectum during attempted evacuation.[120] In one study of 463 patients with constipation, fecal incontinence, or chronic idiopathic rectal pain, a sigmoidocele was diagnosed on defecography in 5.2%.[120] Defecography is the primary method of diagnosis of a sigmoidocele. The severity of a sigmoidocele is determined by the extent of its decline into the pelvis, as compared to the pubococcygeal and ischiococcygeal lines.[120]

While third degree sigmoidoceles likely benefit from a sigmoid colectomy, the significance and optimal management of first and second degree sigmoidoceles are not fully understood.[120] The clinician should also be cognizant of concomitant pelvic floor disorders in these patients.

Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is a functional disorder with multiple manifestations: constipation-predominant (IBS-C), diarrhea-predominant (IBS-D), and mixed (IBS-A). Irritable bowel syndrome is characterized by altered bowel habits and chronic, recurring abdominal pain directly related to defecation, in the absence of an anatomic abnormality.[54] Extracolonic complaints include lower back pain, lethargy, nausea, urinary symptoms, dyspareunia, and dysmenorrhea.[121] The etiology of irritable bowel syndrome is unclear but is believed to involve visceral hypersensitivity to intraluminal stimuli.[54] Aberrant motility, inflammation, anomalies in extrinsic autonomic innervation, abnormal brain–gut interaction, and the role of psychosocial factors have also been extensively investigated. Hormonal factors may be involved, as symptoms are often increased perimenstrually; however, the complaints persist even in the absence of menses.[122] The treatment of IBS is based on the nature and severity of symptoms. Education, reassurance, and the elimination of foods that incite the typical complaints are the initial interventions. In some patients, fiber supplementation exacerbates the IBS.[121] For those who do not respond to conservative measures, medication is considered. However, the pharmacologic therapy of IBS-A has not been well studied.

In approximately one-third of patients with irritable bowel syndrome, constipation is the main feature (IBS-C). Women are primarily affected by IBS-C. The majority of these patients demonstrate normal colonic transit and motility patterns, although there is a possible overlap with slow transit constipation.[123] Tegaserod, an agonist of the 5-HT$_4$ receptor that is involved in the metabolism of serotonin, showed promise as a treatment of IBS-C but was withdrawn by the Food and Drug Administration in 2007 due to a high incidence of myocardial infarction, stroke, and unstable angina.[124,125] In some studies, probiotics such as *Lactobacillus* and *Bifidobacterium* produce variable degrees of alleviation of IBS symptoms such as pain.[126] Lubiprostone (Amitiza®, Sucampo Pharmaceuticals, Inc., Bethesda, MD), a prostaglandin E1 analog, activates type 2 chloride channels on the apical membrane of colonic epithelial cells.[127,128] This medication promotes intestinal fluid secretion and, indirectly, colonic motility in patients with IBS-C.[128] Studies of lubiprostone revealed significant improvement in stool frequency and consistency, abdominal discomfort and pain, straining, and bloating.[128] Cholecystokinin, found in elevated levels in the plasma and sigmoid colon of IBS-C patients, has been implicated in the pathogenesis of IBS: infusion of cholecystokinin induces typical symptoms of irritable bowel syndrome.[129,130] However, in a randomized trial, the CCK-1 receptor antagonist dexloxiglumide led to no amelioration in IBS symptomology; moreover, overall colonic transit was unchanged, although emptying of the ascending colon was delayed.[130] However, a pilot study of a similar CCK-1 receptor antagonist, loxiglumide, yielded some improvement in IBS symptoms.[131] A randomized trial of neurotrophin-3, a protein growth factor integral to the development of the enteric nervous system, in constipated patients revealed more frequent spontaneous bowel movements, a more rapid colonic transit time, and a reduction in associated symptoms.[132] Approximately one-third of subjects experienced transient injection site reactions after subcutaneous administration.[132]

Diarrhea-predominant irritable bowel syndrome is encountered in approximately one-third of patients with IBS. The majority of men with irritable bowel syndrome experience the diarrhea-predominant type. This subtype is often affiliated with urgency and fecal incontinence.[121] IBS-D may follow an episode of acute gastroenteritis, pelvic surgery, or emotional stress.[11] Some patients with IBS-D display accelerated proximal colonic transit, with an increased frequency of high and low amplitude propagated contractions.[11,78] Additionally, the colonic motor response to eating is enhanced in a proportion of these patients, resulting in an intense urge to defecate and abdominal pain immediately after meals.[11] Rectal hypersensitivity is also a feature in some of these patients.[11] Antispasmodics such as hyoscine are prescribed for those with abdominal pain and bloating, especially after meals. Low-dose tricyclic antidepressants (e.g., amitriptyline) are added when the pain is more constant and even disabling; these medications function not as mood stabilizers but instead act directly on the gut and central pain processing.[121,124,133] Loperamide is an antidiarrheal agent safe for long-term use.[121] Diarrhea is effectively addressed by selective serotonin 5-HT$_3$ antagonists such as Alosetron. This drug was initially FDA approved in March 2000, only to be retracted due to reports of ischemic colitis, severe constipation, and even death.[134] In June 2002, it was adopted solely for women with chronic, severe IBS-D.[135] However, the medication may only be supplied by physicians participating in the Prometheus Prescribing Program, after the patient signs a patient–physician agreement.[135] Further investigation into these novel pharmaceuticals for IBS is required.

Ogilvie's Syndrome

Ogilvie's syndrome, initially described in 1948, is also known as acute colonic pseudo-obstruction. This disorder is characterized by an imbalance of autonomic innervation to the colon: the inhibitory sympathetic input exceeds that of the excitatory parasympathetic nerves.[136] A massively

dilated colon – particularly the proximal colon – results from the consequent suppression of peristaltic activity.[136] The specific source for the initial motor disturbance that allows for this scenario is unknown.[136] One hypothesis ascribes this functional obstruction to impairment of the pelvic (parasympathetic) splanchnic nerves supplying the distal colon, giving rise to an atonic segment, lacking peristaltic function.[136] Acute colonic pseudo-obstruction has been reported concurrent with infectious or inflammatory (e.g., acute pancreatitis), cardiovascular (e.g., myocardial infarction), metabolic (e.g., hypokalemia), postoperative (e.g., spinal or pelvic surgery), posttraumatic, neurologic (e.g., Alzheimer's disease), respiratory (e.g., pneumonia), and neoplastic causes (e.g., metastatic disease); drugs (e.g., antidepressants); and old age.[136] As indicated by the law of LaPlace (wall stress = [(transmural pressure) × (radius)]/wall thickness), the cecum is at greatest risk of perforation in light of its thin wall and large diameter.[137] Despite symptoms and signs consistent with a large bowel obstruction, no mechanical blockade is present. The management of Ogilvie's syndrome begins with eliminating the presence of a physical obstruction with a water-soluble contrast enema. In the majority of cases, colonic dilatation responds to conservative therapy, including nasogastric decompression, correction of fluid and electrolyte abnormalities, cessation of antimotility medications such as opiates, and remedy of the underlying illness.[138] In the absence of peritoneal signs or a cecal diameter greater than 12 cm on radiographic studies, conservative measures may be continued for 48–72 h. This approach is associated with a 14% mortality rate.[136] The colon may also be mechanically decompressed via colonoscopy, although, in one study, this difficult procedure in an unprepared colon was affiliated with a 1.7% morbidity and a 3.4% mortality rate; yet, colonoscopic decompression was successful in 79.3% of cases, albeit with a recurrence in 20% of patients.[139] Pharmacologic treatment has become the mainstay of management for acute colonic pseudo-obstruction if conservative measures fail. Neostigmine (2–2.5 mg IV over 1–60 min), an acetylcholinesterase inhibitor, provides a surfeit of acetylcholine to the enteric neurons and the neuromuscular junctions, thus inducing propagating contractions, specifically high amplitude propagating contractions, and the prompt evacuation of stool and flatus.[62,138,140] In a double-blind randomized trial, the initial clinical response to neostigmine was 91%, as compared to 0% among those receiving a placebo; colonic distention recurred in two patients (18%) given neostigmine, ultimately requiring a subtotal colectomy in one patient.[138] Administration of neostigmine may produce bradycardia, abdominal pain, vomiting, and excessive salivation.[138] Alternative, less-studied pharmacologic treatments are comprised of 5-HT$_4$ receptor agonists (e.g., cisapride), motilin receptor agonists (e.g., erythromycin), muscarinic receptor agonists (e.g., bethanechol), neurotrophins (e.g., NT-3), nitric oxide synthase inhibitors (e.g., nitro-L-arginine methyl ester), and somatostatin analogs (e.g., octreotide).[136] Surgical treatment – a cecostomy tube or a subtotal colectomy – is a final option if less invasive techniques are unsuccessful. Even in a nonemergent setting, surgery has a 30% mortality rate.[136] However, failure to decompress the colon may yield cecal ischemia and/or perforation in 14–40% of cases; the mortality of these patients increases to 40–50%.[136]

Implications of Colonic Physiology for the Surgeon

Why is an understanding of colonic physiology important for the surgeon? Knowledge of the embryologic development of the colon is essential when considering nerve preservation, vascular supply, and resection margins during colectomies. The poorly understood topic of colonic motility impacts surgeons, particularly in the phenomenon of postoperative ileus. In a murine model of postoperative ileus, a reduction in the number of interstitial cells of Cajal was evident on both sides of the colonic anastomosis within hours of the surgery; as a consequence, fewer slow waves were identified in that particular segment, possibly giving rise to postoperative ileus.[88] Various disorders of colonic motility may stem from abnormalities of the interstitial cells of Cajal. These cells are significantly depleted in the colons of patients with diverticulosis and with slow transit constipation.[141] As basic science research advances, the surgeon ultimately will be called upon to evaluate and apply novel pharmaceuticals to reduce the impact of postoperative ileus as well as to treat other disorders of colonic motility. Surgeons also will invariably be consulted to assess the suitability of surgical management for abnormalities of colonic motility such as colonic inertia and intractable constipation.

The resection of a portion or the entirety of the colon can have profound functional ramifications for the patient. Prior to a colectomy, the surgeon optimally should discuss these possible outcomes with the patient. Postoperatively, the physiologic consequences of a colectomy must be managed. For instance, a patient with a new ileostomy requires counseling regarding adequate fluid and salt intake to compensate for the loss of the colon. Furthermore, defecatory dysfunction – frequent bowel movements, urgency, or soiling – may occur after a low anterior resection. Subsequent to the procedure, injury of the parasympathetic pelvic splanchnic nerves due to dissection around the inferior mesenteric artery may produce a denervated colonic segment with an increased colonic transit time and a greater proportion of nonpropagating contractions.[142] The neorectum demonstrates a decline in compliance postoperatively, although the maximum tolerated volume returns to normal 6 months later.[143] Yet, the volume needed to elicit the recto-anal inhibitory reflex is persistently reduced even 1 year after surgery.[143]

Conclusion

The colon has proven an enigmatic organ. Its major roles – the salvage of intestinal water and electrolytes, the storage of fecal material, and the production of short-chain fatty acids – seem unambiguous. However, the mechanisms underlying its physiologic and pathophysiologic processes remain difficult to define. Although not essential for life, its normal function is integral to our well-being.

Anorectal Physiology

Richard E. Karulf

Normal bowel continence and evacuation are complex processes that involve the coordinated interaction between multiple different neuronal pathways and the pelvic and perineal musculature.[1] The importance of the anatomic relationships of the pelvic floor in maintaining normal continence has been suggested since the 1950s.[2] However, the complex series of neural and behavioral-mediated interactions, combined with a lack of an ideal study to take all elements into account, makes complete understanding of anorectal anatomy and physiology's role in preserving continence difficult.[3] Complicating this are multiple other factors that play a role in normal regulation such as systemic disease, sphincter integrity, bowel motility, stool consistency, evacuation efficiency, pelvic floor stability, cognitive and emotional affects.[4]

The anus and rectum have been observed, dissected, measured, and recorded in every imaginable condition to try to explain their unique ability to voluntarily withhold and evacuate both solid stool and flatus. Conventional anorectal physiology testing using techniques such as manometry, endoanal ultrasound, electrophysiologic studies, and defecography help to elucidate anorectal structures and function. However, diagnostic dilemmas occur when patients report normal function with grossly abnormal test results or abnormal function with a normal test profile. Physicians with an in-depth knowledge of normal and abnormal anorectal physiology can apply results in a meaningful way to diagnose and direct therapy while searching for other, currently unmeasured, factors. This chapter reviews the current knowledge regarding muscular, neurologic, and mechanical factors.

Muscles of the Pelvic Floor and Sphincter Complex

Control of stool can be thought of as a pressure vector diagram, with continence represented as a balance of propulsive and resistive forces. Contraction of the muscles of the pelvic floor and sphincter complex provides resistance and tone is noted during periods of rest or deep sleep. Voluntary contraction of the puborectalis and external sphincter increase resistance and defers defecation. The anal sphincter is not a paired muscle structure, like the biceps and triceps in the arm; there is no extensor ani muscle. Evacuation occurs when propulsive forces (increased intra-abdominal pressure and peristalsis of the colon and rectum) overcome the resistance of the pelvic floor and sphincter muscles. Simple skeletal or smooth muscles alone cannot perform these functions.

The pelvic floor consists of a striated muscular sheet through which viscera pass. This striated muscle, the paired levator ani muscles, is actually subdivided into four muscles defined by the area of attachment on the pubic bone. The attachments span from the pubic bone, along the arcus tendineus (a condensation of the obturator fascia), to the ischial spine. The components of the levator ani are therefore named the pubococcygeus, ileococcygeus, and ischiococcygeus. The pubococcygeus is further subdivided to include the puborectalis. Between the urogenital viscera and the anal canal lies the perineal body. The perineal body consists of the superficial and deep transverse perinei muscles and the ventral extension of the external sphincter muscle to a tendinous intersection with the bulbocavernosus muscle.[5]

The fourth sacral nerve innervates the levator ani muscles. Controversy continues regarding the innervation and origin of the puborectalis muscle. Cadaver studies differ from in vivo stimulation studies as to whether the puborectalis muscle receives innervation only from the sacral nerve or also from the pudendal nerve. Comparative anatomy and histological studies of fiber typing also support the inclusion of the puborectalis muscle with the sphincter complex and not as a pelvic floor muscle. In addition, electromyography (EMG) studies of the external anal sphincter (EAS) and puborectalis muscle indicate that the muscles function together with cough and strain.[6]

The rectal smooth muscle consists of an outer muscularis mucosa, inner circular muscle, and the outer longitudinal layer. The inner circular muscle forms the valves of Houston proximally and distally extends down into the anal

canal becoming the internal anal sphincter (IAS). This is not a simple extension of muscle as there are histologic differences between the upper circular muscle and the IAS. For instance, the IAS is thicker than the circular muscle due to an increased number of smaller muscle cells. The outer longitudinal layer surrounds the sigmoid colon coalescing proximally into thicker bands called taenia coli. This same layer continues down to the anorectal junction where it forms the conjoined longitudinal muscle along with fibers from the pubococcygeus muscle. Distally, this muscle lies in the intersphincteric plane and fibers may fan out and cross both the internal and EAS muscles. In an ultrasound view of the anal canal, the longitudinal muscle is seen as a narrow hyperechoic line in the intersphincteric space.

The puborectalis muscle, EAS, and IAS muscles are easily viewed with endoanal ultrasound. In the hands of an experienced ultrasonographer, the technique is highly sensitive and specific in identifying internal and external sphincter defects.

External Anal Sphincter

Anatomical and sonographic studies indicate that the EAS begins development, along with the puborectalis muscle, at 9–10 weeks gestation. At 28–30 weeks it is mature and the anal sphincter then consists of three components, the striated puborectalis muscle, the smooth IAS muscle, and the smooth and striated EAS muscle.[7] Further differentiation of the EAS into two or three components is highly debated. In 1715, Cowper described it as a single muscle. Later, Milligan and Morgan promoted the naming of the components as subcutaneous, superficial, and deep. Recently, Dalley makes a convincing point that the three components can only be seen in the exceptionally dissected specimen and, in most cases, the muscle is one continuous mass and should be considered as such.[8]

The EAS is innervated bilaterally by the pudendal nerve arising from S2 to S4. Motorneurons arise in the dorsomedial and ventromedial divisions of Onuf's nucleus in the ventral horn of the spinal cord. Cross-over of the pudendal innervation was first suggested in studies by Swash and Henry on rhesus monkeys.[9] Hamdy and associates evaluated corticoanal stimulation of humans and found variable cross-over which was symmetric in some and either right- or left-sided dominant in others.[10] This has been offered as one possible explanation for the inconsistent relationship between unilateral pudendal neuropathy and fecal incontinence.

The EAS maintains tonic activity at rest due to monosynaptic spinal reflex. The tone can be abolished with spinal anesthesia and in conditions such as tabes dorsalis, where large-diameter afferent sensory fibers are destroyed, and over distension of the rectum, due to the inflation response. Maximum tone, due to phasic activity in the EAS, can be maintained for only about 1 min, before fatigue is encountered. Of interest, the only

other striated muscles that maintain continuous low-level resting activity are the abductor of the larynx, the cricopharyngeus and the external urinary sphincter.[11]

Internal Anal Sphincter

The IAS is an involuntary, smooth muscle. It is the major source of anal resting pressure and is relatively hypoganglionic.[12] There are nerve fibers expected in an autonomic muscle – cholinergic, adrenergic, and nonadrenergic noncholinergic fibers. It receives sympathetic innervation via the hypogastric and pelvic plexus. Parasympathetic innervation is from S1, S2, and S3 via the pelvic plexus. There is considerable evidence that the sympathetic innervation is excitatory but conflicting information regarding the parasympathetic effect.[12] The IAS contributes 55% to the anal resting pressure. The myogenic activity that contributes 10 and 45% is due to the sympathetic innervation. The remainder of the resting tone is from the hemorrhoidal plexus (15%) and the EAS (30%).[13] Spinal anesthesia decreases rectal tone by 50% and the decreased resting tone seen in diabetic patients may be due to an autonomic neuropathy.[14]

The IAS has slow waves occurring 6–20 times each minute increasing in frequency toward the distal anal canal. Ultraslow waves occur less than two times a minute and are not present in all individuals occurring in approximately 5–10% of normal individuals. Ultraslow waves are associated with higher resting pressures, hemorrhoids, and anal fissures.[12] The occurrence of anal slow-wave activity with rectal pressure waves exceeding anal resting pressure suggests a role for anal slow waves in preserving continence.[15] Ultrasound examination of the anal canal shows the hypoechoic IAS ending approximately 10 mm proximal to the most distal portion of the hyperechoic EAS.

Sensory Factors

Many authors describe the important relationship between anorectal sensation and fecal continence. Conventional concepts of the sensory innervation of the rectum have been challenged by data from continent patients following sphincter saving surgery and ileal pouch-anal anastomosis (IPAA).

Anal canal sensation to touch, pinprick, heat, and cold are present from the anal verge to 2.5–15 mm above the anal valves. This sensitive area is thought to help discriminate between flatus and stool but local anesthesia does not obliterate that ability. The rectum is only sensitive to distention. Rectal sensation may be due to receptors in the rectal wall but also in the pelvic fascia or surrounding muscle. The sensory pathway for rectal distention is the parasympathetic system via the pelvic plexus to S2, S3, and S4. Below 15-cm rectal distention is perceived as flatus, but above 15-cm air distention causes a sensation of abdominal discomfort.

Anal canal sensation is via the inferior rectal branch of the pudendal nerve that arises from S2, S3, and S4. This is the first branch of the pudendal nerve and along with the second branch, the perineal nerve, arises from the pudendal nerve in the pudendal canal (Alcock's canal). The remainder of the pudendal nerve continues as the dorsal nerve of the penis or clitoris.[16]

Many articles report daytime continence following low rectal resections with coloanal or IPAA. The reports of nighttime soiling following these procedures suggest that the ability to interpret sensory input from the neo-rectum requires conscious thought and not simple reflex contraction and relaxation. It is not clear if the decreased continence rate at night is solely due to impaired sensation (and subsequent defective discrimination of solid stool and gas) or if other factors limit fine control.

Reflexes

There are a great number of reflexes that end with the name "… anal reflex." The reason for this is, in part, that the EAS is readily accessible and represents a convenient end point for recording during electrophysiological study. Consequently, there are a number of ways that one can assess the integrity of neurological connection through or around the spinal cord.[11]

Cutaneous-Anal Reflex

The cutaneous-anal reflex was first described by Rossolimo in 1891, as a brief contraction of the anal sphincter in response to pricking or scratching the perianal skin.[17] This is a spinal reflex that requires intact S4 sensory and motor nerve roots. Both afferent and efferent pathways travel within the pudendal nerve.[17] If a cauda equina lesion is present, this reflex will usually be absent. Henry et al. recorded the latency of the anal reflex in 22 incontinent patients as compared to 33 control subjects. The mean latency was 13.0 ms vs. 8.3 ms, respectively. The mean latency was within normal range in only three (14%) of the incontinent patients.[18] However, Bartolo et al. have suggested that latency measurement of the cutaneous-anal reflex may be an inadequate means of demonstrating nerve damage in patients with fecal incontinence.[19] From a practical standpoint, this is a sacral reflex that can be interrogated during physical examination by simply scratching of the perianal skin with visualization of contraction of the subcutaneous anal sphincter. The response to perianal scratch fatigues rapidly so it is important to test this as the first part of the sphincter examination.

Cough Reflex

Chan et al., using intercostal, rectus abdominis, and EAS electrodes, studied the latencies in response to voluntary cough and sniff stimulation. When compared to latencies from transcranial magnetic stimulation it appeared that the EAS response was consistent with a polysynaptic reflex pathway.[20] Visible contraction of the subcutaneous EAS as a consequence to cough and sniff stimulation is a simple nonintrusive validation of the pathways involved in the anal reflex. This response can also be displayed during anal sphincter manometry. Amarenco et al. demonstrated that the greater the intensity of the cough, the greater was the electromyographic response within the anal sphincter.[21] The reflex is preserved in paraplegic patients with lesions above the lumbar spine, but it is lost if the trauma involves the lumbar spine or with cauda equine lesions. The mechanism of the cough-anal reflex contributes to the maintenance of urinary and fecal continence during sudden increases in intra-abdominal pressure as might also be seen with laughing, shouting, or heavy lifting.

Bulbocavernosus Reflex

The bulbocavernosus reflex was first described by Bors and Blinn in 1959.[22] The bulbocavernosus reflex is the sensation of pelvic floor contraction elicited by squeezing the glans penis or clitoris.[23] The EAS is used as the end point, because it is easily accessed either for visual assessment or by concentric needle EMG recording. The BCR latency will be prolonged by various disorders affecting the S2–S4 segments of the spinal cord.

Rectal Anal Inhibitory Reflex

The rectoanal inhibitory reflex (RAIR) represents the relaxation of the IAS in response to distension of the rectum. This was first described by Gowers in 1877 and documented by Denny-Brown in 1935.[24,25] It is felt that this permits fecal material or flatus to come into contact with specialized sensory receptors in the upper anal canal.[26] This sampling process, the sampling reflex, creates an awareness of the presence of stool and a sense of the nature of the material present. It is felt that this process of IAS relaxation with content sampling is instrumental in the discrimination of gas from stool and the ability to pass them independently.[26] The degree to which IAS relaxation occurs appears to be related to the volume of rectal distension more so in incontinent patients than in constipated or healthy control patients.[27] Lower thresholds for the RAIR have been found to be associated with favorable response to biofeedback therapy in patients with fecal incontinence for formed stool.[28] The amplitude of sphincter inhibition is roughly proportional to the volume extent of rectal distension.

The RAIR is primarily dependent upon intrinsic nerve innervation in that it is preserved even after the rectum has been isolated from extrinsic influences, following transaction of hypogastric nerves and the presence of spinal cord lesions. The inhibition response is in part controlled by

nonadrenergic, noncholinergic (NANC) mediators.[29] The reflex matures quite early in that it is generally present at birth and has been detected in 81% of premature infants older than 26 weeks postmenstrual age.[30] The reflex is destroyed in Hirschsprung's disease when myenteric ganglia are absent. In addition, the reflex is lost after circumferential myotomy and after generous lateral internal sphincterotomy.[31] Saigusa et al. found that at an average of 23 months following closure of ileostomy after IPAA, only 53% of patients maintained a positive RAIR as compared to 96% preoperatively. The incidence of nocturnal soiling was significantly greater, 72% in those who did not have preserved, or recovered RAIR as compared to those 40% who had postoperative preserved RAIR.[32]

The RAIR appears to be nearly abolished in the early postoperative period following LAR resection for cancer. In a study involving 46 patients, O'Riordain found that the RAIR that had been present in 93% of patients preoperatively was only present in 18% of patients 10 days following low anterior resection. However, at 6–12 months the RAIR was intact in 21% of patients and this increased to 85% after 2 years.[33] Similarly, van Duijvendijk et al., in a study of 11 patients, found the RAIR present in only 36% of patients after undergoing total mesorectal excision for carcinoma at 4 months postoperation. However, 81% of patients had a detectable RAIR at 12 months postsurgery.[26]

Loss of the RAIR is often a consequence of restorative proctocolectomy. Saigusa et al. found that the RAIR was present in only 53% of double-stapled IPAA patients at a mean of 23 months after closure of the ileostomy. Preservation of the RAIR correlated with less nocturnal soiling.[32]

The RAIR in children can be elicited even when general anesthetic agents or neuromuscular blockers are used. Glycopyrrolate, an anticholinergic appears to inhibit RAIR.[34,35]

Disturbances in the RAIR appear to be involved in the incontinence that is associated with systemic sclerosis. Heyt et al. found that 25 of 35 (71.4%) patients with systemic sclerosis demonstrated an impaired or absent RAIR compared with none of 45 controls. Impaired RAIR was closely correlated with fecal incontinence in that 11 of 13 (84%) of incontinent systemic sclerosis patients exhibited an impaired RAIR.[36]

Rectal Anal Excitatory Reflex

The rectal anal excitatory reflex (RAER) or inflation reflex is the contraction of the EAS in response to rectal distension. Rectal distension sensation is most likely transmitted along the S2, S3, and S4 parasympathetic fibers through the pelvic splanchnic nerves.[37] However, on the motor side, a pudendal nerve block abolishes the excitatory reflex suggesting that pudendal neuropathy may interfere with the RAIR. Common methodologies for assessing the integrity of the pudendal nerve involve both single fiber density (SFD) of the EAS and pudendal nerve terminal motor latency (PNTML). However, derangement of the distal RAER was shown by Sangwan

et al. to compare favorably with these more traditional and discomforting methodologies as an indicator of neuropathic injury to the EAS. It would appear that patients that have both an abnormal PNTML and an abnormal distal RAER do not require further study with SFD.[38]

Mechanical Factors of Continence and Defecation

Anorectal Angle and Flap-Valve

As a part of the pelvic floor musculature, the puborectalis arises from the pubic bone and passes horizontally and posteriorly around the rectum as the most medial portion of the levator ani muscle. This forms a U-shaped sling around the rectum near its anatomic junction with the anus, pulling the rectum anteriorly, and giving rise to the so-called anorectal angle. There are differences of opinion as to whether the puborectalis and anorectal angle are truly important in maintaining continence. Unlike the fine control of the external and internal sphincter muscles, the puborectalis sling is felt to be more involved with gross fecal continence.[39] Parks postulated a mechanism by which this takes place.[40] As intra-abdominal pressure is increased – such as with sneezing, coughing, or straining – the force is transmitted across the anterior wall of the rectum at the anorectal angle. The underlying mucosa is opposed against the upper anal canal, creating a flap-valve mechanism that prevents stool from passing to the lower anal canal and preserving continence. Yet other authors have disputed this flap-valve mechanism and downplayed the role and reliability of measuring the anorectal angle. Bannister et al., in a study of 29 patients including 14 patients with incontinence, found no evidence of a flap-valve in the normal subjects by using manometric measurements during rising intra-abdominal pressures.[1] However, in the incontinent patients, the manometric pressures were consistent with a flap-valve. Yet subjects still had leakage of stool, questioning the contribution to overall continence. Bartolo and colleagues also used manometric and EMG measurements in 13 subjects both at rest and during Valsalva, demonstrating a similar rise in rectal and sphincter pressures and puborectalis EMG recordings.[19] Yet, with concomitant barium studies the anterior rectal wall separated from the mucosa, allowing contrast to fill the rectum. The authors proposed that the puborectalis functions more like a sphincter rather than contributing to the flap-valve mechanism.

Furthermore, quantifying the anorectal angle and relating that to patient symptoms has resulted in mixed views. One study noted significant interobserver variation in anorectal angle measurements between three interpreters but good intraobserver consistency, suggesting that variation in anorectal angle measurements may be due to subjective interpretation of the rectal axis along the curved rectal wall. In another study

assessing the reproducibility of anorectal angle measurement in 43 defecating proctograms, the authors found significant intra- and interobserver variations, and concluded that the anorectal angle is an inaccurate measurement.[41] Jorge and associates measured the anorectal angle during rest, squeeze, and push in 104 consecutive patients and also found highly significant differences in each measurement category.[42]

Reservoir

As an additional part of the continence mechanism, the rectum must be able to function as a temporary storage site for liquid and solid stool. With passage of the fecal stream into the rectum, the pliable rectal walls are able to distend and delay the defecation sequence until an appropriate time. This process relies both on rectal innervation to sense and tolerate the rising volume of stool (capacity), as well as maintain a relatively low and constant pressure with increases in volume (compliance). Extremes of either of these components can lead to fecal incontinence through decreased accommodation or overflow states. Although decreased compliance has been demonstrated more often in patients with fecal incontinence, it has also been shown to occur as a normal consequence of aging.[43] In addition, Bharucha and associates in a study of 52 women with fecal incontinence demonstrated that the rectal capacity was reduced in 25% of women, and these lower volume and pressure thresholds were significantly associated with rectal hypersensitivity and urge fecal incontinence.[44] Furthermore, following low anterior resection for cancer, those patients with resultant lower rectal compliance and lower rectal volume tolerability (capacity) have been associated with higher rates of fecal incontinence.[45]

Normal Defecation

The awareness of the need to defecate occurs in the superior frontal gyrus and anterior cingulate gyrus. The process begins with movement of gas, liquid, or solid contents into the rectum. Distention of the rectum leads to stimulation of pressure receptors located on the puborectalis muscle and in the pelvic floor muscles, which in turn stimulate the RAIR. The IAS relaxes allowing sampling of contents. If defecation is to be deferred, voluntary contraction of the EAS and levator ani muscles occurs, and the rectum accommodates with relaxation after an initial increase in pressure. When the anal canal is deemed to have solid contents and a decision to defecate is made, the glottis closes, pelvic floor muscles contract, and diaphragm and abdominal wall muscles contract, all increasing abdominal pressure. The puborectalis muscle relaxes, resulting in straightening of the anorectal angle, and the pelvic floor descends slightly. The EAS relaxes and anal canal contents are evacuated. Upon normal complete evacuation, the pelvic floor rises and sphincters contract once more in a "closing reflex."

Pathologic Conditions

Incontinence

Incontinence is the inability to defer the passage of gas, liquid, or solid stool until a desired time. Numerous alterations in anorectal physiology can lead to incontinence and many patients have more than one deficit. Structural defects in the internal or EAS muscles occur due to obstetric injury, trauma, or anorectal surgery. The keyhole deformity is a groove in the anal canal allowing the seepage of stool or mucus. Originally described as a complication after the posterior midline fissurectomy or fistulotomy, it can also occur with lateral IAS defects. Intact sphincter muscles with impaired neurologic function, due to pudendal nerve damage or systemic disorders, such as diabetes, can also result in incontinence, especially if the impaired sphincter is further stressed by diarrhea or irritable bowel syndrome.

Abnormal rectal sensation can lead to incontinence in two ways. Conditions such as proctitis due to inflammation or radiation can result in hyperacute sensation. The rectum fails to accommodate and the reservoir function is impaired leading to urgency and frequent stools. Fragmentation of stools is commonly described by patients after low anterior resection, particularly if the pelvis has been radiated as in the case of adjuvant therapy for the treatment of rectal cancer. In the case of blunted sensation, due to a large rectocele, megarectum, or neurogenic disorders, the rectum becomes over distended and overflow incontinence occurs.

The majority of patients with rectal prolapse are incontinent. Chronic stretching of the anal sphincters from full thickness prolapse leads to a patulous anus through which gas and liquid stool easily leak. A reflex relaxation of the IAS may also occur as the rectal wall descends toward the anal canal. Patients with mucosal prolapse may have seepage of mucus or small amounts of liquid stool. Correction of the prolapse can resolve the incontinence if the anal sphincter tone sufficiently returns. Age and duration of prolapse can affect this.

Obstructed Defecation

Suspected Enterocele or Rectocele (Obstructed Defecation)

Patients with symptoms of enterocele or rectocele describe prolonged straining at defecation, with a sensation of partial or complete blockage (frequently a "closed trap door" preventing passage of stool). Defecography can demonstrate the presence of a rectocele or enterocele, suggest the presence of a peritoneocele, and clarify contributing disorders such as a nonrelaxing pelvic floor, rectal intussusception or prolapse, and potentially uterovaginal prolapse.

Rectocele

A rectocele is defined as greater than 2 cm of rectal wall outpouching or bowing while straining, and can precede or accompany rectal intussusception. The rectocele can prevent passage of stool both by obstructing the anal orifice and by acting as a diverticulum to sequester stool. Patients with rectoceles commonly complain of the need for frequent sequential episodes of defecation, and even for manual compression or splinting of the anterior perineum or posterior vagina in order to completely evacuate. Additionally, patients may experience incontinence with relaxation, leading to reduction of the rectocele and return of the sequestered stool to the lower rectum.

Van Dam and associates investigated the utility of defecography in predicting the outcome of rectocele repair.[46] Rectocele size, barium trapping, intussusception, evacuation, and perineal descent were measured during defecography exams of 74 consecutive patients with symptomatic rectoceles. The patients then underwent a transanal/transvaginal repair, followed by 6-month postoperative defecography and reassessment of the five most common presenting symptoms (excessive straining, incomplete evacuation, manual assistance required, sense of fullness, bowel movement less than three times per week). No postoperative defecograms demonstrated a persistent or recurrent rectocele; however, one-third of patients had a poor result based on persistent symptoms. There was no association between defecography measurements and outcome of the repair. Still, the authors concluded that defecography serves three major purposes in the evaluation of a rectocele: preoperative evidence of its presence and size, documentation of additional pelvic floor abnormalities, and an objective assessment of postoperative changes.

An abnormal increase in perineal descent (typically greater than 2 cm) has been described among both incontinent patients and continent patients who strain during defecation.[32,33] These conflicting data underscore the poorly understood relationship between neuropathic pelvic floor damage and symptomatology. Bartolo and associates evaluated patients with perineal descent using manometric, radiographic, and neurophysiologic studies.[47] When comparing 32 patients with incontinence and increased perineal descent with 21 patients with obstructed defecation and increased perineal descent, the authors found no significant difference in the extent of perineal descent or neuropathic damage to the EAS. Patients who were incontinent had lower manometric pressures (both resting and squeeze pressures) while those with obstructed defecation had normal manometric pressures. In a separate study, these authors also found that incontinent patients with increased perineal descent had severe denervation of both the puborectalis and the EAS compared to continent patients with increased perineal descent, who had partial denervation of the EAS only.[47] Miller and colleagues evaluated sensation in two similar patient groups.[48] Patients who were frankly incontinent actually had less perineal descent than continent patients with descent but had severely impaired anal sensation.

Berkelmans and others tried to determine if women with increased perineal descent and straining at stool were at risk for future development of incontinence.[49] The authors identified 46 women with perineal descent who strained during defecation but were continent. Twenty-four of the 46 were followed after 5 years and 13 of these (54%) had developed fecal incontinence, compared with 3 of 20 (15%) control patients. During their initial evaluation, the patients who previously strained and later developed incontinence had significantly greater perineal descent at rest and less elevation of the pelvic floor during maximal sphincter contraction than the women who strained but did not develop incontinence.

Thus, perineal descent may be a predictor of incontinence among patients with denervation of both the EAS and the puborectalis, and in patients with impaired anal sensation. Among patients with constipation, perineal descent and straining at stool may predict future fecal incontinence.

Dyskinetic Puborectalis

Dyskinetic puborectalis, paradoxical puborectalis, nonrelaxing puborectalis, and anismus are terms that describe the absence of normal relaxation of pelvic floor muscles during defecation, resulting in rectal outlet obstruction.[50] Once diagnosed, dyskinetic puborectalis is usually treated with biofeedback and bowel management. Patients who fail conservative treatment have been offered botulism toxin injections into the puborectalis muscle with limited success.[51]

Continence

The interplay of all the aforementioned anatomy and physiology ensures continence. It does not follow that a deficit in any one area ensures incontinence. Continence achieved in the ileoanal pouch patient is proof that the rectum is not essential. An intact and functional puborectalis muscle can provide continence in the pediatric imperforate anus patient, but incontinence can ensue during adulthood. Even profound deficits do not necessarily lead to incontinence if stool consistency is solid, while minor deficits can easily lead to incontinence to gas. To determine and treat abnormal fecal incontinence requires a systematic approach focusing on identifying the specific deficits present, applying appropriate testing to elucidate anal physiology and anatomy, and then directing therapy accordingly.

Summary

The unique physiology of the anus and rectum and the ability to master the complex task of fecal continence has many interesting facets. Understanding the anatomy, innervation, and reflexes of the pelvic floor and anal sphincters is the key to assessing disorders of continence. Further work in this area remains promising.

Physiologic Testing

Anders F. Mellgren

Functional anorectal symptoms are common and affect all ages of the population.[1] Normal anorectal physiologic function is complex and relies on a multiplicity of factors, including a intact anatomy and an intact link between somatic and visceral function of the anus rectum and colon. Consequently, a comprehensive evaluation of anorectal function demands a combination of several tests that complement each other. There is no single test that can comprehensively assess the function of the pelvic floor. In the clinical setting, physiologic testing should always be a complement to a proper patient history, physical examination, and frequently other tests including endoscopy and other imaging studies. The history may be complemented by use of questionnaires and quality of life instruments. The clinical utility of some physiologic testing is limited because of a lack of reference data from healthy individuals and lack of standardization.[2,3]

Several of the existing physiologic tests are proven to improve diagnostic yield and to directly influence clinical management.[4] This chapter describes the physiologic tests that are clinically available to assess functional disorders of the pelvic floor and colon (Table 4-1).

Anorectal Manometry

Indications

Anorectal manometry measures the pressures in the anal canal and the distal rectum. This test serves as one of the most accepted and widely used investigations to measure the function of the internal anal sphincter (IAS) and the external anal sphincter (EAS). Evaluation of sphincter function in patients with fecal incontinence is the primary indication for manometry. Other indications for anorectal manometry include screening for functional outlet obstruction (nonrelaxing pelvic floor), Hirschsprung's disease (absence of rectoanal inhibitory reflex (RAIR)), and damage to sacral reflex arc (absence of cough reflex). Manometry is also used for performing and predicting responses to biofeedback training

and to objectively quantify pressure before and after surgical intervention.

Equipment and Testing

There are four essential components in anorectal manometry equipment: (1) a probe for measuring intraluminal pressure; (2) a pressure recording device (amplifier/recorder, pneumohydraulic pump, and pressure transducers); (3) a balloon for inflation inside the rectum; and (4) a monitor/printer/storage system.

The probes can be of different types, including solid state, water perfused, air charged, or microballoon.[5] The diameter of the probe should not exceed 5–6 mm and the probe usually includes sensors radially distributed to measure several pressures at each level. Calibration of the probe and the recorder is critical for accurately measuring and obtaining reproducible results. Bowel enema before the test is optional, but if formed stool is found at digital examination an enema is advisable to avoid interference with the testing. Any manipulation of the rectum, such as digital rectal examination or administration of enema prior to a test should be followed by a minimum of 5 min of rest to allow sphincter activity to return to baseline.[6]

The two most commonly used and clinically available tests for measuring anal canal pressures are the stationary pull-through and the dynamic pull-through technique. The stationary pull-through technique is today the recommended method of choice since the dynamic pull-through technique creates a reflex sphincter contraction due to the stimulation generated by the probe resulting in higher anal pressures. The stationary pull-through measures the resting pressure and the squeeze increase at 6, 5, 4, 3, 2, and 1 cm from the anal verge by extracting the probe in increments of 1 cm from the rectum to the anal verge. Allowing a waiting period between each measurement minimizes artifacts.

Anal Resting Tone

The anal resting reflects the tonic activity of the IAS (55%), the EAS (30%), and the anal cushions (15%).[7] The IAS has

TABLE 4-1. Anorectal and colonic physiologic tests

Type of test	Measured modality	Primary indication
Test of function		
Anorectal manometry	Function of anal sphincter	Fecal incontinence, nonrelaxation of the
	Rectoanal reflexes	pelvic floor, Hirschsprung's disease
	Anorectal sensation	
	Rectal compliance	
	Rectal motor function and coordination (balloon expulsion test, defecatory maneuver)	
Vector volume manometry	Pressure profile and function of the anal sphincter	Fecal incontinence, sphincter injury
Saline infusion test	Rectal continence	Incontinence
Perineometry	Position of the pelvic floor	Pelvic floor laxity
Pudendal nerve terminal motor latency (PNTML)	Pudendal nerve terminal motor latency	Pudendal nerve injury or neuropathy
Electromyography (EMG)	Muscle activation. Motor unit potentials and fiber density (needle EMG)	Sphincter injury, biofeedback, imperforate anus
Test of structure		
Endoanal ultrasound	Two-dimensional or three-dimensional assessment of the internal and external anal sphincter, pelvic floor, and rectum	Fecal incontinence, fistula, tumors
Endoanal magnetic resonance imaging (MRI)	Assessment of the internal and external anal sphincter, pelvic floor, and rectum	Fecal incontinence, fistula, tumors
Test of function and structure		
Dynamic defecography	Rectal evacuation and dynamic assessment of the rectum and vagina	Fecal outlet obstruction, pelvic prolapse
Dynamic MRI	Rectal evacuation and dynamic assessment of the pelvis	Fecal outlet obstruction, pelvic prolapse
Marker study	Global transit time	Constipation
Radionuclide gamma scintigraphy	Global segmental colon transit	Constipation
SmartPill®	Stomach emptying, small bowel transit, colonic transit	Constipation, functional disorders of the stomach and small bowel

an oscillating tonic activity with both slow waves of low amplitude[8,9] and ultraslow waves of high amplitude.[10]

The anal resting tone is usually measured at 6, 5, 4, 3, 2, and 1 cm from the anal verge with the stationary pull-through technique. The maximum resting pressure (MRP) is usually defined as the highest recorded resting pressure.[11] There is some radial asymmetry in pressures in the different parts of the anal canal[12] and therefore the pressures in the four quadrants is usually averaged to account for this asymmetry.[13] The pressure profiles in the anal canal vary also according to gender, age, and measuring technique (Figure 4-1). The length of the functional anal canal or high pressure zone is defined as the length of the anal canal with resting pressures exceeding 30% of the rectal pressure.[11]

Patients with fecal incontinence tend to have lower anal resting tone than do continent patients or normal controls.[14–16] The clinical value of measuring basal anal canal pressures alone is limited, since patients with low pressures may have normal continence and patients with incontinence may have normal pressures. There is also a lack of defined values of what is the normal range for the anal resting tone.

Squeeze Pressure

Squeeze increase of the anal canal pressure is generated by contraction of the EAS and can be calculated as the increase in pressure from the anal canal resting tone during maximal anal squeeze (Figure 4-2).[3,5]

The squeeze increase is usually measured at 6, 5, 4, 3, 2, and 1 cm from the anal verge with the stationary pull-through technique. The squeeze increase is obtained by asking the patient to maximally squeeze the sphincter at each level and hold this squeeze for 3 s. Instructing the patient to avoid contraction of accessory muscles, particularly the gluteal muscles, or to avoid increasing the intra-abdominal pressure reduces the risk of measuring false high squeeze increase. The maximum voluntary squeeze pressure (MSP) is usually defined as the highest pressure recorded above the baseline (zero) at any level of the anal canal during maximum squeeze effort.[11] An alternative measurement is the highest pressure recorded above the resting pressure during maximum squeeze effort. The latter pressure is thus the increment of pressure above the resting tone.

Decreased squeeze pressures are frequently correlated to injuries in the EAS, neurologic damage, or just poor patient compliance/voluntary control. If the latter problem is suspected, the results of decreased squeeze pressure should be interpreted in context with the EAS response to coughing (see the section "Cough Reflex").

The susceptibility for fatigue of the EAS can be estimated by measuring the patient's ability to sustain the squeeze effort over time. The squeeze duration is often reduced in patients

with incontinence.[17] The squeeze durability can be measured as a fatigue index (the coefficient of maximum squeeze pressure and the gradient of decay).[18]

Rectoanal Inhibitory Reflex

Rectal distension or attempted defecation results in a treatment inhibition of the tonic activity of the IAS and the consequent relaxation of this muscle. The RAIR is mediated via the myenteric plexus and it is modulated by the spinal cord.[19,20] This reflex facilitates rectal emptying and it is also believed to serve as a discriminatory function of the rectum, as it can facilitate discrimination of gas from fecal substance and allow rectal contents to be "sampled" by the sensory area of the anal canal. Concomitant with the relaxation of the IAS, there is sometimes a reflex EAS contraction during rectal distension that is automatic and not reflex mediated. By asking the patient to relax, this contraction sometimes can be limited.[21]
FIGURE 4-2. Pudendal nerve motor latency measure twice on each side.

The RAIR can be tested by inflation of a balloon in the whole distal rectum simultaneously measuring the pressure in the anal canal. The anal canal probe is usually positioned at the level of the highest recorded anal resting pressure, as this positioning facilitates the recording of a normal RAIR.

Presence of an intact RAIR is dependent on an intact myenteric plexus and is usually impaired in patients with Hirschsprung's disease.[22] An absence of RAIR may indicate a diagnosis of Hirschsprung's disease[23] and should be followed by a full-thickness rectal biopsy to confirm an agangliotic segment diagnostic of Hirschsprung's disease. Hirschsprung's disease is usually diagnosed in early childhood and therefore rarely newly discovered in adults. The prevalence and the clinical relevance of ultra short Hirschsprung's disease in adults is controversial.[24]

Cough Reflex

A normal response following a rapid increase in intra-abdominal pressure is a contraction of the EAS. This reflex, the cough reflex, maintains continence in case of a rapid increase in intra-abdominal pressure. The cough reflex can be assessed with a probe supplied with an intrarectal balloon (estimating the intra-abdominal pressure) and sensors located in the anal canal. If the increment of the anal canal pressure is higher than the rectal pressure, the reflex is considered to be normal. A sphincter defect or innervations injury may result in a weaker anal pressure increase and an abnormal cough reflex. Even though the clinical use

of this test is limited, it can serve as an instrument to measure compliance in patients with attenuated voluntary squeeze pressures without evidence of spinal damage.[25]

Rectal Sensation and Compliance

Rectal sensation (and rectal compliance) can be measured by intermittent balloon distension in the distal rectum while simultaneously monitoring the patient's response. The first sensation, the first urge, and the maximal tolerable volume are usually recorded. Rectal compliance can also be assessed by measuring the pressure and volume relationship when a balloon is inflated in the rectum. This method is associated with a significant intersubjective variation, but some studies have demonstrated a good reproducibility of the recorded sensory thresholds.[26,27] Some data supports that the sensory perception of the rectal distension is directly related to the rectal wall tension. Reduced sensory threshold levels of the rectum (rectal hypersensitivity) in patients with fecal incontinence could indicate a presence of urge fecal incontinence and increased frequency of defecation,[28,29] whereas incontinent patients with increased sensory threshold levels (rectal hyposensitivity) may suffer from passive (overflow) incontinence.[30]

Vector Volume Manometry

Using a stationary pull-through technique and an eight-channel manometric catheter with radially oriented side holes, a three-dimensional picture of the pressure profile in

the anal canal can be obtained. Pressure asymmetry corresponding to any sphincter defects can possibly be located by this method. The clinical utility of vector volume manometry today has largely been replaced by endoanal ultrasound.

Other Tests of Anorectal Function

Balloon Expulsion Test

Rectal expulsion ability can be evaluated by inflation of a water-filled rectal nonlatex balloon. The main purpose of this test is to identify patients with obstructed defecation [3]. Normal subjects can usually expel a balloon containing 50–150 mL, but patients suffering from constipation with megarectum are frequently unable to expel the balloon even though the intrarectal pressures are within the normal range.[31] A variation of the technique uses a detachable water or air-filled balloon that is inserted into the rectum. The patient is then allowed to sit on a commode in a private bathroom to pass it.[32] This method may be more physiological then trying to pass a balloon attached to a catheter in the lateral position.

There are several factors that may lead to over diagnosis of functional outlet obstruction, including the inability of the balloon to accurately mimic patient's stool, technical challenges to standardize the test, and embarrassment experienced by the patients in the test setting.[33,34] The volume of the balloon may also influence the ability to expel the balloon.[35] The utility of the balloon expulsion test alone is limited, but in addition to other physiologic tests it may assist in the evaluation of patients with a nonrelaxing pelvic floor.[36]

Saline Continence Test

The saline continence test evaluates the ability of the sphincters to remain continent at continuous infusion of saline into the rectum. The time and volume at first leak and total leaked volume are assessed. Approximately 1.5 L can be infused in normal subjects without any significant leakage.[37,38] Patients with fecal incontinence due to weak sphincter function or reduced rectal compliance usually starts leaking after infusion of 250–600 mL saline.[39] This test is used sparingly and may be useful for objectively evaluating patients with fecal incontinence or for assessing improvement to surgical or medical treatment.[37]

Perineometry

There is a relation between increased perineal descent (pelvic floor laxity) and fecal incontinence. The pelvic floor should descend <1.5 cm during normal defecation. The perineometer measures the level of the perineum with respect to the ischial tuberosities and is used to estimate the perineal descent.[40] This test has limited clinical utility because of poor reproducibility and comparatively more accurate radiologic methods for evaluating the movement of the pelvic floor are available.[41]

Neurophysiologic Tests

Pudendal Nerve Terminal Motor Latency

The pudendal nerve innervates the EAS, urethral sphincter, perineal musculature, mucosa of the anal canal, and the perineal skin. The nerve carries both afferent and efferent information originating from the nerve roots S2, S3, and S4 and travels along the lateral pelvic floor and exits the pelvis at the ischial spine into the pudendal canal (Alcock's canal).

Pudendal nerve terminal motor latency (PNTML) is measured with a disposable finger-mounted electrode (St Mark's electrode) with a distal stimulating electrode at the fingertip and a recording electrode located at the finger base. By placing the finger tip as close as possible to the pudendal nerve at the ischial spine, the nerve conduction velocity (latency) from the ischial spine to the EAS (at the finger base) can be measured. PNTML provides an estimation of the fastest conducting fibers in the pudendal nerve with a risk of showing a normal PNTML in a damaged nerve as long as some of the fast conducting fibers remain intact.[42]

The use of this test is controversial because of suboptimal test sensitivity and specificity.[43] However, knowledge of any existing neuropathy or injury of the pudendal nerve may be of importance before sphincter surgery or biofeedback. PNTML is therefore used as a complementary tool in the physiologic evaluation of anorectal function.[44] The American Gastroenterological Association does not recommend PNTML for evaluation of patients with fecal incontinence[2] on the basis of its unknown test reproducibility,[45] age-dependent results independent of continence status,[46] operator dependency[47] and high rate of false-negative result. However, the test is widely performed and relied upon by surgeons who operate on patients with fecal incontinence, constipation, and rectal prolapse.

Electromyography

Anal electromyography (EMG) can be used to sample the activity of striated pelvic floor muscles.[2,48,49] In the clinical setting, EMG is primarily used to identify EAS activity and whether appropriate sphincter relaxation and contraction exists. This information can be obtained using surface electrodes and can identify patients with nonrelaxing pelvic floor (Figures 4-3 and 4-4) and it is also used in biofeedback therapy. Needle EMG can also provide information about possible nerve injury (denervation–reinnervation potentials) and locate muscle in the EAS. The latter indication has today largely been replaced by endoanal ultrasound.

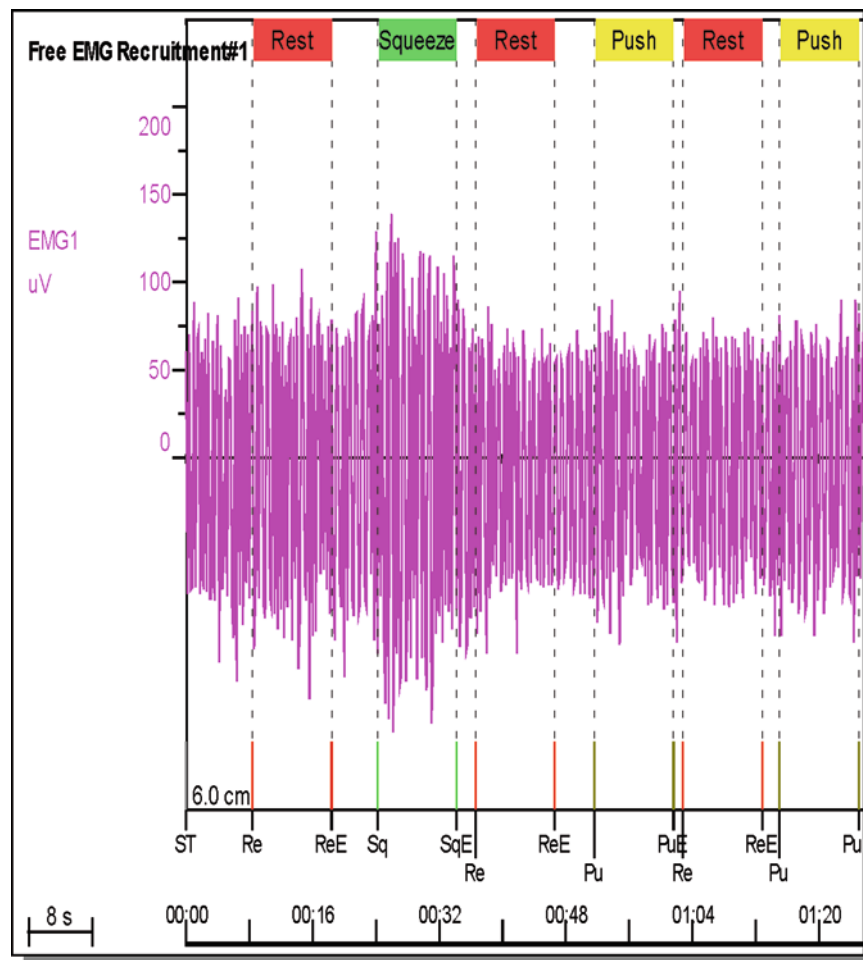
Surface electrodes (anal plug and skin electrodes) are associated with less patient discomfort and a lower risk of infection.[50,51] Surface electrodes are frequently used to measure


FIGURE 4-3. Electromyography recruitment demonstrating equivocal reaction, since the activity is unchanged at "push."

EAS activity to determine appropriate sphincter relaxation and contraction (Figure 4-5). Anal plug electrodes are frequently used in biofeedback training. Using this technique, patients suffering from fecal incontinence or nonrelaxing sphincter are be able to obtain a visual or audible signal as a response to sphincter contraction.

Needle electrodes can be either single-fiber electrodes or concentric needle electrodes. Single-fiber needle electrodes record a single motor unit at a time. Increased fiber density (motor unit grouping) can be detected as evidence of nerve denervation with reinnervation.[49,52] Single-fiber EMG results have shown a high degree of repeatability among independent investigators.[53] Concentric needle EMG, which measures approximately 30 motor units at a time, is useful for detecting polyphasic or prolonged duration of the motor unit potentials as evidence for reinnervation in the EAS.[49] In patients with fecal incontinence, high fiber density and longer motor unit potentials are more commonly detected in EMG than in controls,[42,54–56] but the extent of denervation measured by EMG in the EAS does not appear to influence the severity of incontinence.[57]

The clinical utility of EMG has diminished since mapping of the EAS has been replaced in many centers by endoanal ultrasound,[58] EAS is less painful and provides the examiner with a two- or three-dimensional picture of the anal canal and the anal sphincters.[59] According to the American Gastroenterological Association, EMG still has a role in confirming imperforate anus before surgical placement of the bowel if endoanal ultrasound is not possible or not available and in biofeedback therapy.[2] Many colorectal surgeons find that anal ultrasound compliments rather than replaces EMG. The former test offers gross anatomic information while the latter evaluation reveals more about function rather than structure.

Anatomic Assessment

Endoanal Ultrasound

Endoanal ultrasound is described in more detail in Chap. 7. Endoanal ultrasound is one of the most reliable tests in identifying anatomic defects (Figure 4-6) in the anal sphincters with a high sensitivity and specificity when conducted by experienced
FIGURE 4-4. Electromyography recruitment demonstrates paradoxic reaction, since the activity is increased at "push."

investigators.[58–62] Usually, a 7- or 10-MHz frequency endoanal probe is used for imaging of the sphincters. The latter provides a higher resolution and hence a superior picture quality. The transducer provides a 360° view of the anal canal.

The main indication for endoanal ultrasound is to diagnose defects in the IAS and/or EAS.[62–64] A high correlation between histologic and intraoperative findings has been suggested.[58,65,66] The investigation and the interpretation of the procedure is operator dependent, especially considering evaluation of the EAS.[67] By using three-dimensional endoanal ultrasound, visualization of the EAS anatomy is facilitated and the diagnostic accuracy of detecting EAS abnormalities might improve[68] and anal EMG right at some point in the future be rendered superior.

Endoanal ultrasound can be used as a tool in selecting patients for surgical repair and for assessing the postoperative results.[69–71] Recently, ultrasound has been introduced to document other injuries in the pelvic floor and pelvic prolapse.

Magnetic Resonance Imaging

During the past two decades magnetic resonance imaging (MRI) has become increasingly used to image the anal canal and the pelvic floor muscles. Images can be generated either with use of an endoanal coil or use of an external phased array coil. These two techniques are comparable in diagnosing anal sphincter defects and EAS atrophy,[72] although MRI using an endoanal coil usually are restricted to specialized centers and might be associated with some discomfort when the coil is introduced.

There is no consensus regarding the use of MRI vs. endoanal ultrasound. Some authors recommend the use of endoanal ultrasound as the primary tool in the identification of sphincter injuries and to reserve MRI to be used as a complimentary technique to exclude patients with EAS atrophy in patients considered for surgical anal sphincter repair.[73]

Tests of Function and Structure

The dynamic nature of some of the anorectal disorders, such as rectal intussusception and rectal prolapse, requires a combination of dynamic and structural imaging modalities. Fluoroscopic defecography and MR defecography are methods that can be used to assess the dynamics of the pelvic floor function.
FIGURE 4-5. Electromyography recruitment demonstrates normal reaction, since the activity is increased at "squeeze" and decreased at "push."

Dynamic Fluoroscopic Defecography

Fluoroscopic defecography is a dynamic radiologic test providing morphologic information about the anal canal, rectum, vagina, and the pelvic floor during the defecation maneuver.[74–76] Defecography involves filling of the rectum and if possible also the vagina with contrast. Some centers advocate use of contrast in the small bowel, the bladder, and even the peritoneal cavity.[77,78] The primary indication for defecography is evaluation of patients with outlet obstruction and prolapse. The technique can visualize the defecation process, identify signs of nonrelaxation, and visualize various anatomic abnormalities.

It should be remembered that patients may feel embarrassed by the nature of the test. This reluctance may result in a false-positive test result of pelvic floor relaxation and a false-negative assessment of anatomic abnormalities because of insufficient rectal emptying.[32,79] Another limitation of defecography is an interobserver variation in interpreting results.[80,81] There is also high incidence of "abnormal findings" in both patients with symptoms[82] and in subjects without symptoms.[83]

Anorectal Angle and Rectal Emptying

The anorectal angle is the angle between the anal canal and rectum.[11] The action of the puborectalis muscle during straining decreases this angle from 75–90° in resting to 90–110°, and the angle increases to 110–180° at evacuation. The anorectal angle is believed to play a role in maintaining continence. The quantification of the anorectal angle in defecography has somewhat limited clinical value due to a high observer variation.[81,84]

The ability to relax the puborectalis muscle, and increase the anorectal angle, is pivotal for the evacuation process. A persistent contraction of the puborectalis muscle during the evacuation process is consistent with nonrelaxing pelvic floor, which is also named anismus or paradoxic contraction of the pelvic floor.[85]

Rectal emptying should be rapid (<30 s) and complete (<10% residual contrast). In patients with evacuation difficulties, emptying is frequently achieved in small portions. Perineal descent during emptying is measured relative to a line drawn in between the tip of the coccyx and the pubis bone (the pubococcygeal line). During squeezing the pelvic floor will rise and during straining and evacuation it will descend.
FIGURE 4-6. Sphincter defect in the anterior aspect.

Rectal Intussusception and Rectal Prolapse

Rectal intussusception is a circumferential infolding of the entire thickness of the rectal wall not extending beyond the anal verge, while a rectal prolapse is a protrusion of the entire thickness of the rectal wall extending through and beyond the anal verge.[86]

Rectal intussusception is difficult to diagnose at clinical examination. Defecography can sometimes help in the differentiation between a small rectal prolapse from large hemorrhoids, which sometimes can be difficult. A more important indication for defecography in patients with rectal prolapse at clinical examination is the ability to identify patients with concomitant enterocele or vaginal prolapse that may need surgical attention at the same time as the prolapse repair.

Rectocele

Rectocele is a herniation of the anterior rectal wall into the vagina. The bulge in the anterior part of the distal rectum should be ≥3 cm. Rectoceles are common in both patients and asymptomatic subjects. Barium trapping in the rectocele or facilitation of emptying by digital support of the posterior vagina wall is used by some surgeons to define surgical candidates for rectocele repair.

Peritoneocele, Enterocele, and Sigmoidocele

A peritoneocele is a peritoneal herniation extending the pouch of Douglas below the upper third of the vaginal length and at the same time increasing the distance between the rectum and vagina.[77,87] An enterocele is formed when small bowel descends into the peritoneocele and a sigmoidocele is formed when the sigmoid colon descends into the peritoneocele.[88]

Dynamic MR Defecography

The development of dynamic MR defecography has flourished after the development of fast MRI sequences enabling dynamic evaluation of the pelvic floor. A comprehensive evaluation of the anatomy and function can be obtained by repeating scans during rest, squeezing, straining, and evacuation. The best results are obtained when contrast (usually sonographic gel) is used and emptied. Several of the above-mentioned "abnormalities" are seen only if emptying is obtained.[89]

Dynamic MR defecography can be performed with open- or closed-configuration units. The open-configuration MRI unit, where the patient is sitting during the investigation, is superior to the closed-configuration unit. This equipment is, however, expensive and not readily available in most institutions. The image quality is usually also inferior in open-configuration units, when compared with closed-configuration units. However, closed unit MRI has the disadvantage of only permitting patients to be investigated in a supine position. The influence of having the patient emptying the rectum in the supine position is debated. Some studies report that this has limited influence on the results obtained, with the exception of identifying rectal intussusceptions.[90,91] Dynamic MRI defecography is a nonionizing investigation and provides the investigator with a dynamic picture of the complete pelvic floor and pelvic organs. This can be useful in preoperative planning since concomitant findings are common in patients with pelvic floor disorders. In one study, it was noted that

dynamic MRI defecography changed the type of surgical therapy in 67% of evaluated patients with fecal incontinence.[92] Dynamic MRI defecography might be a more accurate tool to diagnose rectal intussusception than conventional defecography[93,94] and to differentiate mucosal prolapse from full-thickness intussusceptions.[95]

Gastrointestinal Transit Studies

Most of the previously mentioned tests are focused on evaluating the function and/or the anatomy of the rectum, the pelvic floor, and the surrounding organs. Transit studies provide an objective evaluation of the gastrointestinal motility, which is of paramount importance for stool consistency and in facilitating defecation through the "recto-colic reflex."[96] Marker studies and scintigraphy techniques provide estimation of transit times. Recently, a new technique with a wireless capsule (SmartPill®) has been introduced as an instrument for investigating gastrointestinal transit time.

Colonic Markers Study

The most commonly used method for diagnosing patients with slow transit constipation is based on (usually 24 markers) radio-opaque markers. This is a simple technique that requires the patient to ingest a capsule containing radio-opaque markers. Five days after the ingestion of the capsule, a plain supine radiograph is obtained to determine the position and the number of remaining markers.[97] The test is considered to be normal if five or fewer markers (≤20%) still are present in the colon. If more than five markers are present in the colon, the transit time is considered to be prolonged. If the markers are predominantly present in the distal colon, this may suggest a pelvic floor problem resulting in obstructed defecation. If the markers are more diffusely distributed in the colon, this finding may be a sign of gastrointestinal dysmotility or colon inertia.

Alternatives to the above-mentioned technique are used by some centers. Some use an image obtained on the seventh day and others ask the patient to ingest markers over a number of days.[98] An additional variation has the patient ingest markers on Sunday evening and obtain an abdominal X-ray on Monday morning, Wednesday, and Friday. The initial film serves as a gross screening test of gastric and small bowel motility. Patients with normal upper gastrointestinal motility will have all markers in the colon on this first film.

Small bowel transit can be evaluated with oral lactulose ingestion followed by measurement of breath hydrogen excretion. Basically the lactulose ferments in the cecum to release hydrogen allowing inexpensive, safe, rapid and reproducible measurement of orocecal transit time.[99]

Radionuclide Gamma Scintigraphy of the Colon

Radionuclide gamma scintigraphy of the colon is a more complex and expensive evaluation of the colonic transit time compared to colonic marker study and the technique is only available at specialized centers with access to nuclear imaging equipment. By ingestion of a radiolabeled isotope, the colon can be visualized with a gamma camera and frequent scans can be obtained. Scintigraphy provides a quantitative segmental picture of the colon and can potentially provide information about the variability of the motility in different colon segments.[100]

SmartPill®

SmartPill® is a wireless monitoring system built inside a pill that measures temperature, intraluminal pressure, and pH and is recorded by a portable receiver. The capsule is ingested by the patient and a drop in pH and a change in motility delineates the transition from the distal ileum into the cecum. From these data, whole gut transit and colonic transit can be separated and calculated. SmartPill has been compared with colonic scintigraphy and seems to be a promising tool to diagnose and evaluate patients suffering from slow transit constipation,[101,102] but more studies are needed to prove its clinical applicability and utility.

Endoscopy

Charles B. Whitlow

The large intestine from cecum to anus can be effectively and accurately examined as part of a complete physical examination. An ultimate diagnosis of large bowel diseases can only be made by direct observation of the abnormalities and, if indicated, a biopsy. Different equipment is designed and used for different purposes.

Anoscopy

Anoscopy is the examination of the anal canal. The lower part of the rectal mucosa, upper anal mucosa, anoderm, dentate line, internal and external hemorrhoids can be seen through this examination.

There are basically two types of anoscopes: Beveled type such as the Buie or Hirschman scope (Figure 5-1) and the lighted Welch-Allyn scope (Figure 5-2) that uses the same light source as the rigid proctosigmoidoscope. Another type is the side-opening Vernon-David scope with Hirschman handle (Figure 5-3). The Hinkel-James anoscope (Figure 5-4) is much longer than the Vernon-David scope and is suitable for patients with deep buttock cheeks.

Indication

Any anal and perianal diseases or conditions require a full examination of the anal canal. These include anal fissures, anal fistulas, anal Crohn's disease, anal tumors, hemorrhoids, anal condyloma, bright red rectal bleeding and pruritus ani. Anoscopy is frequently used in conjunction with colonoscopy, flexible sigmoidoscopy, and rigid proctosigmoidoscopy as part of the examination.

Contraindications

Patients who have severe anal pain such as an acute anal fissure or a perianal or intersphincteric abscess may not tolerate the examination. In general, if a patient can tolerate a digital examination, anoscopy can usually be done. A 2% lidocaine jelly should be used in patients with anal pain. Anal stricture or severe anal stenosis is another contraindication.

Preparation

No preparation is required.

Positioning

A prone jackknife position gives the best exposure. An alternative is the left-lateral recumbent (Simms) position.

Technique

The Vernon-David, which is a side-opening endoscope, gives the best examination. Inspection of the anal area should always precede any other examination and, for this, good lighting is essential. The cheeks of the buttock are gently spread to gain exposure. Skin tags, excoriation and change in color or thickness of the anal verge and perianal skin can be detected quickly. A scar, patulous, or irregularly shaped anus may give clues to the cause of anal incontinence. Particularly in multiparous women, the anal verge may be pushed down too far during straining – a feature of the perineal descent syndrome. When the anal verge is scratched or pricked with a needle, the external sphincter visibly contracts because of the anal reflex. It is useful for testing the sensibility of the anal canal, which may be absent in areas of previous scar or defect, or in patients with an underlying neuropathy.

The next step is to do a digital examination. The index finger should be well lubricated with a lubricant jelly, and the finger pressed on the anal aperture to "warn" the patient. Then the finger should be gradually inserted and swept all around the anal canal to detect any mass or induration. In men, the prostate should be felt. In women, the posterior vaginal wall should be pushed anteriorly to detect any evidence of a rectocele. Anal tone, whether tight or loose, can be easily estimated. A stricture or narrowing from scarring or a defect in the internal or external sphincters from a

FIGURE 5-1. Buie anoscope.

FIGURE 5-2. Lighted Welch-Allyn anoscope.

FIGURE 5-3. Vernon-David with Hirschman handle anoscope.

previous operation can be felt. A fibrous cord or induration in the anal area and the anal canal may indicate a fistulous tract. The external sphincter, puborectalis, and levator ani muscles can also be appreciated by digital examination.

FIGURE 5-4. Hinkel-James anoscope.

When the puborectalis is pulled in the posterior quadrant, the anus will gape but will close immediately when the traction is released. Persistence of the gaping indicates an abnormal reflex pathway in the thoracolumbar region frequently seen in paraplegic patients. The finger should press gently on these muscles for signs of tenderness. When the person with good anal function is asked to contract the muscles, the examiner not only feels the squeeze of the muscle on the examining finger but also feels the finger pulled forward by the puborectalis muscle.

Insertion of the anoscope should always be done with the obturator in place. The obturator is removed during examination and reinserted to rotate the instrument to another area. In patients with redundant mucosa, reinsertion of the obturator may cause discomfort if the mucosa gets trapped between the obturator and the anoscope. However, if the beveled type of endoscope is used, the endoscope can be rotated without having to reinsert the obturator. If an inverted (jackknife) position is used, the examination table need not be tipped down more than 10–15°. If a left-lateral position is used, an assistant needs to pull up the right cheek of the buttock for exposure. During examination, the patient is asked to strain with the anoscope sliding out to detect any prolapse of the rectal mucosa and the anal cushion. Excoriation, metaplastic changes, and friable mucosa indicate a prolapsed hemorrhoid.

Biopsies may be taken via the anoscope. Care should be taken to have adequate lighting and suction as needed. Local anesthesia is necessary for biopsies of lesions in the anal canal, including the sensate area extending 1–2 cm proximal to the dentate line.

Complications

Anal tear, especially at the posterior midline, can occur in patients with anal stenosis. Additionally, friable hemorrhoids may bleed from contact with the anoscope.

Rigid Proctosigmoidoscopy

Three sizes of rigid proctosigmoidoscope are available (Figure 5-5). A 19 mm×25 cm scope is the standard size for a general examination and for polypectomy or electrocoagulation. A 15 mm×25 cm endoscope is an ideal size for general examination. It is much better tolerated by the patient, causing less spasm of the rectum and thus, minimal air insufflation, yet enables as adequate an examination as the standard-size endoscope. An 11 mm×25 cm endoscope should be available for examining the patient who has anal or rectal stricture, such as Crohn's disease. Some physicians and surgeons prefer a disposable standard-size rigid proctosigmoidoscope for routine examination.

Indications

Rigid proctosigmoidoscopy has largely been replaced by flexible sigmoidoscopy. However, rigid proctosigmoidoscopy is still useful in examination of the anorectum. One of its advantages is that any blood clots or stool can easily be washed out. In fact, in a patient who has massive gastrointestinal bleeding, a rigid proctosigmoidoscopy is the first line of examination to rule out the source of bleeding in the anorectum.

A rigid proctosigmoidoscopy is used when an abnormality of the anal canal and rectum is suspected such as nonspecific proctitis, radiation proctitis, anorectal ulcer, anorectal neoplasm, infectious proctitis, and anorectal Crohn's disease. Rigid proctosigmoidoscopy is also useful to identify the precise site and size of rectal neoplasm.

Contraindications

Patients with severe anal pain from an acute fissure, thrombosed external hemorrhoids, and perianal abscess may not allow an examination. The examination should be postponed to some other date. Anal stricture that will not allow the

FIGURE 5-5. Rigid proctosigmoidoscope. *Top* 19 mm×25 cm, *middle* 15 mm×25 cm, *bottom* 11 mm×25 cm.

passage of the smallest size rigid proctosigmoidoscope is a contraindication to its use.

Patients with acute abdomen of any cause or a rectal or sigmoid anastomosis less than 2 weeks postoperatively should have a rigid proctosigmoidoscopy with caution.

Preparation

Two phosphate enemas should be given within 2 h of the examination. This is not necessary in a patient who has diarrhea or active bleeding. Sedation is unnecessary.

Positioning

A prone jackknife is the position of choice. However, the left-lateral position also gives an adequate examination and should be used in conditions such as pregnancy, severe hypertension, retinal detachment, or postoperative eye surgery and some apprehensive patients.

Technique

Although a standard proctosigmoidoscope is 25 cm in length, the average distance that the scope can be passed is 20 cm. In men, the scope can be passed to 21–25 cm half of the time, and in women, it can be passed that distance one-third of the time.[1] Rigid proctosigmoidoscopy is suitable only to examine the rectum and, in some patients, the distal sigmoid colon. The pain experienced from proctosigmoidoscopy is from stretching the mesentery of the rectosigmoid colon when the scope is pushed against the rectal wall, and from the air insufflation. When properly performed, rigid proctosigmoidoscopy should produce no pain or only mild discomfort. Most patients are fearful of the examination because of past bad experience with the procedure or from what they have heard. A few words of reassurance will be helpful.

With the obturator in place and held steady with the right thumb, the well-lubricated rigid proctosigmoidoscope is gently inserted into the anal canal, aiming toward the umbilicus for a distance of about 4–5 cm. Then the endoscope is angled toward the sacrum and advanced another 4–5 cm into the rectum. The obturator is removed and the bowel lumen is negotiated under direct vision. Air insufflation is limited to the amount necessary to open the lumen. When an angle is encountered, the endoscope is withdrawn 3–4 cm and then readvanced. This may be repeated several times to straighten the angulation. If further advancement is unsuccessful, the procedure is terminated at this point. Careful examination is done as the instrument is withdrawn. It is usually necessary to insufflate a small amount of air for good visualization of the lumen. The instrument should be rotated on withdrawal to ensure examination of the entire circumference. The mucosal folds in the rectum (valves of Houston) can be flattened with the tip of the endoscope to see the area immediately proximal to them. The length of insertion should be measured from the

anal verge without stretching the bowel wall. The appearance of the mucosa and depth of insertion should be accurately described. If a lesion is seen, the size, appearance, location and level are recorded. If a biopsy is performed, the location, level, number of biopsies and whether electrocoagulation is necessary should be noted. During the entire procedure, suction and water irrigation should be available. A rigid cautery snare (Frankfelt snare) and cautery tip attachments are useful for excision or ablation of rectal neoplasms.

Complications

If not careful, the tip of the endoscope can tear the mucosa; a small or moderate amount of bleeding may occur. Abdominal pain and distention can occur from excessive air insufflation.

Perforation from diagnostic rigid proctosigmoidoscopy is extremely rare. Gilbertsen[2] reported an incidence of five perforations in 103,000 examinations. Nelson et al.[3] reported two perforations in over 16,000 examinations.

Flexible Sigmoidoscopy

The present day flexible sigmoidoscope is no longer fiberoptic but contains a videochip at the tip of the endoscope. This videochip transmits the image through the processing unit to the monitor. The flexible videosigmoidoscope is 60 cm in functional length (Figure 5-6). The entire sigmoid colon can be reached by the flexible sigmoidoscope in 45–85% of cases and in some cases the splenic flexure can also be visualized.[4,5] The discrepancies in success depend on patient selection and the experience of the endoscopist. For selective screening examination, flexible sigmoidoscopy has a three to six times greater yield than does rigid proctosigmoidoscopy in detecting colonic and rectal abnormalities, especially neoplasms.[6,7] Because of this higher yield and better exposure, many physicians have discarded rigid proctosigmoidoscopy.

FIGURE 5-6. Flexible video sigmoidoscope.

Indications

The role of flexible sigmoidoscopy is difficult to define, because it can examine only the sigmoid colon and rectum in most cases. However, it is more convenient to use, and in many cases the entire colon need not be examined.

In acute diarrhea, flexible sigmoidoscopy can be used to rule out Clostridium difficile colitis, acute bacterial colitis, amebic colitis, and ischemic colitis particularly after aortic aneurysm repair. Flexible sigmoidoscopy is also an excellent tool to examine bright red rectal bleeding to detect its cause such as nonspecific proctitis, radiation proctitis, anorectal Crohn's disease, rectal ulcer, and also anorectal neoplasm. Additional common indications for flexible sigmoidoscopy include postoperative evaluation to look for anastomotic strictures and to detect local recurrence of neoplasms treated by transanal excision or radical excision. Flexible sigmoidoscopy is also used for colorectal cancer screening in conjunction with tests for fecal occult blood and to complement a barium enema examination. In this situation, CO_2 may be used for air insufflation if a barium enema is to follow.

Contraindications

Patient with severe anal pain from anal diseases may not tolerate the insertion of the scope. This also applies to anorectal stricture and colorectal anastomosis less than 2 weeks postoperatively. Other contraindications include acute sigmoid diverticulitis, toxic colitis, and patients with an acute abdomen.

Preparation

Bowel preparation with two fleet enemas given within 2 h of examination is adequate. The patient may eat normally. Patients with diarrhea do not require the enemas.

Positioning

Left-lateral recumbent or prone jackknife position.

Technique

Sedation is unnecessary. The anal canal is lubricated by digital examination. A well-lubricated flexible sigmoidoscope is then inserted. Advancement of the endoscope is performed under direct vision. Pushing the endoscope through a bend in the bowel is a poor technique. Instead, the endoscope should be withdrawn to straighten the bowel. The key to success is short withdrawal and advancement of the endoscope or a to-and-fro movement ("dithering"), together with rotating (torquing) the instrument clockwise and/or counter clockwise as needed. Use of air insufflation should be kept to a minimum. The procedure should be completed within 5–10 min. If a lesion is detected and proved by biopsy to be a neoplasm, a complete colonic investigation is indicated, ideally by total colonoscopy at some other date. A polyp up to 8 mm in size

can be sampled and frequently completely excised with cold biopsy forceps. Alternatively, cautery forceps (hot biopsy) and fulguration can be used. To prevent possible explosion, due to hydrogen or methane gas in the lumen, air should be exchanged in the colon and rectum with repeated insufflation and suction. For larger polyps and in those cases when a full colonoscopy is planned, delay in treatment until time of colonoscopy with full bowel preparation is preferable.

Complications

Excessive air insufflation can cause acute abdominal distention and abdominal pain. This is best corrected by reinsertion of the endoscope and aspiration of air. Too rough and improper technique can cause perforation and other injuries, such as mucosal laceration with associated bleeding.

    The most common site of perforation in flexible sigmoidoscopy is in the distal sigmoid colon where it is angulated from the relatively fixed rectum at promontory of the sacrum. Complications from flexible sigmoidoscopy are uncommon but can be serious. They can be immediately apparent or delayed. Gatto et al.[8] reported a large population-based cohort that consisted of a random sample of 5% of Medicare beneficiaries living in the region of the USA covered by the surveillance, epidemiology, and end results program registries between 1991 and 1998. There were 35,298 flexible sigmoidoscopies performed. The perforation rate within 7 days of the procedure was 0.9/1,000. Anderson et al.[9] evaluated the 10-year experience between 1987 and 1996 at Mayo Clinic, Scottsdale, Arizona. There were 49,501 flexible sigmoidoscopies performed. Two perforations occurred – one was in the cecum, most likely from excessive air. The other was in the sigmoid colon but was not detected until 17 days later as a pelvic abscess. Both required operation. There was no mortality. Levin et al.[10] analyzed 107,704 individuals who underwent 109,534 flexible sigmoidoscopic screenings as part of Colorectal Cancer Prevention Program from 1994 to 1996 at North California Kaiser Permanente Medical Care Program. There were two perforations, two episodes of diverticulitis requiring operation, two cases of bleeding requiring blood transfusion and one episode of unexplained colitis. In this study in multivariate models, complications were significantly more common in men than in women (odds ratio, 3.34; confidence interval 95%).

Ileoscopy

Examination of the small intestine via an ileostomy can be performed using a rigid proctosigmoidoscope or a flexible scope.

Indications

Indications for endoscoping the terminal ileum are few. Most of the time it is to rule out recurrent Crohn's disease or to find an abnormality in patients with high ileostomy output.

Contraindications

Stricture of the stoma.

Preparation

Bowel preparation is not required, but it is helpful if the patient has been on a clear liquid diet for 1 day. Sedation is not required.

Positioning

Supine.

Technique

The examination starts with a digital examination to gently dilate the stoma which is frequently slightly stenotic. The well-lubricated rigid scope is introduced directly into the ileostomy. The terminal ileum is quite active with frequent spasm. It requires more air insufflation than scoping the rectum. The distance traversed by the endoscope is usually limited to 12–15 cm. In patients with a large para-ileostomy hernia, the endoscope may usually not be passed beyond 10 cm.

    Flexible ileoscopy is much easier to perform. The angulation of the small bowel can be straightened by push, pull, and rotation of the scope. A moderate amount of air insufflation is usually required.

Complications

The small bowel has thin walls and requires gentle maneuvering of the endoscope. Perforation can easily occur. If an angle cannot be straightened the procedure should be terminated.

Pouchoscopy

Kock Pouch or Continent Ileostomy

Indications

Although the ileoanal pouch has completely replaced the Kock pouch, there are still many patients with a Kock pouch. One of the most common problems that require endoscopy is the extrusion of the valve causing difficulty or impossibility of intubation to evacuate the stool. The examination is performed to help decompress the obstructed pouch and to place a draining tube. Other indications include Crohn's disease and complication of the pouch with fistulas and high output of the pouch.

    Both rigid and flexible endoscopes can be used. Church et al.[11] advised using a pediatric flexible endoscope.

Contraindications

Stricture of the stoma. Unless the procedure is performed under a general anesthetic.

Preparation

Bowel preparation is unnecessary and sedation is not usually required. If possible, the pouch should be emptied or irrigated immediately prior to the examination. It is preferable if the patient has been on a clear liquid diet for 1 day prior to the procedure.

Positioning

Supine.

Technique

The endoscope can usually be passed easily into the pouch with inspection of the stoma being performed on insertion or withdrawal. The pouch can be lavaged as necessary.

A general inspection of the pouch is performed noting the mucosal appearance, the pouch size, distensibility and the status of suture lines. If possible, the afferent loop of ileum should be intubated, especially in patients presenting with pouch inflammation. The endoscope must be retroflexed within the pouch to check valve length and symmetry. A careful search for foreign material should be made, particularly around the base of the valve. If mesh was used to reinforce the nipple valve, a fistula may form at this area. In patients with slippage or extrusion of the valve, passing the endoscope will be difficult.

For an obstructed pouch from a slipped valve, Church et al.[11] used a flexible endoscope as an obturator to insert the rigid proctosigmoidoscope. The rigid endoscope is placed over the flexible endoscope, which is itself inserted into the pouch. Then the rigid endoscope is advanced over the flexible endoscope into the pouch. Now the flexible endoscope can be withdrawn and a drainage catheter inserted to temporarily relieve the obstruction. Another option is to pass a guide wire or forceps through the biopsy channel of the flexible endoscope that has been inserted through the valve into the pouch. The wire or forceps (with the handle removed) is then left in the pouch and the scope is withdrawn, a drainage catheter can then be passed into the pouch over the wire or forceps, and surgical repair of the nipple valve is almost always required.

Complications

Perforation can occur, particularly when there is an obstruction of the pouch.

Ileoanal Pouch

Examination of the ileoanal pouch is best performed using a flexible sigmoidoscope although a rigid proctoscope can also be used. Unless there is an anastomotic anal stricture, the examination is usually easy. The endoscope can be used to examine the entire pouch and usually the terminal ileum proximal to the pouch.

Indications

Examination of the pouch is indicated for patients with bleeding from the pouch, diarrhea, recent onset of fecal incontinence, obstructive symptoms, pouchitis, for surveillance follow-up examination to exclude neoplastic changes and to rule out Crohn's disease.

Contraindications

Severe anal or anastomotic stricture, unless the procedure is performed under general anesthetic.

Preparation

The patient is prepared by taking clear liquids for 1 day or administered a small enema before the examination. Sedation is not required.

Positioning

Left-lateral recumbent or prone jackknife position.

Technique

The examination starts with a digital examination to evaluate the anal canal and the anal anastomosis. If there is a stricture, it should first be dilated with a finger or with Hegar dilators.

The well-lubricated flexible sigmoidoscope or a colonoscope is introduced into the anal canal. The endoscope is advanced into the pouch. The terminal ileum proximal to the pouch can usually be intubated. The examiner should evaluate the mucosa of the pouch and anal canal for any edema of the mucosa, granularity, mucosal bleeding, contact bleeding, erosion, fibrin exudate, pattern of mucosal ulceration, plaque and mass. Abnormal mucosa should be biopsied. Only cold biopsy should be performed.

Complications

Tear of the anal canal can occur if there is stricture of the anus or anastomosis. Traumatic injury from the scope may cause moderate bleeding which usually stops spontaneously. A perforation can occur from the instrumentation or a biopsy.

Colonoscopy

With the many methods available for evaluation and often therapy of colorectal disorders, colonoscopy has emerged as the gold standard for diagnosis. It is also, in some areas, an increasingly frequent option for therapy, be it definitive or palliative.

Indications

Indications for diagnostic colonoscopy include: the evaluation of virtually all symptoms associated with potential benign or malignant, acute or chronic diseases of the colorectum; for resolution of abnormalities seen on other imaging modalities; for investigating otherwise unexplained symptoms such as anemia; the evaluation of chronic and acute bleeding per annum; for screening and surveillance of patients at high risk for colon adenomas or carcinoma; localization of nonpalpable lesions at open or laparoscopic operation. It is also increasingly possible to combine diagnostic colonoscopy and other imaging techniques such as ultrasound.

Contraindications

Contraindications to diagnostic colonoscopy may be classified as *absolute* or *relative*. Although colonoscopy is appropriately considered a minimally invasive procedure there are risks involved which may be avoided or, at least minimized, by careful patient selection and certainly these risks should be discussed prior to the performance of the procedure.

Absolute contraindications are as follows: suspected bowel perforation, established peritonitis, or fulminant colitis.

Relative contraindications include suspected ischemia and acute colitis, in either of which instance an experienced examiner may safely perform a limited examination. Patients with a recent anastomosis may be examined with caution. Active bleeding, once a relative contraindication to colonoscopy, is being used more and more in this setting. This is described in both the prepped and unprepped colon with low complication rates.[12] The author performs colonoscopy in acute lower gastrointestinal bleeding in patients who have evidence of ongoing bleeding and either a (1) negative nuclear medicine tagged red blood cell scan or (2) positive tagged red blood cell scans followed by negative mesenteric angiography.

Preparation

Preparation for colonoscopy, of necessity, should include preparation of the endoscopist, preparation of the patient in general and of the colon specifically. Several organizations have prepared and published guidelines for credentialing the individual who is permitted to perform colonoscopy in an institutional setting[13] and, in some institutions, Credentials Committees have been established which grant privileges. Although there is some controversy involving required numbers of experiences in training, all recommendations include the following elements: background knowledge of anatomy, physiology and pathology of the colon; familiarity with instruments and accessories used in endoscopy; some formal training; and quality assurance practices. The concept of proctoring has also been addressed by some.[14] Equipment for resuscitation should be available and individuals qualified to perform cardiopulmonary resuscitation should be present in the area where colonoscopy is performed. The necessity for qualified assistance during the performance of the procedure and for monitoring the patient's condition cannot be overstated.

Obtaining informed consent is an opportunity for discussing with the patient elements of the past and present medical history, especially medications and operative procedures, which may expose psychological concerns or the need to modify preparation or change medication, timing, and dosage. It is necessary to point out the potential hazards of colonoscopy, noting aspects of the process that might cause discomfort but it is also important to give reassurance that while the risk of complication is low the examiner is prepared for prompt management. The question of the need for antibiotic prophylaxis stems from concern that although diagnostic colonoscopy is a low-risk procedure for bacteremia, infection of damaged cardiac valves or implanted prosthesis is a risk. The American Heart Association (AHA) and the American Society for Gastrointestinal Endoscopy (ASGE) have issued guidelines stating that antibiotic prophylaxis is not required for gastrointestinal endoscopy solely for prevention of infectious endocarditis.[15,16] A separate scientific statement from the AHA does not recommend routine antibiotic prophylaxis in patients who have nonvalvular cardiovascular devices (including vascular grafts) and are undergoing gastrointestinal procedures.[17]

Preparation

Thorough mechanical preparation of the colon is absolutely essential for efficient, safe, and complete endoscopic examination. In addition, should perforation occur, the empty colon certainly poses less risk of significant peritoneal contamination. There are various forms of mechanical preparation possible, but the most thorough and safest current regimen involves the use of polyethylene glycol electrolyte lavage solutions. Other forms of preparation that are sometimes employed involve ingestion of a saline cathartic (usually sodium phosphate or magnesium citrate) as well as enemas. Sodium phosphate bowel preparations have been associated with acute phosphate nephropathy, which has lead to the discontinuation of most over the counter sodium phosphate preparations. A consensus statement from the ASGE, the American Society of Colon and Rectal Surgeons (ASCRS) and the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) from 2006 includes sodium phosphate bowel preparation in its "regimens of colon cleansing before colonoscopy." Contraindications include pediatric or elderly patients, patients with bowel obstruction, renal insufficiency or failure, congestive heart failure, or liver failure.[18] An addendum to this statement was published shortly after its release, which adds the "Food and Drug Administration (FDA) warning about oral sodium phosphate." This statement includes additional risk factors for acute phosphate nephropathy including "medications that affect renal perfusion or function…."[19]

Monitoring

Although the use of pulse oximetry, heart rate, and intermittent monitoring of blood pressure, as well as electrocardiography (if clinically indicated), have now become standard procedures, it is important for the assistant as well as the endoscopist to be aware of any changes in the patient's level of awareness, respirations, and abdominal distention.

Bleeding Prophylaxis

Although bleeding is rarely associated with diagnostic colonoscopy there are concerns about bleeding at or after colonoscopy, if biopsy or polypectomy are contemplated. This has led to modification of anticoagulation regimens and cessation of drugs which might alter platelet function. Recommendations for periprocedural management of anticoagulants must take into consideration the magnitude of risk of a thromboembolic event and its attendant morbidity/mortality vs. the risk of bleeding from the procedure and the morbidity/mortality from those events. Two resources have thorough discussions of these issues and recommendations for management.[20,21] A summarization of these recommendations are that patients who are on chronic warfarin, who are at high risk for a thromboembolic event, and who are undergoing a high risk procedure (e.g., colonoscopy with polypectomy), should be managed with discontinuation of warfarin, "bridging" anticoagulation with heparin (intravenous unfractionated heparin or subcutaneous low-molecular weight heparin), and postprocedural resumption of their oral anticoagulation. Recommendations from the American College of Chest Physicians for antiplatelet therapy (including clopidogrel) and are updated regularly and practitioners performing colonoscopy should familiarize themselves with these guidelines.[21]

Technique

For successful passage of the colonoscope to the most proximal desired anatomic region (cecum or anastomosis) it is imperative that a few principles be understood.[22] The examiner must appreciate that the colon is of variable length, that respiratory and peristaltic activity is in progress during the examination, and that some areas of the colon are more fixed (by normal anatomy, previous inflammation, or postoperative change). It is dangerous to proceed with introduction of the endoscope without knowing at all times the location of the lumen.

Before starting the examination the equipment should be checked to verify that it is in good working order that irrigation, suction, and air insufflation channels are open, and that the directional controls are in the unlocked position. With the patient in the left-lateral recumbent position, the examination is initiated by thoroughly inspecting the perianal area for fissures, fistulae, hemorrhoids, condylomata and rarer conditions such as melanoma, Bowen's disease, extramammary Paget's disease, squamous and anal gland carcinomas. Next, the lubricated gloved right index finger is inserted into the anus and a rectal examination carefully performed, paying special attention to the surface of the prostate gland in the middle aged and older male patient. With the right index finger still in the rectum, the endoscopist then holds the tip of the instrument in the left hand, places it at right angles to the right index finger and by effacing the sphincter with gentle pressure of the right index finger, the instrument tip can be gently inserted as the right index finger is withdrawn. The examiner then grasps the head of the instrument in the palm of the left hand, leaving the thumb and index finger free to manipulate the knobs for tip deflection with the former and the air and water insufflation as well as suction buttons with the other. The right hand is placed on the instrument shaft. With the instrument in the rectal ampulla it is usually necessary to insufflate the lumen with a small amount of air in order to visualize the direction of the lumen.

The main objective on insertion of the instrument is to reach the most proximal point desired in as expeditiously a fashion as possible, leaving detailed inspection until the process of withdrawal of the endoscope. However, detection of an abnormality on insertion may require a change in strategy. For example, it may be important to detect, localize, sometimes biopsy, or even remove a small lesion for fear of not being able to find it easily on withdrawal. In some circumstances at least localization and biopsy should be performed, even on insertion.

One of the earliest challenges to insertion is advancing the instrument into the descending colon. The unprepared examiner, looking at the stylized cartoons of many an endoscopy record form and even many anatomical and surgical textbooks may not recognize how long the sigmoid colon can be and how easy it may be to insert a considerable length of the instrument into it. Because the sigmoid is commonly not fixed, it accepts the instrument so readily that when the acute angle at the junction of the sigmoid and (fixed) descending colon is reached the inexperienced examiner may think that he has achieved insertion to the splenic flexure. Attempts at further insertion may be hindered then by the loop created in the sigmoid colon. Most of the time this frustrating situation may be entirely avoided by attempting to keep the sigmoid collapsed and shortened as early as possible. Some have found that a clockwise turn with the right hand on the shaft of the instrument and with jiggling of the shaft, as well as back and forth motion, will often allow the bowel to fall over the instrument, so to speak, allowing insertion with a less than one-to-one motion. It is this pleating or "accordioning" of the bowel over the instrument with alternating release that allows for efficient advancement and more than one-to-one motion. As a matter of fact, the recognition of this intermittent intussusception and reduction as part of the normal advancement of the instrument makes it understandable that, in estimating the extent of intubation or the location of a lesion, the least accurate determination is measuring on the shaft of the instrument.

Having entered the descending colon with the sigmoid shortened and "straight," it is usually quite easy to advance to and around the splenic flexure. Difficulty in intubation beyond the splenic flexure is more common when the patient has undergone previous operation within this area with adhesions in the left upper quadrant which may produce fixation. Alternatively, a high, acutely angulated flexure can cause difficulty. If the endoscopist recognizes the distal transverse colon by endoscopic anatomy or transmitted aortic pulsation, it is to be recalled that, like the sigmoid, the transverse colon is on a long mesentery and is rarely fixed. The hepatic flexure can be more easily reached by keeping the transverse colon as collapsed as possible.

The hepatic is often a more complicated flexure than is the splenic and one may wander a while before entering the distal ascending colon. However, once the latter has been entered and there has been no prior right abdominal operation (for example, cholecystectomy or appendectomy) the cecum is often rapidly reached by application of suction to collapse the bowel over the instrument. A change in position from lateral to supine may also be helpful. It is important to be fully cognizant of the vagaries of endoscopic anatomy in order to confirm cecal intubation – by visualization of the appendiceal orifice and the ileocecal valve. Looking for transillumination from the instrument tip through the abdominal wall in the right lower quadrant is, unfortunately, a trap for the unsophisticated endoscopist who uses it to verify cecal entry. It merely points out that the instrument tip is in the right lower quadrant but the endoscopic tip may be in any mobile part of the colon, for example, the transverse colon or even the sigmoid. In fact, the student of anatomy recognizes that the cecum is not always in the right lower quadrant. There are aids to overcoming obstacles to cecal intubation. One is changing the patient's position from left-lateral to supine if this was not done earlier. This maneuver can also be helpful when progress is impeded at the rectosigmoid junction or the flexures. A second common technique is attempting to keep the sigmoid in a straight position so that on further insertion the tip may progress proximally. Abdominal pressure by an assistant is often used in an attempt to keep the sigmoid from reforming a loop since once it has already been straightened. One should not expect or direct the assistant to reduce the loop by compression because this could theoretically lead to injury of the bowel wall. Rather, the sigmoid has to be straightened and then pressure may be used to keep the loop from being reformed. If one reviews a series of barium enema films or has acquaintance with the position of the omega loop of the sigmoid at abdominal operation it helps to understand these maneuvers. For those who have the capability of fluoroscopy in their endoscopy units, much can be learned and much assistance provided in this maneuver, especially in the individual's early endoscopic experience. For one, it is humbling to recognize how inaccurate one can be of the extent of insertion or the shape of the bowel with the endoscope inserted. There are two recent developments in endoscopic and related instrumentation which may facilitate overcoming the difficult sigmoid loop, still the most challenging aspect of diagnostic colonoscopy. One is the development in the design of some colonoscopes for the endoscopist to vary the stiffness of the endoscope to allow a previously shortened and straightened segment of bowel from reforming a loop. The assumption is that the endoscopist knows with certainty that the loop has been adequately reduced and that it is safe to insert a now more rigid instrument. Those who have expertise with fluoroscopy know that this can be a fallible assumption. Another development is an extracorporeal magnetic device that can track the course and shape of the endoscope during insertion.[23] If proven accurate this device could potentially obviate fluoroscopy for localization, reduction of difficult loops, and even allow for safer stiffening of the endoscope utilizing either a variable stiffness endoscope or the external splinting device introduced by Shinya in the early days of colonoscopy. Certainly, the external splinting device should never be used without the benefit of fluoroscopic assistance, because with an angulated segment of bowel, it is possible to damage the bowel wall if the mucosa is caught in the space between the edge of the splinting device and the shaft of the instrument. When using the external splinting device the fluoroscope is used to first verify that the tip of the instrument is just beyond the splenic flexure and acutely angled (Figure 5-7). The deflection knobs are then placed in the locked position and, as the instrument is withdrawn and the sigmoid loop straightened under fluoroscopic control, the external splint is advanced over the endoscope up to but not beyond the proximal descending colon.[22] One does not wish to advance it to the splenic flexure where the lienocolic ligament may be vulnerable to avulsion. An assistant has to keep

FIGURE 5-7. Use of external splint.

the splinting device fixed at the anus so that the examiner does not insert it further than desired during the remainder of the examination.

External manipulation may also be helpful in two other circumstances. Sometimes the transverse colon, having a long mesentery, may form a loop extending well into the pelvis. Reduction of this loop by withdrawing the instrument and utilizing suction will usually achieve rapid progress into the ascending colon. But one can sometimes keep the loop from reforming by having an assistant apply pressure from the right abdomen directed to the left upper quadrant (because the transverse colon mesentery is longer on the right and the loop is therefore more prominent in the right portion of the abdomen or pelvis). If the cecum is not fixed (as from prior operation, for example, appendectomy or pelvic surgery), it may be possible with gentle pressure or the abdominal wall to collapse it onto the tip of the instrument, remembering, however, that the cecum is not always in the right lower quadrant. Sometimes placing the patient in the prone position allows easier intubation of the cecum

On withdrawal of the instrument one has to be sure that the entire mucosa is visualized. The author has found it helpful to place the patient supine for withdrawal. This aids in localization as fluid will collect in the most dependent portions of the colon – cecum, hepatic and splenic flexure, and rectum. Additionally, fluid and solid matter will move with gravity, thereby exposing portions of the colonic wall that were obscured in the left-lateral position. As one withdraws the instrument and the bowel recedes inspection is accomplished, but it requires close attention since one can easily withdraw too rapidly as a previously accordioned segment escapes without the examiner's control. It may be necessary to go back over an area not adequately visualized initially. In this connection, adequate preparation is even more important at this time than on insertion. If liquid material is present but too thick to be aspirated by suction through the instrument channel one may purposefully change the patient's position to allow the fluid to shift to another area. Withdrawal through the sigmoid colon perforce requires more time and attention because there are more folds and recesses. While the experienced examiner can usually withdraw very slowly through the anal canal and thus visualize its entire circumference this is sometimes better if complemented by retroflexing the tip of the instrument in the anal ampulla to visualize the region of the dentate line (if the rectal ampulla is readily distensible). As the endoscope is withdrawn through each segment of the colon, it is useful to decompress each examined segment with suction so that at the conclusion of the examination the abdomen is minimally distended.

Normal Endoscopic Anatomy

Some segments of the colon are more readily recognized than others and one has to be careful not to be overconfident unless a classic appearance is present. On insertion it is important to first recognize the three rectal valves of Houston since the relationship of a lesion to them will have great relevance if surgical intervention is to be contemplated. Diverticula may be seen throughout the intraperitoneal colon but rarely below the peritoneal reflection. The descending colon, being fixed along the white line of Toldt will often present a long straight "tunnel view." Occasionally the splenic flexure is specifically recognized if there is an external bulging bluish mass indenting the colon, descending with respiration. More common in the sigmoid colon, diverticula may be seen throughout the length of the large intestine. Their orifices may be so wide that they may be mistaken for the bowel lumen. It is therefore safer to back away somewhat and have a longer view to be sure of the location of the lumen. In any one field of view, the diverticulum will of course be at right angles to the lumen (Figure 5-8). The transverse colon, on insertion, being suspended by the three taenia coli presents the appearance of an equilateral triangle (the so-called cathedral ceiling appearance). Quite commonly, the distal transverse colon can be identified in relation to the proximal since the point of maximal impulse of the aorta is transmitted through the diaphragm which overlies the distal transverse colon. Especially, in thin patients, the liver casts a broad flat bluish green cast outside the colon but since this may be seen for a variable distance from distal transverse colon to mid ascending colon, it is not particularly helpful with localization of a lesion. At the hepatic flexure the colon often assumes a spiral configuration which can cause the tenia to so approximate each other as to make the novice assume the cecum has been reached (what has been called "the fool's cecum" or "the faux cecum").

The interhaustral folds in the ascending colon are low in profile compared with those in the left colon. The ileocecal valve is most commonly recognized as an eccentric bulge with a sometimes visible umbilication. Because there is more adipose tissue in it the appearance is often a yellowish color compared with the pink of the rest of the colon. The ileocecal valve is rarely seen head on but it is, of course, more easily recognizable when it is. It is important to intubate proximal to the valve since the true caput of the colon may be at a variable distance from the ileocecal valve. As the three tenia merge at the caput(often appearing like the branches of a tree or a crow's foot), the appendiceal orifice is commonly recognized, even in the patient who has undergone previous appendectomy. Whenever possible, the ileocecal valve should be intubated and the granular appearance of the small bowel noted. Routine practice of this improves the endoscopists proficiency for cases when intubation of the small bowel is likely to be of most value, for example, in acute lower gastrointestinal bleeding and inflammatory bowel disease.

Abnormal Findings

Exophytic lesions are the easiest to visualize and recognize at colonoscopy, the most common being adenocarcinoma.
FIGURE 5-8. Finding lumen in diverticulosis.

All polypoid lesions of the colon may be visualized at colonoscopy and virtually all have distinguishing characteristics. Many are submucosal (lymphoid hyperplasia, stromal tumors, lipomas, carcinoids, endometriomas, hemangiomas, neurofibromas, or lymphoma). A few are metastatic from other organs (for example, prostate, pancreas, or kidney). The diagnosis of most of these lesions can be made by endoscopic visualization or sampling. Some, being of no clinical consequence, require only recognition (lymphoid, hyperplasia, and lipoma). Chromoendoscopy and narrow band imaging are techniques which may improve polyp detection rate and differentiation of polyp type. As of this writing, neither technique has demonstrated widespread benefit.[24–26] Additionally, a retroscope that fits through the working channel of the colonoscope has also been described, but its usefulness has yet to be proven.

In addition to lesions which protrude, there are numerous inflammatory or degenerative conditions which have a recognizable endoscopic appearance and many can be safely sampled if necessary. These include the various colitides (bacterial, viral, ulcerative, granulomatous), ischemia, radiation proctopathy (formerly called "proctitis") and melanosis coli. Melanosis coli, when marked, may help in visualization of adenomatous tissue since the pigment is not deposited in only normal mucosa. Areas of angiodysplasia (vascular ectasias, arteriovenous malformations) can be recognized on diagnostic colonoscopy but must be distinguished from bruises created from instrumentation or even preparation. The endoscopist has to recognize colonic anatomy disturbed by previous operation and therefore has to be familiar with the variety of intestinal anastomoses performed.

Areas of stenosis and stricture may be encountered secondary to benign conditions (previous resection and anastomosis, diverticulitis, colitis, radiation injury) or malignancy. Other rare findings to be recognized include colitis cystica profunda, pneumatosis, and Behçet's syndrome. The manner in which the nature of a lesion is established at diagnostic colonoscopy will vary. A tiny sessile lesion (for example, a diminutive polyp) may be removed in its entirety with the biopsy forceps for pathologic examination. A pedunculated lesion suspected of being a benign adenoma may be removed at the time of diagnostic examination by snare polypectomy. Larger sessile lesions may be elevated with submucosal injection with saline and then excised with a snare completely or piecemeal. Fulguration with monopolar cautery or argon plasma coagulator may be used to ablate tissue. A sessile lesion suspected of being a carcinoma may be biopsied at one or more sites or even partially removed with a snare and cautery to obtain a satisfactory specimen. A stricture may be sampled for possible malignant cells by advancing a cytology brush into the stricture ahead of the colonoscope (Figure 5-9). Malignant cells may thus be harvested even though the stricture cannot be traversed with the endoscope. A lesion which appears vascular and friable may be simply photographed. A submucosal lesion may be exposed by disrupting the overlying mucosa with sequential bites from a biopsy forceps. Lesions which are not located near a definitive landmark (cecum, ileocecal valve, rectum) and are likely to require colonic resection, should be marked with a submucosal (India ink) tattoo placed in all four quadrants of the colonic lume approximately 5 cm distal to the lesion.
FIGURE 5-9. Cytology through stricture.

Complications

While colonoscopy is an overall safe procedure, it is invasive and adverse events do occur. The most common serious complication of diagnostic colonoscopy is perforation but the reported incidence of 0.03–0.7% and a mortality rate of 7–26% for patients who sustain a perforation.[27–30] Other reported complications include abdominal distension, dehydration, respiratory depression, vasovagal reaction, thrombo phlebitis, incarcerated hernia, splenic capsular tear and subcutaneous and/mediastinal emphysema and equipment failure.

In diagnostic colonoscopy, perforation may be instrumental (instrument, overtube, or accessory device), traction on a fixed segment of colon or over insufflation of a segment, especially a closed loop as may occur in patients with multiple strictures (inflammatory bowel disease) or as a consequence of prior radiation therapy and with hernia incarceration. Impaction of the instrument in a diverticulum with overdistention of the latter has also been a cause of perforation. As one studies the types of complications reported, it becomes clear that adequate training and experience should decrease these adverse events to a minimum. Because of perforation related to the use of coagulation ("hot") biopsy forceps and the low risk of bleeding from multiple forceps biopsies, there has been a falling off of usage of this instrument despite the advantages of obtaining a good specimen and simultaneously achieving hemostasis. Perforation during diagnostic colonoscopy tends to be detected earlier when it is from instrumental causes, whereas perforation from therapeutic procedures is frequently related to thermal injury and is often delayed. Indeed the management of perforation following colonoscopy is still controversial.[31,32] While there is universal agreement that perforation with generalized peritonitis suggests continuing contamination of the peritoneal cavity and therefore demands operation to halt the process, some feel that if the onset of symptoms is delayed and signs localized with a patient who is not septic (even with the demonstration of pneumoperitoneum) that nonoperative management may be undertaken. An uncommon presentation of a contained perforation may be the presence of retroperitoneal or mediastinal air and even subcutaneous emphysema which usually resolves without treatment.

Avoidance of perforation during diagnostic colonoscopy, related as it is to training, skill and experience may be best achieved by avoidance of dehydration and over sedation, discontinuation of the procedure if the preparation is poor, avoiding forceful instrument insertion, recognition of vulnerable bowel (inflammation, ischemia, narrowing, fixation); careful identification and avoidance of diverticular ostia, avoidance of bowing of the instrument, awareness of fixation from pelvic adhesions or tumor extending through and beyond the colon wall, insuring that abdominal and inguinal hernias remain reduced, avoiding over insufflation, and looping in the splenic flexure region. There should be constant identification of the location of the lumen with avoidance of "slide by" (sidewise passage of the instrument without direct visualization of the lumen). Colonoscopy during acute bleeding is technically more difficult and should not be attempted if one has not had adequate experience with routine diagnostic colonoscopy.

If perforation occurs, early diagnosis will ensure more efficient management. Undue and sustained pain (especially shoulder discomfort), absence of liver dullness on percussion, demonstration of pneumoperitoneum on upright chest film and subcutaneous emphysema, are all help in making the diagnosis. Signs and symptoms will in general be related to factors such as adequacy of bowel preparation, size of injury, and underlining pathologic state of the colon. For example, the ischemic colon or one involved with active colitis will be more vulnerable to instrumental injury. Surgical intervention is favored by most surgeons for early recognized perforation at diagnostic colonoscopy. There are, however, some patients with either a delayed perforation or one that has remained localized without symptoms or signs of diffuse peritonitis. Nonoperative management but continuing observation of this subset of patients may be entirely satisfactory. With early surgical intervention of a mechanical perforation, if technically feasible, primary closure with or without protective proximal stoma is the most desirable and usually is feasible. However, the surgeon must use good judgment in assessment of such factors as adequacy of tissue perfusion, degree of spillage, and colon tissue free of inflammation.

Radiology

Jaime L. Bohl and Alan E. Timmcke

The aim of this chapter is to discuss the radiology studies that are diagnostic and therapeutic adjuncts to the Colon and Rectal surgeon's daily clinical practice. It is imperative that the Colon and Rectal surgeon use radiological studies as a way to narrow a differential diagnosis or treat a specific disease process. To achieve this goal, the surgeon must choose an appropriate radiological study based on the known strengths and limitations of each modality, the anticipated findings and the intended therapeutic outcomes.

Plain Films

The picture provided by plain films is the result of differential absorption of X-rays by various components of the abdominal wall, bony skeleton, and the intra-abdominal contents. In particular, it is the interface between organs with varying degrees of radiolucent fat and radio-opaque gas which overlay one another and produce diagnostic boundaries on the abdominal plain film. These interfaces delineate the liver edge, renal shadow, and psoas shadow and allow differentiation of the stomach, small bowel, and colon.[1]

In order to extract the maximal amount of information from an abdominal plain film, the position of the patient, the number of views needed and the known sensitivity of this modality for various diagnoses should be considered. An abdominal plain film is referred to as a KUB (kidneys, ureter, and bladder). An acute abdominal series is comprised of an upright chest, supine abdomen, and upright, decubitus or cross table lateral of the abdomen. The series of radiographs with the patient in various positions is meant to maximize the diagnostic yield of plain films. However, Mirvus et al. found that the upright abdominal view added little additional information and that the supine abdominal view in combination with the erect chest film identified 98% of imaging abnormalities.[2] Whether two or three abdominal films are obtained is of secondary importance. The most important goal is to image the entire abdominal cavity and ensure that the diagnostic question is addressed.

The American College of Radiology suggests the use of abdominal plain films for certain symptoms or diseases which may be encountered by the Colon and Rectal surgeon (Table 6-1). It is important to remember that plain films are not a screening tool and when used as such may contribute to increased radiation exposure for little diagnostic yield. If the clinical scenario suggests a diagnoses which is better imaged with a different radiologic modality, the alternate imaging study should be used as the initial or only examination for that patient.[3] As such, plain abdominal films are useful to the colon and rectal surgeon to identify foreign bodies, check the position of drains and catheters, evaluate changes or abnormalities in intestinal gas distribution and occasionally identify skeletal or mucosal changes associated with inflammatory bowel disease.

The most amount of information can be extracted from the abdominal plain film with a systematic diagnostic approach.[4] The first step is to identify abnormalities in the bony skeleton and abnormal intra-abdominal calcifications. This step rarely identifies a primary problem for the Colon and Rectal surgery patient but can diagnose secondary complications of a primary disease process. For example, plain films may provide information regarding the extraintestinal manifestations of IBD including sacroileitis, ankylosing spondylitis, and osteopenia secondary to chronic steroid use.[5] The second step to plain film examination is the identification of catheter, drain and foreign body location, and position. While the confirmation of appropriate intravascular catheter or intra-abdominal drain placement is self-evident, the evaluation of a rectal foreign body is not. Retained anal foreign bodies may migrate proximal to the anal sphincter as far up as the descending or sigmoid colon.[6] If there is proximal migration, the object may change axial position, induce bowel wall edema and become entrapped by the curvature of the rectum and sacrum. Plain abdominal films not only document the proximal extent of the object but can determine the number, size, and shape of the foreign body (Figure 6-1A and B). These evaluations assist the clinician in determining a plan for successful removal.

TABLE 6-1. Indications for abdominal radiography

Abdominal, flank, or pelvic pain
Vomiting
Abdominal distention, bloating, or increased girth
Evaluation for and follow-up of bowel obstruction or nonobstructive ileus
Constipation
Diarrhea
Palpable abdominal mass or organomegaly
Follow-up of the postoperative patient
Blunt or penetrating abdominal trauma
Search for foreign bodies
Assessment of the GI tract for residual contrast which can interfere with another imaging study
Evaluation of medical device position
Evaluation of pneumoperitoneum
Follow-up of contrast examinations of the gastrointestinal or urinary tracts

Additional steps for reading abdominal plain films depend on the determination of abdominal gas locations and patterns.[4] Gas collections may be extraperitoneal or intraperitoneal. Extraperitoneal collections in the soft tissue of the abdominal wall may reflect a necrotizing infection or recent intervention such as surgical incision. Intraperitoneal air may be located outside the intestinal lumen (free air), within the wall of the bowel or within the confines of the bowel wall. Appropriate localization of abdominal gas collections along with clinical correlation assists the clinician in distinguishing a benign condition from a surgical emergency.

Pneumoperitoneum or air outside the confines of the bowel wall is diagnostic of a perforated viscus and can be diagnosed with high sensitivity using an upright chest film.[7] However, if the patient has peritonitis or is extremely ill and cannot sit upright, a left lateral decubitus film can be obtained. The left lateral decubitus film in the expiratory phase or the upright chest in the midinspiratory phase have a high sensitivity and can be diagnostic of as little as 1 cm^3 of free intraperitoneal air.[8] The left lateral decubitus film is preferred to the right, because it allows air movement between the liver and right hemidiaphragm where it is easily imaged and not confused with the gastric bubble. It is important to maintain the left lateral decubitus position for at least 5–10 min prior to imaging in order to allow migration of air.[9]

Diagnostic signs of free intraperitoneal air have been widely recognized and described. Two signs that are most commonly present are right upper quadrant gas and Rigler's sign (Figure 6-2A and B).[10] A right upper quadrant gas sign is a triangular or linear gas collection which has an oblique (superomedial to inferolateral) orientation between the liver and right hemidiaphragm. Rigler's sign, outlining of both the mucosal and serosal sides of the bowel wall with associated bowel wall thickening (1–8 mm) is also indicative of free intraperitoneal air. Other less commonly seen diagnostic signs include the falciform ligament sign (a thin linear soft tissue density in the right upper quadrant caused by free intraperitoneal air lining both sides of the falciform ligament), the football sign (visualization of gas anterior to
FIGURE 6-1. **A** Radiograph of rectal foreign body (anterior posterior). **B** Radiograph of rectal foreign body (lateral).
FIGURE 6-2. **A** Upright radiograph of the abdomen demonstrates a collection of air within the peritoneal space between the liver and the diaphragm. **B** Plain radiograph demonstrates the "Rigler" sign or "double lumen" sign (gas on both sides of the bowel wall).

loops of bowel within the central abdomen), and the inverted V sign (visualization of the medial umbilical folds in the pelvis). A diagnosis of free intraperitoneal air must always be correlated with the clinical condition of the patient. For instance, free intraperitoneal air can be a normal finding after surgery.[11] Free air is typically reabsorbed over several days following surgery but reabsorption may be delayed in the recumbent or thin patient. Increasing amounts of air imaged over time or in association with increasing abdominal pain may be indicative of an anastomotic leak or intestinal perforation. In addition, various conditions may be mistaken for free air. Chilaiditi syndrome is the interposition of the colon between the liver and diaphragm and can mimic the finding of pneumoperitoneum on plain abdominal films.[9]

Extralumenal air may also be located within a loculated abscess cavity, within solid organs that do not typically contain air, in the venous system or within the bowel wall. Portal venous air is peripherally located air which may have entered the portal venous system as a result of bowel ischemia and necrosis or a gas-producing bacteria. In contrast, pneumobilia or air within the biliary tract is centrally located and can result from a cholecystoduodenal fistula or from an endoscopic sphincterotomy. Finally, linear air within the bowel wall (pneumatosis intestinalis) may result from bowel ischemia and necrosis while cystic air collections within the bowel wall signify a benign condition called pneumatosis cystoides.[11]

Determination of intralumenal bowel gas patterns can help differentiate a small from large bowel obstruction or a bowel obstruction from a paralytic ileus. Bowel dilation is identified by the 3, 6, 9 rule. The small bowel is dilated when the diameter is 3 cm, the colon when it reaches 6 cm and the cecum when it dilates to 9 cm.[12] The small bowel can be differentiated from the colon by valvulae conniventes which cross the entire bowel loop and are more narrowly spaced compared to the haustra of the colon which are thicker, further apart, and only extend halfway across the colon diameter. In addition, dilated small bowel loops may form a stepladder appearance when dilated from obstruction (Figure 6-3). The valvulae conniventes may trap air between them as the obstructed small bowel fills with fluid giving a string of beads appearance. This finding is sensitive for a high-grade small bowel obstruction (SBO).[4] However, other signs of obstruction can be misleading. Air-fluid levels may be indicative of a SBO, gastroenteritis, or paralytic ileus. Ileus may be differentiated from obstruction by air found throughout the small bowel and colon (Figure 6-4). In contrast, a completely obstructed bowel may be void of air distal to the obstruction. In a partial or early bowel obstruction, distal air evacuation may not be present and the distinction between ileus and obstruction is impossible.[13]

Large bowel obstructions clinically appear like a distal SBO. On plain abdominal films the colon alone may be dilated if the ileocecal valve is competent (Figure 6-5). This causes the cecum to dilate. Acute cecal dilation beyond 12 cm places the patient at risk of perforation. In the setting of an incompetent ileocecal valve, air refluxes proximally into the small bowel which can make it difficult to distinguish between a paralytic ileus or distal bowel obstruction

FIGURE 6-3. Plain film of small bowel obstruction with dilated small bowel loops, forming a stepladder.

FIGURE 6-5. Large bowel obstruction secondary to sigmoid cancer. Competent ICV.

FIGURE 6-4. Small bowel obstruction air-fluid levels.

(Figure 6-6).[4] Volvulus in the cecum or sigmoid gives rise to a closed loop obstruction within the colon and can result in characteristic findings on abdominal plain films. The classic finding of a sigmoid volvulus is a U-shaped loop of colon projected toward the right upper quadrant in the shape of a "bent inner tube." In the middle of the sigmoid loop the medial walls of the obstructed sigmoid colon point into the pelvis (Figure 6-7). These findings are also associated with a dilated colon and small bowel proximal to the sigmoid. Cecal volvulus is characterized by a dilated cecum in the left upper quadrant with a "coffee bean" or "kidney" shape because of the medially placed ileocecal valve (Figure 6-8).[14,15]

Finally, the abdominal radiograph can reveal changes in mucosal contour and thickness. Normal bowel wall thickness is less than 2 mm. However, various forms of colitis may give rise to bowel wall thickening and mucosal irregularity. Thumbprinting is a radiographic sign that signifies bowel wall and mucosal edema, and in the setting of colon dilation may signify the presence of toxic megacolon with risk of impending perforation. Chronic mucosal inflammation may lead to haustral blunting and a tubular burned out colon from longstanding colitis (Figure 6-9).[4,5]

Abdominal plain films can yield a large amount of information if used in the appropriate clinical setting. In addition, they are inexpensive and can be performed at the patient's bedside. However, abdominal plain films are insensitive and other imaging modalities may be needed for definitive diagnosis.

Contrast Studies

Contrast Enemas

Contrast enemas can be performed as a single contrast or double contrast enema. The single contrast enema is performed by filling the colon and rectum with barium or a water-soluble agent through a rectal catheter. In double contrast enemas or air contrast enemas, barium is instilled into the colon and rectum until the mid-transverse colon is reached. The colon is then drained of excess barium and air is instilled to allow lumenal distention and prevent mucosal wall apposition. The radiologist can then change the position of the patient and use fluoroscopic guidance to obtain images of the colonic and rectal mucosa throughout its length and in multiple projections without overlap. The double contrast provides mucosal coating and detail that cannot be seen in single contrast studies. Careful technique with mucosal coating, adequate distention, and numerous projections allow discrimination of mucosal abnormalities with the double contrast enema.[16]

The limitations of a contrast enema need to be considered prior to subjecting the patient to this study. In order to visualize the mucosa, the patient must undergo a complete bowel preparation. If a patient does not have mobility to change position on the fluoroscopy table or does not have enough rectal tone to hold the contrast enema, the mucosal coating and projections obtained will be of limited diagnostic value. An incompetent ileocecal valve may allow reflux of contrast into the small bowel and further obscure colonic findings. The rectal catheter may obscure the distal rectum so that internal hemorrhoids or a distal rectal cancer cannot be appropriately discriminated.[17] Finally, there is a risk of perforation as a result of this study. Because barium causes an intense inflammatory response within the peritoneal cavity, in clinical situations for which intestinal continuity is in question or when the bowel wall may be weakened, a water-soluble contrast agent should be used. These scenarios include question of anastomotic integrity, evaluation of a large bowel obstruction, acute colitis, recent snare or forceps biopsy of the colon wall, and suspicion of colonic fistulas.[18] In comparison to barium studies, water-soluble enemas do not coat the mucosa and do not discriminate mucosal changes.

The double contrast technique can be used to detect mucosal disease in an elective setting. This includes the evaluation of colonic polyps and cancer, inflammatory bowel disease, diverticulosis and other mural abnormalities like lipomas, lymphoma, and endometriosis.

The most common reason for a double contrast enema is for colon and rectal cancer screening. Sensitivity of the study depends on the size of the lesion in addition to the coating, distention, and projection of the colon mucosa mentioned earlier. Polyps may be seen as a filling defect if imaged in a puddle of barium or may be outlined as sessile or pedunculated projections into the colon lumen (Figure 6-10). The double contrast enema has a sensitivity of 50% for polyps and cancer

FIGURE 6-10. ACE of polyp or early cancer.

less than 1 cm in size, and 90% sensitivity for those greater than 1 cm.[19,20] Increasing size, ulceration, and circumferential involvement increase the possibility that a polyp has an underlying malignancy. Semiannular lesions, which are seen on contrast enema with abrupt transition from normal to irregular mucosal patterns, shelf-like overhanging borders, and circumferential bowel narrowing, are characteristic of an apple core lesion and are diagnostic of cancer (Figure 6-11). In comparison, benign strictures from ischemic, infectious, or inflammatory etiologies have smooth tapering borders.[21] Overall, double contrast barium enema has a positive predictive value of 96% for a malignant stricture and 84–88% for a benign stricture.[22] Double contrast barium enema has been recommended as one screening modality for patients greater than 50 years of age at average risk of colon and rectal cancer.

Double contrast barium enema can also be diagnostic in the setting of inflammatory bowel disease. It can be used to differentiate Crohn's disease from ulcerative colitis, define the extent and severity of disease burden as well as visualize complications of the disease. In acute ulcerative colitis the mucosa appears stippled with shallow punctuate ulceration (Figure 6-12A). As the inflammation progresses the ulcers enlarge as crypt abscess rupture and expose the submucosa leading to pseudopolyps, which appear as irregular mucosal projections on the contrast enema (Figure 6-12B). Eventually, there is loss of mucosal detail and haustral folds which cause
FIGURE 6-11. ACE of annular cancer and "apple core sign."

a tubular or lead pipe appearance of the colon (Figure 6-13). Strictures from ulcerative colitis appear as smooth, symmetric, and circumferential colonic narrowing.[23] In Crohn's disease, the mucosal changes are not continuous and are deeper than the changes seen in ulcerative colitis. Early aphthous ulcers appear as shallow depressions with a radiolucent halo (Figure 6-14A). As Crohn's disease progresses the ulcers widen and coalesce as the muscle in the bowel wall is penetrated. This leads to cobblestoning which appears as irregular white stripes within the colon wall on contrast enema (Figure 6-14B). Deep linear ulceration along the mesenteric border causes "rake" or "bear claw" ulcers that can cause stricturing from transmural fibrosis. Strictures from Crohn's disease appear as noncircumferential, irregular areas of narrowing that are centered at the mesenteric edge (Figure 6-15).[24,25] Complications of Crohn's disease such as strictures and fistulas are well imaged with the double contrast barium technique. In contrast, other complications of inflammatory bowel disease are not easily diagnosed with enema studies. In both ulcerative colitis and Crohn's disease it is difficult to distinguish inflammatory polyps from dysplasia or cancer.[26]

Diverticular disease can also be well characterized with contrast enemas. The size, shape, number, and location of diverticuli are well imaged. In profile, diverticuli appear flask shaped with a neck, which points away from the colonic lumen. En face diverticuli appear as a white spot or meniscus within the colon lumen (Figure 6-16). With acute

FIGURE 6-12. **A** Contrast enema of ulcerative colitis showing stippling ulcers or early colitis. **B** Contrast enema of ulcerative colitis with pseudopolyps.

diverticular inflammation, secondary signs of inflammation such as narrowing of the colon lumen from extrinsic compression and mucosal edema are evident. Complications

FIGURE 6-13. Contrast enema of chronic ulcerative colitis.

of diverticulitis can also be seen. Diverticular perforation results in leaking of extralumenal contrast into the peritoneal cavity, a contained cavity or a blind sinus that drains back into the colon lumen. Strictures appear as smooth transitions in colon caliber with intact mucosa. Abscesses are suggested by a smooth contour defect within the colon lumen which does not distend with additional air or contrast instillation. Fistulae between proximal intestinal loops, the vagina, and bladder may also be seen. Barium contrast enema is safe to perform with active diverticular inflammation in the absence of peritonitis. However, the sensitivity of the contrast enema is low and may not be diagnostic in a patient with complicated diverticulitis.[27]

Double contrast enemas may also reveal colonic lipomas, endometriosis, and lymphoma. Lipomas are seen as a submucosal mass or polypoid lesion with smooth overlying mucosa. The soft pliable nature of the lipoma may be imaged in real time as the barium and air are instilled and show compression of the mass known as the "pillow sign." Endometriosis appears as an extracolonic process with intact but

FIGURE 6-17. Contrast enema showing endometriosis.

bunched up mucosal folds that result in luminal narrowing and in extreme cases scarring and lumenal contracture (Figure 6-17). Lymphoma appears different from adenocarcinoma on a double contrast enema. In contrast, lymphoma does not narrow the lumen but causes folding and thickening of the mucosa from bowel wall infiltration. The mucosa maintains a smooth appearance (Figure 6-18). All these findings on double contrast enema while suggestive of a specific diagnosis, require correlation with clinical information to be diagnostic of the condition.[28,29]

Water-soluble enemas do not result in the same mucosal coating and colonic distention that can be achieved with double contrast enemas. However, water-soluble contrast is not toxic to the peritoneal lining and can therefore be used in clinical situations in which bowel integrity may be compromised. This includes clinical situations suspicious for colonic obstruction caused by cancer, acute episodes of inflammatory bowel disease, intussusception, volvulus, and fecal impaction. Water-soluble enemas may also be used for evaluation of anastomotic integrity. Colonic intussusception occurs when a portion of proximal colon or ileum telescopes into the lumen of distal colon. A water-soluble contrast enema demonstrates a spring coil appearance or crescent sign as contrast gets trapped between the lumens of the two bowel segments and leaves a thin circular line that outlines

FIGURE 6-18. Contrast enema showing colonic lymphoma.

FIGURE 6-19. Contrast enema showing colonic intussusception.

the proximal bowel in the distal bowel lumen (Figure 6-19). While barium, air, and water-soluble enemas have been used to hydrostatically decompress an intussusception, this is not typically attempted in the older child or adult because the cause is usually a pathologic lead point.[30] Water-soluble enemas can be used to diagnose and occasionally spontaneously decompress a colonic volvulus. Sigmoid volvulus appears as a "bird's beak" as the mucosal folds spiral into the point of obstruction.[31] In cecal volvulus there is abrupt contrast cutoff distal to the torsed colonic segment with a dilated ectopic cecum. This is known as the "column cutoff sign" (Figure 6-20). In the setting of fecal impaction, water-soluble contrast is instilled up to the site of obstruction under fluoroscopic guidance. The high osmolality of the substance allows it to emulsify stool and release impacted stool into smaller pieces that can be passed per anus.[32] Water-soluble enemas are also useful prior to takedown of a diverting stoma, when a colonic stenosis is suspected or in the early postoperative period when a leak is suspected (Figure 6-21A and B). Views of the colon should be obtained in the anteroposterior and lateral views during early luminal filling, full colonic distention and after evacuation of contrast. Multiple colon projections with varying degrees of contrast distention allow for the diagnosis of subtle leaks that may be obscured by full colonic distention with contrast.[16] Overall, water-soluble enemas may not have the same diagnostic sensitivity as a double contrast barium enema but they remain useful in the diagnosis and treatment of colon and rectal disease.

Small Bowel Series and Enteroclysis

The small bowel can be imaged using several methods. To obtain a small bowel series, a patient drinks a large volume of dilute barium and contrast is followed as it advances through the small bowel with fluoroscopy images taken every 15 min. In order to improve visualization of small bowel loops, abdominal pressure and compression can be used to flatten bowel loops and decrease small bowel loop overlap. Transit of contrast through the small bowel normally takes 90–120 min. In comparison, small bowel enteroclysis is a more labor and time intensive method for imaging the small bowel. The patient must undergo colonic cleansing to decrease both the time needed for contrast to reach the terminal ileum as well as the amount of contrast needed to fill the small bowel.[25] With this method, two contrast agents are instilled into the duodenum at separate points in time through a tube inserted through the nose and advanced into the proximal duodenum. The rate of contrast instillation is modified according to the amount of small bowel distention achieved and patient tolerance. Administration of barium in addition to air or methylcellulose allows the barium to act as an interface with the small bowel mucosa for detection of mucosal lesions or subtle mucosal changes. Serial images are obtained with enteroclysis as is done with small bowel series. In comparison to small bowel series, small

FIGURE 6-21. **A** Contrast enema showing a contained anastomotic leak. **B** Contrast enema showing a free-flowing leak.

bowel enteroclysis requires placement of a nasogastric tube, high radiation doses (up to 21 mSv), and administration of a hyperosmotic contrast agent.[33] Overall, fluoroscopy is a time and labor-intensive method of obtaining radiographic images of the small bowel.

Small bowel imaging is typically useful for patients with unexplained gastrointestinal bleeding, suspected small bowel tumors, Crohn's disease, and partial SBOs. For patients with Crohn's disease, the severity and distribution of disease can be determined (Figure 6-22A and B). In addition, the site of small bowel complications such a fistula and stricture can be located. For patients with suspected SBOs, dilute barium can be used to image the small bowel when there is unclear etiology of the obstruction or when localization of the obstructing point is important. Unlike the colon, barium does not become inspissated in the small bowel while hypertonic water-soluble contrast agents may exacerbate lumenal distention already present in SBO.[34] In all, the small bowel contributes a large amount of mucosal surface and length to be studied. Small bowel radiography should be undertaken only after ruling out other parts of the intestine as the cause of the patient's symptoms or for specific diagnoses that affect the small bowel.

Computed Tomography

Computed tomography (CT) has become a routine examination to evaluate a wide range of disease processes, because it is an easy, fast, and accurate test. CT provides detailed and high-resolution cross-sectional images of hollow viscous and solid organs. Accurate interpretation requires optimal opacification of the gastrointestinal tract and vascular structures. The bowel is opacified by administering a water-soluble oral contrast agent. The density of barium interferes with the acquisition of data during the scan and thus should be avoided as a contrast agent. The oral contrast is typically administered 45–60 min before scanning to allow

FIGURE 6-23. CT scan showing colon cancer primary lesion and adenopathy.

the contrast to opacify as much of the bowel as possible. If pelvic or rectal pathology is being evaluated, the contrast may also be administered per rectum at the time the scan is being performed. Intravenous (IV) contrast agents typically are iodinated so it is important to take a thorough history of allergies. Anaphylactic reaction to the iodinated contrast is a contraindication for administration but simple allergies such as hives can be prevented with steroids and diphenhydramine. Iodinated contrast is administered as a bolus at the time of the examination. The reason for the examination dictates the exact timing between when the contrast is administered and when the CT images are acquired (i.e., venous vs. arterial phase). The CT scan uses ionizing radiation to acquire the images with 5- to 10-mm collimation. Smaller collimation allows for sharper, more detailed images. Radiation exposure to the patient varies depending on protocol design and the type of CT scanner used. However, the average radiation dose for a multidetector CT of the abdomen and pelvis is 13.3 mSv and for a CT of the chest is 6.8.[35] CT is sensitive for the staging of colon and rectal cancer and diagnosis of inflammatory and infectious conditions of the colon, bowel obstruction, and postoperative complications.

Colon and Rectal Cancer

CT of the abdomen and pelvis is useful for the initial staging of colon and rectal cancer. CT assists the surgeon in determining the location of the primary tumor, involvement of adjacent organs, enlargement of regional lymph nodes and the presence of distant (liver) metastases. Colon and rectal cancer primary lesions may appear as an exophytic mass within the colon lumen or as an apple core lesion with irregular circumferential bowel wall narrowing (Figure 6-23).[36] CT accuracy for predicting tumoral extension beyond the muscularis propria can be as high as 70–82%[37]; however,
FIGURE 6-24. CT showing a large colonic mass in the descending colon that narrows the lumen. CT cannot differentiate tumor extension through the wall from pericolonic edema or desmoplastic reaction. (From Blanchard TJ, Altmeyer WB, Matthews CC. Limitations of colorectal imaging studies. In: Whitlow CB, Beck DE, Margolin DA, Hicks TC, Timmcke AE, editors. Improved outcomes in colon and rectal surgery. London: Informa Healthcare; 2010. p. 97–131. With permission).

FIGURE 6-25. CT scan showing liver metastasis.

inaccuracies result from the inability to distinguish gross tumor extension from peritumoral desmoplastic reaction (Figure 6-24). CT is also advantageous for determining adjacent organ involvement which will require more extensive en bloc resection of the tumor. Adjacent organ involvement may include the peritoneum, duodenum, stomach, vagina, bladder, and abdominal wall.[38] Lymph nodes are considered pathologic if they are >1 cm in size on CT scan. Accuracy in detecting lymph node involvement can be limited by normal size of tumor bearing nodes and enlargement of lymph nodes in the peritumoral region without nodal metastases.[39,40] Overall, preoperative CT scans can assist the surgeon in determining local tumor extension.

CT scan is an accurate imaging modality for the detection of hepatic metastases as well as hepatic recurrence of colon and rectal cancer. CT images are typically obtained in two phases: the hepatic artery phase (20–25 s after the IV contrast is infused) and the portal venous phase (65–70 s after the IV contrast is infused). Colon and rectal metastases are supplied by the hepatic artery while most of the liver parenchyma is supplied by the portal vein. Therefore, during a portal venous phase CT, colon and rectal liver metastases appear as solid hypodense lesions that do not have dynamic enhancement changes (Figure 6-25).[41] These characteristics allow hepatic metastases to be differentiated from fluid filled hepatic cysts, hemangiomas, and hypervascular liver malignancies. Preoperative CT scan is 85% sensitive for colon and rectal hepatic metastases.[42] Because liver lesions that are <1 cm in size do not demonstrate contrast-enhancing

properties, they are labeled as indeterminate lesions. Follow-up studies of patients with colon and rectal cancer and indeterminate liver lesions show that up to 11% of indeterminate lesions on initial CT may progress on subsequent imaging and, therefore, represent early metastases.[43]

CT scan is a recommended part of some surveillance programs for colon and rectal cancer patients in order to detect recurrence. Although surveillance programs have not been shown to improve overall survival, intense follow-up has been shown to improve postrecurrence survival.[44] CT scan, along with carcinoembryonic antigen levels, chest X-ray, and colonoscopy, has been shown to detect asymptomatic recurrence.[45] Recurrence of colon and rectal cancer on CT scan is demonstrated by interval enlargement of soft tissue masses, enlarging lymph nodes, and invasion of adjacent organs (Figure 6-26). New metastases may also be visualized within the liver. Because evidence is lacking that routine CT scan after colon and rectal cancer resection improves overall survival, the ASCRS practice parameters do not recommend routine abdominal imaging as part of a cancer surveillance program.[46]

Other Tumors of the Colon

CT remains the imaging study of choice for detection of benign and malignant tumors of the colon other than adenoma and adenocarcinoma. Metastases to the colon can be seen on contrast-enhanced CT, if they are large enough; but CT cannot differentiate primary tumor from metastasis.[47] One of the most common benign colonic tumors is a lipoma. Lipomas can be easily diagnosed by demonstrating a 2–3 cm, round or ovoid, sharply defined tumor with homogenous fat density.
FIGURE 6-26. CT showing thickening of the peritoneal surfaces, ascites, and two large peritoneal nodules in a patient with colon cancer. (From Blanchard TJ, Altmeyer WB, Matthews CC. Limitations of colorectal imaging studies. In: Whitlow CB, Beck DE, Margolin DA, Hicks TC, Timmcke AE, editors. Improved outcomes in colon and rectal surgery. London: Informa Healthcare; 2010. p. 97–131. With permission).

FIGURE 6-27. CT showing a large heterogenous exophytic mass with cystic degeneration and necrosis that communicates with the lumen of adjacent colon and small bowel. (From Blanchard TJ, Altmeyer WB, Matthews CC. Limitations of colorectal imaging studies. In: Whitlow CB, Beck DE, Margolin DA, Hicks TC, Timmcke AE, editors. Improved outcomes in colon and rectal surgery. London: Informa Healthcare; 2010. p. 97–131. With permission).

Colonic lymphoma usually appears as either a marked thickening of the bowel wall that often exceeds 4 cm, or a homogeneous soft tissue mass without calcification. Lymphoma characteristically causes much larger soft tissue masses than adenocarcinoma. Owing to the softness of the tumor, the lumen is commonly dilated or normal, rather than constricted, and bowel obstruction is uncommon. The absence of desmoplastic reaction and diffuse lymphadenopathy help to differentiate lymphoma from adenocarcinoma.[48,49]

Gastrointestinal stroma tumors (GIST) can be benign or malignant and cannot be differentiated on cross-sectional imaging without distant metastases to the liver or peritoneum.[50] GISTs can appear as an exophytic or intraluminal mass, and size varies from few millimeters to 30 cm (Figure 6-27). Cystic degeneration, hemorrhage, and necrosis are common in large lesions with calcification rarely noted. The tumor cavity may communicate with the colon lumen and contain air or oral contrast. Sarcomas that arise in the bowel, anorectum, or omentum are indistinguishable from malignant GIST.[50] Tissue types include leiomyosarcoma, fibrosarcoma, and liposarcoma.

Diverticulitis

CT scan is the most accurate imaging modality for the diagnosis of diverticulitis and its complications. CT findings of diverticulitis include soft tissue stranding of the pericolonic fat, diverticula, colon wall thickening, and abscess formation.[51] Normally, the colon mesentery and pericolonic tissues are hypodense secondary to the high water content of fatty

tissue. This creates sharp boundaries between the colon, colonic mesentery, and adjacent organs. As the inflammatory process develops, the mesentery becomes edematous and hypervascular. The sharp contrast between tissue planes is obscured resulting in so-called dirty fat. When the mesenteric and pericolonic inflammation is associated with colon wall thickening within the sigmoid mesentery, the diagnosis is diverticulitis (Figure 6-28). The inflammatory process can be extensive with an associated phlegmon but no organized abscess. Depending on the size of diverticular perforation, there may be small flecks of extraluminal air within the mesentery or in the upper abdomen above the liver.[52] The identification of diverticula within the colon is not mandatory for the CT diagnosis of diverticulitis. Overall, the CT diagnosis of diverticulitis is based on a thickened short segment of colon with surrounding pericolonic inflammation.

CT scans are also useful for the diagnosis of complicated diverticulitis. Pericolonic abscesses are fluid collections adjacent to the inflamed colon (Figure 6-29). Abscesses are best visualized when surrounding loops of bowel are opacified with oral or rectal contrast and the rim of the abscess is enhanced with intravenous contrast. A colovesicular fistula, an abnormal connection between the colon and bladder, can be diagnosed in several ways. Air within the bladder without previous catheterization is diagnostic (Figure 6-30). In addition, thickening of the bladder wall with adjacent inflamed sigmoid colon can be suggestive of bladder involvement. If the fistula is large enough, enteral contrast may enter the bladder via the intestinal segment.[53] In all, CT is able to diagnose diverticulitis and its complications with a high degree of accuracy.
FIGURE 6-28. CT showing uncomplicated diverticulitis.

FIGURE 6-30. CT demonstrating a colovesical fistula.

FIGURE 6-29. CT showing a diverticular abscess.

The most important diagnostic determination is to distinguish diverticulitis from colon cancer. Certain CT features may suggest one diagnosis over another. Diverticulitis is more likely to involve a longer colonic segment (>5 cm), cause pericolonic inflammation, perivascular engorgement and fluid at the root of the mesentery.[51] Conversely, colon cancer is more likely to be associated with an intraluminal mass, asymmetric wall thickening, and enlarged lymph nodes.[54] Regardless, a mucosal examination of the affected colon segment should be performed after resolution of the inflammatory changes to make a definitive diagnosis.

Inflammatory Bowel Disease

Crohn's Disease

CT scan is useful for both the diagnosis of Crohn's disease and evaluation of established Crohn's disease. The most common findings associated with Crohn's disease are bowel wall thickening, peri-intestinal inflammation, and regional lymphadenopathy. The bowel wall can reach 11–13 mm in thickness, which can be either symmetric or asymmetric. The halo sign, which is a low-attenuation ring caused by submucosal deposition of fat between the enhancing mucosa and bowel musculature, is a common finding associated with Crohn's disease. The transmural nature of the inflammatory process allows it to extend into the mesentery and adjacent structures so there is often an extensive inflammatory response centered on the affected bowel (Figure 6-31A and B).[55] The presence of creeping fat or fat proliferation within the mesentery separates bowel loops. This can give a characteristic appearance of a predominance of fat and inflammation on one side of the abdomen and a shift of unaffected, healthy bowel on the other side of the abdomen. Complications of Crohn's disease may also be seen on CT scan and include abscesses within mesentery, bowel loops, psoas muscle, pelvis, and abdominal wall (Figure 6-32). Fistulae between bowel loops, the abdominal wall, vagina, and bladder may also be seen on CT. Finally, intestinal strictures with homogenous enhancement from chronic inflammation and fibrosis may also be seen on CT.[56,57] Overall, CT is useful for delineating the extent and severity of Crohn's disease and its complications.

Ulcerative Colitis

Like Crohn's disease, ulcerative colitis is characterized by thickening of the colon wall on CT scan. However, ulcerative colitis is not a transmural disease and, therefore, results in a lesser degree of bowel wall thickening (7–8 mm) in comparison to Crohn's disease (10–20 mm). In addition, bowel wall thickening in ulcerative colitis is circumferential while Crohn's disease may cause eccentric wall thickening.

B

FIGURE 6-31. **A** CT showing terminal ileum Crohn's disease with abscess. **B** CT showing Crohn's colitis.

FIGURE 6-32. CT showing a psoas abscess related to Crohn's disease.
FIGURE 6-33. CT with coronal reformatting showing wall thickening and marked irregularity of the mucosa in the ascending and descending colon consistent with ulcerative colitis. (From Blanchard TJ, Altmeyer WB, Matthews CC. Limitations of colorectal imaging Studies. In: Whitlow CB, Beck DE, Margolin DA, Hicks TC, Timmcke AE, editors. Improved outcomes in colon and rectal surgery. London: Informa Healthcare; 2010. p. 97–131. With permission).

In ulcerative colitis, inflammatory changes extend from the rectum proximally and are continuous (Figure 6-33). Crohn's disease typically affects the terminal ileum and proximal colon, but any area of the intestinal length can be involved with intervening segments of normal bowel (i.e., "skip lesions"). Although ulcerative colitis can cause luminal narrowing of the colon from pseudopolyps, the outer bowel wall tends to remain smooth. In contrast, bowel that is affected by Crohn's disease can be irregular on both the inner and outer bowel wall lining. Finally, ulcerative colitis is not typically associated with abscesses and fistulae. By identifying patterns of bowel involvement, a distinction between Crohn's disease and ulcerative colitis can usually be made with CT scan.[55,58,59]

Other Colitides

Colitis is characterized by colonic wall thickening and may be indicative of an infectious, inflammatory or ischemic process. Colonoscopic evaluation can confirm the underlying disease process as infectious (15%), inflammatory (9%), ischemic (36%), or malignant (7%).[60] However, just as patterns of involvement can differentiate Crohn's disease from ulcerative

colitis, they can also be used to differentiate the various causes of bowel wall thickening. In addition, the clinical presentation of various types of colitis differ, so combining the presenting signs and symptoms with the distribution of CT findings will usually lead to the correct diagnosis.

Neutropenic enterocolitis or typhlitis typically occurs in patients who are neutropenic either from cytotoxic chemotherapy or severe immunosuppression. The terminal ileum, cecum, and right colon are most frequently affected. CT is the study of choice for the diagnosis. Circumferential thickening of the terminal ileum, cecum, and variably the right colon are the common CT findings consistent with typhlitis (Figure 6-34). The bowel wall may become so thickened because of edema that a hypodense ring develops between the mucosa and musculature. Complications such as pneumatosis or perforation can also be detected.[61]

Ischemic colitis is the most common vascular abnormality of the colon. Presenting symptoms include abdominal pain associated with bloody diarrhea. The age of the patient and onset of symptoms will help to differentiate between IBD, infectious colitis, and ischemic colitis. Endoscopy is the gold standard for diagnosing ischemic colitis. CT is much more readily available so it is often the first test ordered. The colitis may be segmental or diffuse, typically occurring in the watershed areas of the right colon, splenic flexure, and rectosigmoid. CT findings consist of thickened, edematous colon in these areas (Figure 6-35). The typical "thumbprinting" in the colonic mucosa can be seen on CT scan as well as plain films. There may be a halo sign of either low attenuation caused by edema or high attenuation caused by hemorrhage within the bowel wall. A pericolonic inflammatory response is often present as well. Thrombus within the colonic mesenteric vessels may also be seen. Finally, pneumatosis or portal venous gas may be present indicating bowel infarction.

FIGURE 6-35. CT showing of ischemic colitis.

FIGURE 6-36. CT showing pseudomembranous colitis.

Pseudomembranous colitis resulting from the toxins produced by *Clostridium difficile* can cause profound inflammation of the colon. Computed tomographic findings include nonspecific thickening and edema of the colon and pericolonic inflammation. Generally, the edema and thickening of the colon is greater than that seen with infectious colitis or other inflammatory processes. The presence of pancolitis also tends to suggest pseudomembranous colitis vs. other colitides (Figure 6-36). Once again, the CT results must be interpreted in the clinical context of the patient.

Small Bowel Obstruction

SBO is a clinical diagnosis based on the signs, symptoms, and clinical condition of the patient. Radiologic studies are obtained to confirm the clinical diagnosis. The use of CT in the evaluation of an SBO is expanding and in many cases can eliminate delays in diagnosis. CT has the advantages

FIGURE 6-34. CT showing neutropenic enterocolitis.
FIGURE 6-37. CT showing a simple small bowel obstruction.

FIGURE 6-38. CT showing an incarcerated hernia.

of being able to identify the site of obstruction, cause of obstruction, and it can provide information regarding vascular compromise of the bowel. Indications when a CT scan is particularly helpful include (1) a patient with no prior surgery, (2) a patient with equivocal plain films and an uncertain diagnosis, and (3) a patient with known intra-abdominal pathology such as Crohn's disease or cancer.[62]

Oral contrast is not always necessary and should be avoided in patients with a high-grade or complete bowel obstruction. The intraluminal fluid often distends the bowel and acts as a natural contrast agent. The low-density intestinal fluid also augments the enhancement of the bowel wall after the administration of IV contrast, which can provide information regarding the flow of blood of the bowel.

The CT diagnostic criteria of a SBO are based on the presence of dilated proximal small bowel (>2.5 cm) and collapsed distal bowel. When a transition between dilated and collapsed bowel is identified, then the diagnosis is confirmed (Figure 6-37). When a transition point is not identified, it is difficult to distinguish between an SBO and adynamic ileus. In such cases, one must search for other clues to differentiate the processes. For example, the presence of "small bowel feces," which are gas bubbles mixed within particulate matter and located in the dilated bowel, is a reliable indicator of a SBO. The presence of other intra-abdominal pathology, particularly inflammatory processes, would generally indicate an adynamic ileus. This is a case in which oral contrast may be particularly helpful because if contrast reaches the colon, a complete SBO is not present.[63,64]

CT can also provide significant information regarding the cause of the obstruction. Once again, the findings must be interpreted in context of the patient's clinical situation. When there is a sharp transition from dilated to decompressed bowel in the absence of other findings, this is highly suggestive of an SBO secondary to adhesions. CT does an excellent job identifying hernias such as inguinal, umbilical,

incisional, or other atypical hernias. Often these hernias contain bowel but not all are obstructing. Clues indicating obstruction are dilated bowel going into the hernia and collapsed bowel exiting the hernia, oral contrast proximal to the hernia and no contrast distal to the hernia, and a localized inflammatory process surrounding the hernia, particularly in the subcutaneous tissues (Figure 6-38). Another common extrinsic cause of obstruction is recurrent cancer. A CT scan is often able to demonstrate a mass at the site of obstruction and may also provide evidence of more widespread peritoneal disease. Unexpected causes of obstruction may also be identified such as Crohn's disease, intussusception, or small bowel cancers.[65]

When the affected bowel becomes strangulated, the morbidity and mortality associated with a SBO increase significantly. No test is able to provide definitive proof of strangulated bowel, but CT is able to provide a wealth of information that can indicate concern for vascular compromise. Thickened, congested bowel with increased attenuation at the site of obstruction associated with engorgement of the mesenteric vasculature is concerning for strangulation (Figure 6-39). The mesentery may become hazy or the vasculature may be obliterated as the inflammation progresses, and it becomes filled with fluid or even blood.[66] Other findings of ischemia include lack of enhancement after IV contrast administration or the presence of ascites. The presence of pneumatosis and portal venous gas are the more ominous signs of intestinal ischemia. Finally, a spiral pattern of engorged mesenteric blood vessels may indicate an internal hernia or rotation of small intestine around fixed adhesions.[67]

Postoperative Evaluation

CT has greatly impacted the postoperative evaluation of the surgical patient. It is typically used to evaluate a patient with

FIGURE 6-39. CT showing a small bowel obstruction with evidence of ischemia.

FIGURE 6-40. CT showing a colorectal anastomotic leak.

abdominal pain, fevers, leukocytosis, or persistent ileus in the postoperative period. The yield of a CT scan is greatest when it is obtained 5 days or more after surgery. Before postoperative day 5, it is difficult to differentiate normal postoperative intraperitoneal free air and fluid from air and fluid that represent a leak from a hollow viscus or abscess cavity. It usually takes more than 5 days for an abscess to organize into a walled-off, contained collection.[68] Once again, the findings of the CT scan must be interpreted in the context of the clinical condition of the patient. Therefore, the yield will be greatest when the scan can address a specific question.

Findings highly suggestive of an anastomotic leak include an inappropriate volume of free air or fluid in the abdomen. The presence of extraluminal oral contrast confirms perforation of a hollow viscous. The presence of localized fluid and air around an anastomosis are concerning for a leak but must be taken in context to the postoperative period and the condition of the patient. Water-soluble enemas are more sensitive than CT with rectal contrast for the detection of a colonic anastomotic leak (Figure 6-40). However, a CT is often more easily and readily obtained. An abscess is defined as an organized fluid collection with or without air that has an enhancing rim (Figure 6-41).[69,70] As mentioned above, CT is very good at distinguishing between an ileus and a mechanical bowel obstruction, which is an important distinction in the perioperative period.

Computed Tomography Enterography

Computed tomography enterography (CTE) is a technique that uses multidetector row CT to examine the small bowel in a continuous fashion. The volume of information produced can be reconstructed in any plane to produce high-resolution

FIGURE 6-41. CT showing an anastomotic leak. *Arrows* point to pneumoperitoneum and high density ascites which represents extravasated oral contrast. (From Blanchard TJ, Altmeyer WB, Matthews CC. Limitations of colorectal imaging studies. In: Whitlow CB, Beck DE, Margolin DA, Hicks TC, Timmcke AE, editors. Improved outcomes in colon and rectal surgery. London: Informa Healthcare; 2010. p. 97–131. With permission).

scans with superb image quality.[71] For high quality images the patient must ingest over a liter of oral contrast in a rapid fashion (<1 h) and intravenous contrast is administered for enhancement. Advantages of CTE include the ready availability of CT scanners, a straightforward technique, the speed of the exam (10–15 min), and the potential for less radiation than a standard small bowel follow through. Intestinal and extraintestinal findings of Crohn's disease can be seen on CTE.[72] Intestinal findings include wall hyperenhancement, wall thickening (generally >3 mm), and luminal narrowing (Figures 6-42 and 6-43). Extraintestinal findings include
FIGURE 6-42. **A** CT enterography of strictured ileal Crohn's disease. Axial scan through the pelvis shows narrowed, strictured neo-terminal ileum (*large arrow*). Note the thin, inner wall hyperenhancement and the peripheral wall hypoenhancement giving a target appearance or mural stratification. Additionally, the inner portion of the wall of the immediate upstream ileum (*long small arrow*) also hyper enhances. The stricture causes significant upstream obstruction. **B** CT enterography of strictured ileal Crohn's disease. Coronal, thin MIP scan through the pelvis shows narrowed, strictured neo-terminal ileum (*arrow*) just proximal to the cecum (C). (From Baker ME, Veniero JC, Kiran RP. Computed tomography enterography and magnetic resonance enterography: the future of small bowel imaging. Clin Colon Rectal Surg. 2008;21:213–19. With permission).
FIGURE 6-43. **A** CT enterography of distal ileal Crohn's disease. Axial scan through the pelvis shows a long segment of disease proximal to an end ileostomy (*arrows*). There is mild-to-moderate upstream small bowel (B) dilation. Interestingly, the endoscopy was normal, but the pathology was positive for active disease. **B** CT enterography of distal ileal Crohn's disease. Coronal thin MIP reconstruction through the pelvis shows a long segment of disease proximal to an end ileostomy (*arrows*). (From Baker ME, Veniero JC, Kiran RP. Computed tomography enterography and magnetic resonance enterography: the future of small bowel imaging. Clin Colon Rectal Surg. 2008;21:213–19. With permission).

peribowel vascular engorgement, peribowel fat proliferation, strictures, fistulae, and abscesses. In many centers, CTE is replacing the traditional small bowel follow through.

CT Colonography

CT colonography or virtual colonoscopy is a method for imaging the colon and screening for advanced polyps and colorectal cancers. This technique requires cleansing of the colon to allow differentiation of polyps and haustral folds from fecal material. A newer method of stool tagging which involves patient ingestion of low-density barium and water-soluble contrast the night before the study along with the colon preparation, increases the sensitivity of the exam. The colon is distended during the study through the manual or automated instillation of air or carbon dioxide. The colon is then imaged in two patient positions (supine and prone) using multidetector row CT with thin collimation. The images are then viewed in two- and three-dimensional views for interpretation by a computer and the radiologist. Computer-aided detection identifies suspicious areas and increases the diagnostic accuracy of the reading radiologist. Advances in this technique which include stool tagging, automated colon distention, and multiplanar views of the colon have increased the utility of this technique for colon polyp and cancer screening. In addition, the short amount of time required to obtain images (<15 min), the absence of conscious sedation, and a low perforation rate make CT colonography a promising alternative to optical colonoscopy for colon cancer screening.[73]

CT colonography allows detection of polyps based on size. Polyps which are >10 mm in size are considered high risk and the patient is referred for same day colonoscopy. Polyps between 6 and 10 mm in size are detected and reported but current treatment protocols call for variable management of these polyps. Some patients may be offered CT surveillance and others optical colonoscopy (Figures 6-44 and 6-45). Although polyps which are 5 mm or less in size may be seen on CT colonography, they are not reported in the radiologist's interpretation of the study. This approach has been shown to decrease the number of referrals for optical colonoscopy without sacrificing early treatment of high risk polyps.[74] CT colonography has been shown to have similar sensitivity to optical colonoscopy for the detection of middle and large size polyps in average risk individuals.[75]

Despite advances in sensitivity with CT colonography, this technique still has limitations that must be overcome before its widespread use in screening protocols. For example, CT colonography has a poor sensitivity for flat lesions and may miss up to 66% of flat lesions over 5 mm.[76] In addition, CT colonography is a diagnostic not therapeutic procedure. Up to one in five patients undergoing CT colonography may be referred to optical colonoscopy. CT colonography may also reveal extracolonic findings. While extracolonic cancers have been diagnosed using this technique, between 5 and 16% of patients will be referred for additional imaging and diagnostic

FIGURE 6-44. Axial two-dimensional image from a CT colon study shows a well-defined 6-mm polyp in the sigmoid colon.

FIGURE 6-45. Three-dimensional image confirms the presence of the polyp in Figure 6-4.

procedures when CT colonography findings have no clinical significance.[77] Finally, insurance coverage for this screening technique is limited. For these reasons, CT colonography is recommended for patients who are unable to have a complete colonoscopy, for those who have significant medical problems that put them at increased risk for optical colonoscopy complications (significant pulmonary disease or anticoagulation), and to identify synchronous cancers or polyps in patients with

obstructing lesions. CT colonography is contraindicated in patients who are at high risk for colon and rectal cancer such as inflammatory bowel disease patients or those with known genetic syndromes for colon or rectal cancer.[73]

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is an imaging technique that measures proton behavior after excitation by a radiofrequency pulse in a magnetic field. Protons within water dense or fat dense tissue can be selectively displayed so that adjacent tissues demonstrate different levels of intensity. Advantages of this technique include the avoidance of ionizing radiation as well as iodinated contrast agents.[78] However, MRI requires expensive equipment and radiologist expertise for interpretation and, therefore, may not be widely available. In addition, image resolution may be degraded by respiratory motion or peristalsis of the bowel. Newer advances enhance image quality despite challenges with motion artifact. Integration of a pelvic phased array coil with the endorectal coil (Figure 6-46) or an external phased array coil used independently results in high-resolution images with a large field of view.[79,80] MRI cannot be performed in patients with implanted devices which may malfunction in a strong magnetic field (cardiac pacemakers, cerebral aneurysm clips, cochlear implants). In addition, patients with chronic renal insufficiency who will require gadolinium for MRI image acquisition are at risk for nephrogenic systemic fibrosis, a progressive fibrotic syndrome which affects the skin and other organs.[81] Despite the utility of MRI in imaging rectal and anal disease with respect to the entire pelvis, not all patients will be candidates for MRI imaging.

MRI can be used for staging rectal cancer. Pretreatment staging of rectal cancer has been shown to have similar accuracy for detection of tumor depth and nodal involvement as endorectal ultrasound.[82] Tumor depth can be determined secondary to the low signal intensity of the muscularis propria which sits between the high intensity layers of the submucosa and perirectal fat (Figure 6-47). Lymph node involvement is not judged solely by size but also by irregular borders and heterogenous signal intensity. Agreement between MRI and pathology staging is 94% for tumor depth, 85% for nodal involvement and 92% for circumferential margin involvement.[83] Advantages of MRI for initial rectal cancer staging include accuracy that does not vary with the height of the rectal lesion and visualization of the entire pelvis This allows surgeons to assess of the radial margin and pelvic sidewall prior to surgery.

Studies have been performed to test the utility of MRI in restaging of rectal cancer after neoadjuvant chemoradiation and after rectal cancer recurrence. The difficulty is in distinguishing inflammation from tumor deposits. Tumor has a high signal intensity and rapid enhancement on T2 images. Granulation tissue, hematoma and radiation-induced inflammation also have a high signal intensity.[82] Therefore, MRI images have a low sensitivity for diagnosing tumor persistence after chemoradiation therapy.[84] Even as inflammation matures over time into fibrosis which appears as an area of low intensity and slow enhancement, the specificity of MRI remains low (29–86%) and can lead to a diagnosis of recurrence when there is not.[84] Overall, utility of MRI in restaging rectal cancer after neoadjuvant treatment and in detecting rectal cancer recurrence remains low.

MRI is now increasingly used for the imaging of complex fistula in ano and fecal incontinence. Fistula in ano is often diagnosed and treated with an exam under anesthesia. However, MRI images may assist the surgeon in identifying primary and secondary fistula tracts and the internal anal

FIGURE 6-46. Endoanal MRI demonstrates a nondisrupted (normal) signal of the internal and external sphincter.

FIGURE 6-47. Endorectal MRI examination shows an ulcerated plaque-like cancer arising from the mucosa and extending to the first muscular layer of the muscularis propria.

canal opening with respect to the sphincter complex prior to definitive surgery. Unlike endoanal ultrasound (EAUS) which may also assist the surgeon, the MRI allows for a large field of view which includes the pelvis, ischiorectal fossa, and gluteal regions that are outside the scope of EAUS images but may be involved if fistulous disease is extensive. In addition, patients with active proctitis or anal stenosis may be more comfortable with an external phased array coil rather than an endoanal coil or ultrasound probe.[85] MRI may also be used for patients with fecal incontinence. While MRI demonstrates defects in the external and internal anal sphincters just as EAUS, MRI may better for imaging external anal sphincter atrophy and other defects in pelvic musculature (puborectalis and levator ani).[86] In all, MRI is an alternative to EAUS for image acquisition in patients with fistula in ano or fecal incontinence and it offers some advantages over the ultrasound technique.

Radionuclide Imaging

Radionuclide images are acquired based on physiologic rather than anatomic differences between tissues. These images have a wide spectrum of use in clinical medicine. Radiopharmaceuticals and gamma cameras are the mainstay of radionuclide imaging. Specific radionuclides are chosen based on their affinity for a particular organ system or ongoing physiologic process (i.e., glucose metabolism or GI bleeding). The image quality depends on the sensitivity of the radionuclide for the target organ or physiologic process. Gamma cameras then generate images based on the summed location and intensity of gamma photons emitted by the radionuclide substance.[87]

Positron Emission Topography

Positron emission topography (PET) is an imaging modality which relies on the physiologic differences in glucose metabolism that exists between tissue types.[88] Cells which have a higher baseline metabolic rate or increased mitotic activity will absorb glucose at a high rate. PET takes advantage of this difference as metabolically active cells will absorb a radioactive analog of glucose, 18-F-2-fluoro-2-deoxy-D-glucose (FDG) at a high concentration. However, structural changes in the FDG molecule prohibit further metabolic degradation and FDG accumulates in the intracellular space of metabolically active tissues.[89] Images are then generated based on differential FDG uptake.

PET image acquisition depends on differential glucose utilization by tissues. In order to maximize tissue differences, prior to the study patients should avoid carbohydrates, fast for 4–6 h immediately before and control serum glucose (<200 mg/dl).[90] Tissues that display increased FDG uptake include the urinary and gastrointestinal tracts, tissue with active inflammation secondary to leukocyte and macrophage activity and malignant tissue.[88] Because of increased FDG avidity of malignant cells, PET scans have become an invaluable tool for the staging of primary and recurrent cancers.

PET is currently approved for use in patients with colon and rectal cancer. While colon and rectal cancer is usually diagnosed with colonoscopy and an initial staging CT, PET obtained for other reasons may be diagnostic of high-grade colon or rectal lesions in 3.3% of patients.[91] However, PET is not recommended for primary staging of colon or rectal cancer where the likelihood of a change in surgical management is low.[92] If there is a question of resectability at initial diagnosis, especially in regard to liver metastases, PET is more accurate in detecting extrahepatic disease and characterizing liver metastases than CT (Figure 6-48A–C). Therefore, PET may be used to determine treatment course in patients with indeterminate initial staging. PET is also useful for the detection of recurrent disease and acts as a complement to CT, CEA, and colonoscopy surveillance.[93] PET is also more sensitive than these other surveillance tests for determining extent of recurrence so a change in CT imaging or CEA level which suggests recurrence can be confirmed by PET imaging (Figure 6-49A and B).[94] Clinical situations in which PET has been studied for use but is not currently approved include monitoring response to chemotherapy and monitoring response after ablation of liver metastases. PET has not been found to be useful in restaging rectal cancer after neoadjuvant chemoradiation since radiation therapy results in inflammation within the tumor bed that causes difficult to interpret changes in FDG avidity. PET has also been investigated for use in anal squamous cell cancer. PET may aid in the initial staging of anal cancer by detecting inguinal lymph node involvement. However, the specificity of inguinal lymph node involvement is low and inguinal nodes may display FDG avidity with benign inflammation.[95] Overall, PET is useful for staging and treatment planning in colon and rectal cancer recurrence or metastatic disease which has been treated medically and is being evaluated for surgical resection.

PET imaging has certain limitations. For example, traditional PET imaging has low spatial resolution. New techniques allow fusion of PET and CT images taken in one imaging session to allow localization of FDG avid structures in relation to specific organ structures. PET also has low specificity resulting in false-positive and -negative studies secondary to inflammation, normal gastrointestinal physiologic uptake, and cancers with low cellular or metabolic density (i.e., mucinous adenocarcinoma or carcinoid).[90] PET/CT allows correlation of FDG avid areas with specific organs found on CT. Therefore, PET/CT not only improves localization of FDG avid lesions but also enhances the certainty in interpreting lesions as normal or abnormal.[96] Overall, PET/CT is proving to be a more accurate test than either of its individual components or the sum of its components viewed side by side in regard to colon and rectal cancer staging.[97] Further studies are required to determine the clinical scenarios in which PET/CT is most appropriate.
FIGURE 6-48. **A** PET scan showing multiple discrete areas of hypermetabolism within the liver, representing metastatic colon adenocarcinoma. **B** A noncontrast CT of the same patient. The multiple metastatic foci are nearly impossible to detect without contrast. **C** Iodinated contrast helps to delineate between normal hepatic tissue and hypodense metastatic disease (From Blanchard TJ, Altmeyer WB, Matthews CC. Limitations of colorectal imaging studies. In: Whitlow CB, Beck DE, Margolin DA, Hicks TC, Timmcke AE, editors. Improved outcomes in colon and rectal surgery. London: Informa Healthcare; 2010. p. 97–131. With permission).

RBC Scintigraphy

Radionuclide imaging studies are widely used in the diagnosis of lower gastrointestinal bleeding. The principle is that the intravascular tracer will be extravasated into the bowel lumen during active bleeding. Concentration of the radioactive tracer on the acquired images allows for identification of the bleeding site. Technetium 99mTc is the radionuclide used in bleeding scans. This radiopharmaceutical can be used to label colloid or patient red blood cells (RBCs). Radiolabeled colloid is readily available and requires less preparation time. However, the colloid is rapidly metabolized resulting in a lower sensitivity for the detection of gastrointestinal bleeding.[98] RBCs take longer to label but they are metabolized slower and can remain active up to 24 h after injection. Therefore, the use of labeled RBCs is preferred as multiple scans can be obtained in patients with intermittent bleeding episodes. Tagged RBC scans are considered positive if the tracer pattern conforms to bowel anatomy, uptake increases in intensity over time and the tracer propagates in an antegrade or retrograde fashion (Figure 6-50).[99] These criteria help to distinguish true gastrointestinal bleeding from other lesions within the intestine with a high blood density (hepatic hemangioma, colonic angiodysplasia). Tagged RBC scans are sensitive for bleeding but may result in a false negative if the rate of bleeding is below 0.2 cm^3/min or the bleed is episodic. [100] Similar to PET, tagged RBC scans have a low spatial resolution and locate only the vascular territory of the bleed. In addition, the time for radionuclide appearance on bleeding scans may have prognostic significance. Patients who have an early
FIGURE 6-50. 99mTc-tagged red blood cell study shows early blood pool activity within the ascending colon in this patient with bleeding after a recent polypectomy.

FIGURE 6-51. 99mTc-pertechnetate scan (Meckel's) shows a discrete focus of increased uptake in the right lower quadrant, with approximately the same intensity as the stomach indicating gastric mucosa is present within this Meckel's diverticulum.

FIGURE 6-49. **A** CT in a patient who had prior rectal resection for carcinoma shows soft tissue mass in the surgical bed of the perirectal fat. **B** Follow-up PET examination shows intense FDG uptake within this soft tissue mass consistent with recurrence.

positive scan (<2 min) are more likely to have a blush on arteriogram that can be treated compared to patients with a late positive scan who are more likely to benefit from resuscitation and colonoscopy if necessary.[101] RBC scintigraphy is useful for the stratification of patients with active large volume gastrointestinal bleeding who will benefit from subsequent angiography and those who can be managed with less invasive techniques.

Meckel's Scintigraphy

A Meckel's scan, although not used as often as the tagged RBC scan, can be useful in the evaluation of young patients with occult gastrointestinal bleeding with no identifiable colonic source. Meckel's diverticulum causes abnormal bleeding as a result of aberrant gastric mucosa that lines the diverticulum. 99Tc pertechnetate is a radionuclide which is actively concentrated and then excreted by mucous-secreting cells in gastric mucosa.[102] Native as well as ectopic gastric mucosa will concentrate the radionuclide and be visualized within 30–60 min after injection (Figure 6-51). Delayed images will obscure ectopic foci of uptake, secondary to rapid transit of the radiotracer through the gastrointestinal tract. The sensitivity of the Meckel's scan is 85% and the specificity is 95%.[103]

Arteriography

Arteriography is an invasive procedure performed by specialty trained physicians and is used in the diagnosis and treatment of a variety of colorectal diseases. The arteriogram is performed through a percutaneous approach under sterile conditions. The femoral artery is a preferred puncture sight although axillary and brachial arteries may be used. A guidewire is introduced through the needle and a catheter is introduced over the guidewire. Various catheters and guide wires allow the interventional radiologist to access the vessels in question. Arteriography is an invasive procedure with an overall mortality of 1 in 40,000.[104] Complications from the performance of the procedure and manipulation of the wires and catheters are more common than reactions to the contrast itself.[105] The most common complications are related to hematomas or pseudoaneurysms at the puncture sight, dissection or embolization secondary to catheter manipulation. Contrast reactions and contrast toxicity (renal failure) occur in <1% of studies done. Experience and technique can minimize many of the complications. Hydration and IV mannitol can reduce the nephrotoxicity. If the patient has allergies to iodine or has had a prior contrast reaction, premedication with methyl prednisolone is done 12 and 2 hours before arteriography.

The arteriogram is a useful diagnostic and therapeutic modality in the treatment of active lower GI bleeding. If a radionuclide scan is performed and localizes the site of bleeding, a selective angiogram can then be performed. For bleeding localized to the left colon on tagged RBC study, the inferior mesenteric artery is selected first. The superior mesenteric artery is selected first for those bleeds that occur in the right colon. If the bleeding site is not identified after injection of both the superior and inferior mesenteric arteries, a celiac run is performed looking for an upper intestinal bleeding source. Active bleeding can be diagnosed by the accumulation of contrast in the arterial phase that persists through the venous phase (Figure 6-52). Bleeding needs to occur at a higher rate for a positive angiogram (0.5 ml/min) than for nuclear imaging (0.1–0.2 ml/min). Because lower GI bleeding can be intermittent, the bleeding site is sometimes not identified at the time of the angiogram.

Diverticulosis and vascular ectasias are presumed to be the leading cause of lower GI bleeding in most patients. Diverticular bleeds appear as a blush of contrast contained within a diverticulum. Vascular ectasias often occur in the right colon and appear as small vascular clusters, a blush in the wall of the colon, and early opacification of a draining vein.[106] Arteriovenous malformations are developmental in origin and are often seen in the small bowel. They appear as tortuous, dilated arteries and early prominent veins. Capillary telangiectasias (common in Osler Weber Rendu syndrome) appear as multiple, tiny areas of blush and no arteriovenous shunting. Postpolypectomy bleeding has been diagnosed and treated with angiography. A rapid blush of dye occurs at the site of bleeding and often stops with direct infusion of vasopressin or embolization (Figure 6-53A and B).

FIGURE 6-52. Mesenteric angiogram shows pooling of contrast in the sigmoid colon in this patient with surgically proven diverticular bleeding.

Acute mesenteric ischemia is one of the most common intestinal disease processes for which arteriography is used for diagnosis and treatment. Acute mesenteric ischemia can be either nonocclusive or occlusive. Nonocclusive mesenteric ischemia arises from a "low flow" state typically secondary to reduction in mesenteric blood flow from cardiac failure or hypotensive shock. This diagnosis can frequently be made with clinical symptoms and computer tomography images. The typical early angiographic images show diffuse vasoconstriction of mesenteric arterial branches and decreased parenchymal vascularity (Figure 6-54). In the late stage there is increased accumulation of contrast in the bowel wall. Treatment includes volume resuscitation and cardiac support. The diagnostic percutaneous catheter can be used to treat the mesenteric phase of constriction with IV glucagon or intra-arterial infusion of the papaverine in an intensive care unit setting.

Occlusive acute mesenteric ischemia is a medical emergency, thus early diagnosis and treatment may prevent bowel necrosis and perforation. These patients typically have severe abdominal pain with nonspecific physical findings.[107] An arteriogram is the most useful diagnostic examination for patients in whom one has a high clinical suspicion of acute occlusive mesenteric ischemia.[47] A catheter is inserted into the aorta and an aortogram is obtained. The celiac and superior mesenteric arteries are catheterized and injected with contrast in order to identify the level of occlusion and document collateral circulation. A superior mesenteric artery embolus typically lodges just proximal or distal to the take off of the middle colic artery and is seen as a meniscus at the site of occlusion and blockage of contrast (Figure 6-55). Atherosclerotic occlusion will often involve the origin of the
FIGURE 6-54. Mesenteric angiogram shows vasoconstriction and pruning of the superior mesenteric artery and its branches in this patient who presented with mesenteric ischemia secondary to severe hypotension.

FIGURE 6-53. **A** Mesenteric angiogram shows extravasation of contrast indicating an acute bleed. **B** Acute gastrointestinal bleed that was successfully treated after infusion of pitressin.

superior mesenteric artery seen as stenosis or plaque with a trickle of glow beyond. Collaterals will develop from the inferior mesenteric artery through the marginal artery. If the inferior mesenteric artery is occluded or absent, the collaterals will develop from the middle or inferior hemorrhoidal arterial branches of the internal iliac artery.[108,109]

Endoluminal Ultrasound

Donald G. Kim and W. Douglas Wong[†]

Evaluation of the anal canal and rectum has traditionally relied on digital examination, anoscopy, and rigid or flexible proctosigmoidoscopy. The introduction of imaging methods, particularly endoluminal ultrasonography, has brought a greater degree of objectivity to the evaluation of the anorectum.

Endoluminal ultrasound has become the diagnostic procedure of choice in the evaluation of many anorectal disorders. Endorectal ultrasound (ERUS) has evolved into the best imaging modality for accurate staging of rectal neoplasms. The accurate determination of tumor penetration depth and regional lymph node status has become critical to guiding subsequent treatment of rectal malignancies. In addition, endoanal ultrasound (EAUS) has become invaluable in the diagnostic workup of fecal incontinence and anorectal suppurative conditions. This chapter will focus on the use of endoluminal ultrasound in the evaluation of patients with benign and malignant conditions of the anorectum.

History

Endoluminal ultrasound of the rectum was first introduced by Wild and Reid in 1952.[1] They were the first to develop an "echoendo probe," but it was never used clinically. Because of limitations in technology, it was not until 1983 that this type of imaging was introduced into clinical practice by Dragsted and Gammelgaard.[2] They used a Bruel and Kjaer (Type 8901) ultrasound probe with a rigid rotating endosonic probe with 4.5-MHz transducer initially designed for prostatic ultrasound. Thirteen primary rectal cancers were evaluated and invasion was correctly predicted in 11 cases when compared with the final histopathology. Two patients could not be adequately imaged because of stricture. Although successful, they did not define their reporting criteria. In 1985, Hildebrandt and Feifel[3] found that ultrasonography correlated with pathologic finding in 23 of 25 rectal cancers.

They proposed a modification of the tumor-node-metastasis (TNM) classification[4] for ultrasound tumor staging (uTNM).[3] The prefix "u" indicated ultrasound staging as opposed to the prefix "p" representing pathologic staging. Similar to Dragsted and Gammelgaard, they also made no reference to the reporting criteria used for degree of invasion. Further refinements of the technique and improvement in the ultrasound equipment have made endoluminal ultrasound routine in the evaluation of patients with anorectal disorders.

Endorectal Ultrasound

As the treatment for rectal cancer has evolved, the importance of accurate preoperative staging of the lesion has become paramount in determining the patient's treatment regimen. Radical surgery, either low anterior or abdominoperineal resection is not always the initial or only therapy available for patients diagnosed with rectal carcinoma. With the development of preoperative neoadjuvant therapies for rectal cancer, accurate staging of these patients' lesions has become increasingly important. In addition, local excision has become an option in highly selected early-stage rectal cancers necessitating accurate preoperative staging.

The goal of preoperatively staging the rectal lesion is an accurate evaluation of the primary tumor, which includes the depth of tumor penetration and an evaluation of regional lymph node disease. ERUS accomplishes these goals using an intraluminal high-frequency sonographic transducer via a handheld rotating probe to accurately image the rectal wall and adjacent structures. For this reason, ERUS has become the preferred method used to stage the patient with rectal cancer.

Equipment and Technique

Equipment used for endoluminal ultrasonography includes a handheld endocavitary probe with rotating transducer which acquires a 360° image. Most investigators use a B-K Medical

---

[†]Deceased

scanner with a rigid handheld Type 1850 rotating probe and a 7- or 10-MHz transducer (B-K Medical, Wilmington, MA). Transducers of 7 and 10 MHz provide a focal length of 2–5 and 1–4 cm, respectively, rotating in a 90° scanning plane at four to six cycles per second to obtain a 360° radial scan of the rectal wall and surrounding structures. Because of its superior near-image clarity, the 10-MHz transducer is preferred. Rectal imaging requires a latex balloon covering the transducer for acoustic contact. The balloon is instilled with water allowing the ultrasound signals to easily pass through the water to image the rectum. The water instilled distends the rectum allowing the balloon to maintain contact with the rectal wall without separation, preventing any distortion of the image by the interposition of nonconductive air between the probe and the rectal wall.

Patients receive one or two phosphosoda enemas to cleanse the rectum before examination. The procedure is performed with the patient in the left lateral decubitus position without sedation. A digital rectal and proctoscopic examination is performed to assess the tumor size, appearance, location, and distance from the anal verge. Any residual stool or enema effluent that might interfere with the ultrasound is removed. A wide-bore ESI proctoscope (Electrosurgical Instrument Company, Rochester, NY) is inserted into the rectum to examine the rectum and lesion of interest. Optimally, the proctoscope is advanced proximal to the lesion to facilitate complete examination of the tumor by the transducer. The wide-bore ESI proctoscope permits passage of the ultrasound probe through the proctoscope to facilitate positioning of the probe above the lesion. This facilitates complete imaging of the lesion from its most proximal to distal extent as well as the proximal mesorectum, which may harbor involved lymph nodes. This approach is preferred to blind insertion of the ultrasound probe into the rectum. With blind insertion, distortion of the image can occur and the proximal areas of a lesion as well as the adjacent mesorectum will often be missed.

After correct positioning of the wide-bore ESI proctoscope, the ultrasound probe with latex balloon is lubricated and passed through the proctoscope to its full extent. The ultrasound probe is oriented with the stopcock and syringe positioned upright to the patient's right. The proctoscope is slightly withdrawn keeping the ultrasound probe in place to expose the transducer protruding beyond the end of the proctoscope, above the rectal lesion. The latex balloon is filled with 30–60 ml of water providing an optimal acoustic environment surrounding the rotating transducer. Initial preparation of the ultrasound probe includes careful removal of all air bubbles within the latex balloon to minimize acoustic interference. The probe and attached proctoscope are slowly withdrawn together carefully scanning the rectum from proximal to distal. The ultrasonographer observes for alterations of the rectal wall and perirectal tissues to assess depth of invasion and perirectal lymph node involvement. Optimal

evaluation often requires several passes back and forth across a lesion. The evaluation of the lesion occurs on the basis of real-time imaging intermittently capturing still images that are representative of the lesion being studied. With the patient and ultrasound probe positioned as above, the images obtained are oriented radially similar to a computed tomography scan, looking up from the patient's feet. The patient's right side is oriented to the left of the image, anterior is up, and posterior is down. The studies can also be videotaped for further review.

Image Interpretation

Most ERUS images display a series of five distinct layers can be identified in the rectal wall. They consist of three hyperechoic (white) layers separated by two hypoechoic (black) layers. Beynon and colleagues[5] proposed a five-layer model based on an anatomic study, demonstrating that the five basic layers seen on an ultrasonographic scan of the rectal wall correspond directly to the anatomic layers present in the rectal wall. It is this five-layer model that we continue to use today (Figure 7-1). The five layers from the center to the periphery consist of the following:

First hyperechoic layer: Interface between the balloon and the rectal mucosal surface
Second hypoechoic layer: Mucosa and muscularis mucosa
Third hyperechoic layer: Submucosa
Fourth hypoechoic layer: Muscularis propria
Fifth hyperechoic layer: Interface between the muscularis propria and perirectal fat

Occasionally, a seven-ring model may be visualized when the muscularis propria is observed as two black rings separated by a white ring (Figure 7-2). This model represents the inner circular and outer longitudinal muscle layers as hyperechoic (black) rings separated by a hypoechoic (white) interface.

FIGURE 7-1. Five-layer anatomic model of an ERUS scan. Three hyperechoic (*white*) layers and two hypoechoic (*black*) layers are visualized. *A* anterior, *L* left, *P* posterior, *R* right, *T* transducer.
FIGURE 7-2. The typical five layers of the rectal wall. Seven layers are depicted anteriorly, where an interface can be seen between the *inner circular* **A** and outer longitudinal **B** muscle layers of the muscularis propria.

TABLE 7-1. Ultrasound staging classification (uTNM) for rectal cancer

uT0	Noninvasive lesion confined to the mucosa
uT1	Tumor confined to the mucosa and submucosa
uT2	Tumor penetrates into but not through the muscularis propria
uT3	Tumor extends into the perirectal fat
uT4	Tumor involves an adjacent organ
uN0	No evidence of lymph node metastasis
uN1	Evidence of lymph node metastasis
FIGURE 7-3. A benign uT0 lesion in the left posterolateral aspect of the rectum. There is an expansion of the *inner black line* that represents the mucosa **A**, but the submucosa **B** is seen to be completely intact.

Assessment of Rectal Neoplasms

Depth of Invasion

As discussed above, ultrasound classification of rectal tumor stage was initially proposed by Hildebrandt and Feifel[3] as a modification of the TNM classification. Ultrasound staging classification (uTNM) is presented in Table 7-1. The depth of invasion is classified as follows: uT0 lesions are benign, noninvasive lesions confined to the mucosa; uT1 lesions indicate an invasive lesion confined to the mucosa and submucosa; uT2 lesions penetrate but are confined to the muscularis propria; uT3 lesions penetrate the entire bowel wall and invade the perirectal fat; and a uT4 lesions penetrate a contiguous organ (i.e., uterus, vagina, cervix, bladder, prostate, seminal vesicles) or the pelvic sidewall or sacrum.

uT0 Lesions

uT0 lesions are benign, noninvasive lesions confined to the rectal mucosa. Sonographically, the mucosal layer (inner black band) is expanded with an intact submucosa (middle white, hyperechoic line) (Figure 7-3). Benign rectal villous adenomas are classified as uT0 lesions and may be treated with local excision with excellent results. Important in this decision is to accurately exclude any focus of invasion. The accuracy of ERUS is probably highest for T0 lesions. In an initial study by Deen et al.[6] from the University of Minnesota, 47 of 53 lesions (89%) were correctly staged preoperatively. A more recent update reported 129 of 148 patients (87%) were correctly staged preoperatively from that same institution.[7] Pikarsky et al.[8] reported that 25 of 27 patients (96%) were accurately staged a benign lesion when compared with pathologic results. Rectal adenomas excised transanally are frequently misdiagnosed on initial biopsy with the subsequent finding of an invasive cancer in the final pathologic specimen. For this reason, Worrell et al.[9] conducted a systematic literature review to assess the utility of ERUS in the assessment of rectal villous adenomas. He compared the diagnosis by biopsy alone with diagnosis by a combination of biopsy and ERUS. This meta-analysis revealed that, of 258 biopsy-negative rectal adenomas, 24% had focal carcinoma on final histopathology and that ERUS correctly detected the cancer in 81%.

uT1 Lesions

uT1 lesions are early invasive cancers. uT1 lesions have invaded the mucosa and submucosa without penetrating into the muscularis propria. Sonographically this is characterized by an irregular middle white line (submucosa) without alteration of the outer black line (muscularis propria) (Figure 7-4). Irregularities are indicated by a thickening or stippling of the submucosal layer but there must not be a distinct break in the submucosal layer. A distinct break in the submucosal (middle white line) layer indicates invasion of the muscularis propria, hence a T2 lesion.

Local transanal excision is an acceptable treatment method for selected T1 lesions highlighting the need for accurate staging of these cancers. Criteria for the use of local therapies to treat early rectal cancers have been described[10] and include tumor size less than 4 cm, involvement less than one-third of the rectal circumference, location less than 8 cm from the anal verge, well- to moderately well-differentiated histology, absence of lymphatic or vascular invasion, and no involvement of perirectal lymph nodes.

uT2 Lesions

uT2 lesions penetrate into the muscularis propria (second hypoechoic, black line) but are confined to the rectal wall. Sonographically the hallmark finding is a distinct break in the submucosal layer. Characteristically, there is an expansion of the muscularis propria (outer black line) but the interface between the muscularis propria and the perirectal fat (the outermost white line) remains intact. The expansion of the muscularis propria may be variable depending on the degree of invasion. "Early" uT2 lesions may just invade the muscularis propria with minimal expansion of the layer. "Deep" uT2 lesions have significant expansion of the muscularis propria (outer black line) and may appear to scallop the outer aspect of the muscularis propria but preserve the interface with the perirectal fat. An example of a uT2 lesion is illustrated in Figure 7-5.

uT3 Lesions

uT3 lesions penetrate the full thickness of the muscularis propria and into the perirectal fat. Contiguous structures are not involved. The sonographic appearance reveals disruption of the submucosa, thickening of the muscularis propria, and disruption of the outer hyperechoic, white line indicating penetration into the perirectal fat (Figure 7-6). The recognition of perirectal fat invasion is an important determinant in the preoperative evaluation of the rectal cancer patient. Because of the high incidence of lymph node metastases (30–50%), local therapy cannot be recommended for these patients, who are usually candidates for preoperative radiation and chemotherapy followed by surgery. ERUS obviously has an important role in selecting those patients who will undergo preoperative radiation and chemotherapy.

FIGURE 7-4. A uT1 cancer in the left lateral wall of the rectum. The *middle white line* or submucosa is irregular and somewhat thickened **A** but not completely disrupted.

FIGURE 7-5. A uT2 lesion is identified in the right anterior location. The hallmark of a uT2 lesion, as seen on endorectal ultrasonography, is the distinct break **A** in the submucosa (the *middle white line*) as seen in this image.

uT4 Lesions

uT4 lesions are locally invasive into contiguous structures such as the uterus, vagina, cervix, bladder, prostate and seminal vesicles, or involve the pelvic sidewall or sacrum. They are clinically fixed and tethered. Sonographically, there is
FIGURE 7-6. A uT3N1 lesion. The tumor disrupts all layers of the rectal wall, with extensions evident into the perirectal fat **A**. A lymph node **B** is identified in the left posterior location within the mesorectum.

FIGURE 7-7. A T4 lesion in the distal rectum and upper anal canal extending to the vagina. The *curved white line* **A** seen anteriorly represents the examiner's finger in the vagina, and the hypoechoic anterior tumor **B** can be seen to extend into the vagina.

loss of the normal hyperechoic interface between the tumor and adjacent organ (Figure 7-7). Therapy of a T4 lesion usually requires preoperative radiation and chemotherapy followed by surgical resection of the rectal cancer and involved

adjacent organ. The overall prognosis is poor, with less than half of patients resected for cure. Preoperative radiation and chemoradiation therapy can shrink the tumor for increased resectability and decreased local recurrence. ERUS provides the means to preoperatively identify those lesions with T4 involvement to adequately plan the patient's treatment.

Nodal Involvement

Lymph node involvement in rectal cancer is associated with decreased survival rates and increased local recurrence rates. ERUS is able to detect metastatic lymph nodes in the mesorectum. Unfortunately, the accuracy of detecting involved lymph nodes is less than the accuracy in determining the depth of invasion. The accuracy of ERUS in detecting lymph node metastases ranges from 50 to 83%.[7,11,12] ERUS determination of metastatic lymph nodes is certainly more accurate than clinical (digital) evaluation[13–15] as well as other imaging modalities including computed tomography (CT)[11,16–18] and conventional magnetic resonance imaging (MRI).[18,19] However, phased array MRI and endorectal coil MRI are comparable to ERUS in lymph node assessment.[20–22]

As indicated in Table 7-1, lymph node staging parallels pathologic TNM staging classifying tumors with (uN1) or without (uN0) lymph node involvement. Undetectable or benign-appearing lymph nodes are classified as uN0. Malignant-appearing lymph nodes are classified as uN1. Normal, nonenlarged lymph nodes are usually not detectable by ERUS. Inflamed, enlarged lymph nodes appear hyperechoic with irregular borders. Lymph nodes suspicious for malignancy include larger, round, hypoechoic lymph nodes with an irregular contour. ERUS findings consistent with metastatic lymph nodes are demonstrated in Figure 7-8. Hypoechoic lymph nodes greater than 5 mm are highly suspicious for metastases. Involved lymph nodes are usually found adjacent to the primary tumor or within the proximal mesorectum.

The echogenic pattern and size of imaged lymph nodes have been suggested to be indicators of metastatic nodal disease. Tio and Tytgat[23] were the first to recognize the hypoechoic pattern of malignant lymph nodes using ERUS. Hildebrandt et al.[24] differentiated two main groups of lymph nodes: hypoechoic and hyperechoic lymph nodes. Compared with pathologic findings, hypoechoic lymph nodes represent metastases, whereas hyperechoic lymph nodes are visualized because of nonspecific inflammation. There is no definitive size threshold to determine if an identified lymph node is malignant. Lymph nodes smaller than 5 mm can harbor metastatic disease.[25–27] In a pathology-based study, Herrera-Ornelas et al.[25] found that two-thirds of metastatic lymph nodes from colorectal cancer were smaller than 5 mm in diameter. Katsura et al.[26] found that 18% of nodes measuring 4 mm or less on ERUS were involved with metastatic disease. Similarly, Akasu et al.[27] found that approximately 50% of cases of lymph nodes measuring 3–5 mm on ERUS harbored metastases. Sunouchi et al.[28] described a "small
FIGURE 7-8. A typical metastatic lymph node **A**, which is round and hypoechoic.

spot sign" for lesions at the margin of rectal carcinomas on ERUS measuring 1–3 mm in diameter. The small hypoechoic "spots" correlated with massive venous or lymphatic invasion histologically.

Nodes larger than 5 mm harbored metastatic disease 54% of the time. Sunouchi et al.[29] studying hypoechoic lesions larger than 5 mm on ERUS demonstrated that 68% were metastatic lymph nodes and 20% were tumor deposits. Statistically, the incidence of metastatic disease increases as lymph node size increases.

Overall, four nodal patterns are seen with differing probabilities of being involved with metastatic disease. Nonvisible lymph nodes on ultrasound have a low probability of harboring lymph node metastases. Hyperechoic lymph nodes with nonsharply delineated boundaries are more often benign resulting from inflammatory changes. Hypoechoic lymph nodes larger than 5 mm are highly suggestive of lymph node metastases. Mixed echogenic lymph nodes larger than 5 mm are difficult to classify but should be considered malignant.

Accurate lymph node staging of rectal cancers by ERUS relies on the experience of the examiner. False-positive results may occur because of inflammatory lymph nodes or confusing the cross-sectional appearance of perirectal blood vessels for metastatic lymph nodes. Scanning longitudinally will distinguish between blood vessels and lymph nodes because blood vessels will extend longitudinally, change direction, and/or branch. The sonographic continuity of the hypoechoic vessel over a distance greater than the cross-sectional area is the criterion used to distinguish the two. Three-dimensional imaging can help in making this distinction.

False-negative results are also problematic in interpreting nodal involvement on ERUS. Lymph nodes harboring micrometastases are difficult to detect. Grossly malignant lymph nodes may be present outside the range of the ultrasound probe and remain undetectable. This may be the case of lateral pelvic lymph nodes such as the obturator nodes as well as those within the mesorectum beyond the proximal extent of the rigid probe.

Accuracy of Ultrasound in the Diagnosis of Rectal Cancer

The success of any imaging modality is the result of its diagnostic accuracy. Preoperative therapy for rectal cancer depends on the accurate staging of the primary lesion. The determination of the lesion's depth of invasion (T stage) and lymph node involvement (N stage) are important factors dictating the therapeutic options. ERUS has the ability to determine the depth of tumor invasion and lymph node involvement of rectal cancers. ERUS has been found to be accurate in determining the tumor's depth of invasion within the bowel wall, although ERUS is only moderately accurate in the assessment of lymph node involvement.

The accuracy of ERUS for the staging of rectal cancer has been established from studies comparing preoperative ultrasound staging with the pathologic staging from the operative specimens. The accuracy of ERUS for tumor depth of invasion has been reported in the range of 63–93% (Table 7-2). Overstaging has been reported in approximately 11% of patients[16] and is believed to be the result of peritumoral inflammation beyond the leading edge of the tumor. Understaging for depth of wall invasion has been reported to be approximately 5%[16] and is considerably more serious than overstaging because inadequate management may result. With overstaging, potentially more aggressive management is recommended than might be required.

Detection of lymph node metastases with ERUS has been less accurate, ranging from 50 to 83% in reported series (Table 7-2). Solomon and McLeod[41] reviewed the literature and pooled raw data were collected from eight published cross-sectional surveys assessing the degree of tumor penetration in 873 patients and lymph node involvement in 571 patients with primary rectal cancer. As previously noted, ERUS was very accurate in determining tumor penetration ($\kappa=0.85$), but only a moderate correlation was found between ERUS and histopathology for detecting lymph node involvement ($\kappa=0.58$). Furthermore, the positive predictive value was 74% with a negative predictive value (NPV) of 84%, indicating only moderate accuracy among the included series.

Puli et al.[18] recently conducted a meta-analysis and systematic review to determine the accuracy of ERUS in determining lymph node invasion of rectal cancers. Only ERUS confirmed by surgical histology were selected. Data

TABLE 7-2. Accuracy of ERUS in the staging of rectal cancer

Kauer et al.[40]	2004	458	69	68

were extracted from 35 studies ($N = 2,732$) that met the study inclusion criteria. The meta-analysis demonstrated moderate sensitivity and specificity. Pooled sensitivity of ERUS in determining nodal involvement by rectal cancer was 73.2% with a pooled specificity of 75.8%. The positive likelihood ratio of ERUS was 2.84 (95% CI 2.16–3.72) and the negative likelihood ratio was 0.42 (95% CI 0.32–0.52). The positive likelihood ratio of a diagnostic test measures how well the test correctly identifies a disease state. The higher the positive likelihood ratio, the more likely the diagnostic test will correctly identify the true disease state. Contrarily, the negative likelihood ratio of a diagnostic test measures how well the test correctly excludes a disease state. The lower the negative likelihood ratio, the better the diagnostic test's ability to exclude a disease state. ERUS has a low negative likelihood ratio but the positive likelihood ratio is modest. Therefore, based on this meta-analysis, ERUS can better exclude nodal invasion by rectal cancer than confirm nodal invasion. In other words, one would be more confident in a negative (nodal invasion absent) diagnosis than a positive (nodal invasion present) diagnosis.

There is a significant learning curve associated with the performance and interpretation of ERUS. Accuracy rates have been demonstrated to improve significantly with experience.[35] ERUS is highly operator dependent and thus accuracy is dependent on the experience and expertise of the examiner.[7,33]

Several factors can lead to the misinterpretation of ERUS images.[42,43] These factors include a lesion in close proximity to the anal verge, improper balloon inflation with associated balloon-wall separation, a nonperpendicular imaging plane, shadowing artifacts caused by air or stool, reverberation artifacts, refraction artifacts, and a transducer gain setting

that is too high.[42] A technically difficult ERUS is likely to give an inconclusive or inaccurate result.[43] Factors causing technical difficulties include stenotic lesions, patient discomfort, poor bowel preparation, and scarring from previous surgery.[43]

Postbiopsy and postsurgical changes, hemorrhage, and bulky or pedunculated tumors can cause changes in the ultrasound image significantly affecting the accuracy of the ERUS interpretation.[44]

The accuracy of ERUS after neoadjuvant therapy is decreased for both depth of penetration and nodal status.[45–50] Radiation therapy can significantly downstage tumors and may in fact leave no residual tumor within the pathologic specimen. In fact, up to 24% of patients treated with preoperative radiation therapy have a complete pathologic response with no evidence of residual tumor.[51] Radiation therapy can cause tissue edema and fibrosis of the rectal lesion making ERUS interpretation difficult. One cannot accurately distinguish radiation-induced changes from residual tumor. In contrast with the disappointing accuracy of ERUS for both T and N staging, the NPV is relatively high (81–82%) in several series.[45,47,48,52] ERUS may allow good prediction of node-negative rectal cancers.[47,48] This may be helpful when local therapy may be considered for a patient after preoperative chemoradiation. Typically, ERUS is felt to be inaccurate and unreliable after radiation therapy, and is not recommended.

Postoperative Follow-Up

Local recurrence continues to be a difficult problem in the treatment of rectal cancer. Overall, local recurrence rates have been reported between 4 and 30% after curative rectal cancer surgery. More than 50% of patients will have local recurrence

only at the surgical site without distant metastases.[53,54] Even with newer adjuvant therapies available, surgical resection remains the best chance of cure for the patient with isolated local recurrence. Clearly, early detection of local recurrence is important and follow-up programs should be directed at this goal in order to be successful. ERUS may be used in a variety of settings for surveillance purposes after surgery for rectal cancer. When used in combination with a digital rectal examination and endoscopic surveillance, ERUS may significantly improve the sensitivity of detecting recurrent lesions.[55–57] ERUS may improve the ability to diagnose recurrent neoplasm by as much as 30%.[58] In a series studying ERUS as a means to identify local recurrence, overall local recurrence ranged from 11 to 20% with the proportion of local recurrences diagnosed exclusively by ERUS varying from 18 to 35%.[57–59] These ERUS-only recurrences represent only 3.2–5% of the entire group of patients. The University of Minnesota group presented similar results although the impact on overall survival is unclear.[56]

Although local recurrence can occur within the lumen at the anastomosis, locally recurrent tumors more often extend from extrarectal lesions that invade through the rectum, often at the level of an anastomosis. Extrarectal tumor not involving the mucosa may be undetectable endoscopically but can be identified at an early stage with ERUS. Recurrent tumor appears as a circumscribed hypoechoic lesion in the para-anastomotic tissues with all or a portion of the rectal wall intact on the inner, luminal aspect (Figure 7-9). Early postoperative changes, particularly adjacent to the anastomosis, can make the interpretation of the ERUS difficult. Interpretation is aided if a "baseline" ultrasound is obtained soon (3 months) after surgery and compared with subsequent surveillance images. A baseline examination is useful to document postoperative scarring and to evaluate that area for potential changes on serial examinations. Lesions that increase in size on subsequent examinations are more likely to represent recurrent tumor. Because ERUS cannot establish that a lesion is malignant with absolute certainty, a biopsy of suspicious lesions is recommended to confirm recurrent disease.[60] Biopsies may be performed by ultrasound-guided biopsy or computed tomography scan-guided biopsy.

The optimal interval and length of time for serial follow-up ERUS examinations have not been determined. Because most recurrences present within the first 2 years after surgery, more intensive follow-up is justified during this period. Imaging every 3–4 months for the first 2–3 years may be appropriate with less frequent, every 6-month evaluations until 5 years.

Comparison of Endorectal Ultrasound, Computed Tomography, and Magnetic Resonance Imaging

In a meta-analysis by Kwok et al.[16] ERUS, CT, and MRI were evaluated as preoperative staging modalities in rectal cancer. In his evaluation of ERUS, Kwok found an overall

FIGURE 7-9. A recurrent rectal cancer. It is located in the left lateral rectal wall. Note the intact *inner three lines* **A** on the ultrasound image, indicating no involvement of the mucosa or submucosa but an obvious abnormality at the level of the muscularis propria **B**, representing the recurrence.

accuracy rate of 87% (sensitivity, 93%; specificity, 78%) for depth of penetration. Nodal status demonstrated a pooled accuracy rate of 74% (sensitivity, 71%; specificity, 76%). Among those cases staged by TNM classification, 11% were overstaged and 5% were understaged.

In his evaluation of CT, the overall accuracy for depth of penetration was found to be 73% (sensitivity, 78%; specificity, 63%).[16] Nodal status was accurately assessed 66% of the time (sensitivity, 52%; specificity, 78%). Of those staged by TNM classification, 13% were overstaged and 7% were understaged.

With respect to MRI, the accuracy of all MRI modalities for depth of penetration was 82% (sensitivity, 86%; specificity, 77%).[16] Nodal involvement accuracy for MRI was 74% (sensitivity, 65%; specificity 80%). Of those cases staged by TNM classification, 13% were overstaged and 13% understaged. Subgroup analysis found that MRI with an endorectal coil was equivalent to ERUS for depth of penetration with an overall accuracy rate of 84% (sensitivity, 89%; specificity, 79%). Overall accuracy for nodal status was 82% (sensitivity, 82%; specificity; 83%).

In another meta-analysis, Bipat et al.[20] also compared ERUS, CT, and MRI in rectal cancer staging. In this review, duplicate studies were excluded. Studies with the most details or the most patients were included. For muscularis propria invasion, ERUS and MRI had similar sensitivities; specificity of ERUS (86%) was significantly higher than

that of MRI (69%) ($P = 0.02$). For perirectal tissue invasion, sensitivity of ERUS (90%) was significantly higher than that of CT (79%) ($P < 0.001$) and MRI (82%) ($P = 0.003$); specificities were comparable. For adjacent organ invasion and lymph node involvement, sensitivities and specificities for ERUS, CT, and MRI were comparable.

In the most recent comparative study, Dinter et al.[22] evaluated ERUS, hydro-CT, and high-resolution endorectal MRI in the preoperative staging of rectal cancer. A total of 23 patients with histologically proven rectal cancer underwent all examinations followed by surgery. All modalities demonstrated correct depth of penetration in 19 of 23 patients (83%). Lymph node staging was correctly determined by ERUS in 19 of 23 patients (83%). Hydro-CT correctly staged lymph nodes in 20 of 23 patients (87%) with endorectal MRI correctly staging 19 of 23 (83%). Only two previous studies have compared ERUS, endorectal MRI, and CT.[21,61] These older studies may have been limited by the available equipment. In the study by Kim et al.[21] CT was performed with a helical single detector scanner with 10-mm slice thickness as compared to a multidetector spiral CT. In Meyenberger's[61] study, only a limited number of patients were evaluated with all methods: 32 patients underwent ERUS, 16 patients underwent CT, 9 MRI, and only 5 endorectal MRI. Overall accuracy of the Dinter et al.[22] study was comparable to that of Kim et al.[21] In lymph node staging, the results were better in all modalities when compared to those of Kim et al.[21] with ERUS accuracy of 83% vs. 63.5%, CT 87% vs. 56.5%, and MRI 83% vs. 78.5%.[22] Although only a limited number of patients were examined, the Dinter et al.[22] study indicates that improved results may be attainable as a result of better technical equipment.

Endoanal Ultrasound

EAUS is useful in the evaluation of the anal canal in both benign and malignant disease. The anal sphincter anatomy can be clearly identified detecting abnormalities in the external and/or internal sphincter. EAUS is routinely used in the evaluation of fecal incontinence and may be particularly useful in the evaluation of complex perianal abscesses and fistulas. EAUS is also useful in the evaluation of anal canal neoplasms accurately staging these lesions.

Equipment and Technique

The equipment used for EAUS is similar to that used for ERUS. The same B-K scanner is used with the 1850 rotating probe and 10-MHz transducer (B-K Medical). In place of the latex balloon, a translucent plastic cap (B-K type WA0453) is placed over the transducer to maintain contact with the anal canal. The plastic cap is again filled with water to provide the acoustic medium. There is a pinhole in the apex

of the plastic cap that permits the escape of any air through displacement of the space with water.

The examination technique for EAUS is similar to that of ERUS. Patients are examined in the left lateral decubitus position, again usually without sedation. A careful external examination of the perianal area followed by a digital rectal examination is performed. The probe is lubricated with a water-soluble gel and gently inserted into the anal canal until the plastic cap is no longer visible. This will usually ensure that the transducer is at the level of the upper anal canal. The probe is slowly withdrawn to image the full length of the anal canal. Images are typically obtained in the upper, mid, and distal anal canal. In most instances, patients can be reassured that the examination should cause no more discomfort than a digital rectal examination. Certain instances of complex anorectal sepsis may be painful and require examination under anesthesia to adequately image the patient with EAUS.

Image Interpretation

Normal anal canal anatomy is well visualized with EAUS. As with the rectum, the interpretation of these images must be based on a precise definition of normal endosonographic anatomy of the anal canal that correlates well with anatomy. EAUS of the anal canal and pelvic floor have been correlated with cadaveric anatomic dissections.[62] The ultrasonographic anatomy of the anal canal is generally divided into three levels: the upper, mid, and distal anal canal. Each level has a different appearance on EAUS. The upper anal canal is illustrated in Figure 7-10. The puborectalis is an important

FIGURE 7-10. The ultrasound appearance of the upper anal canal at the level of the puborectalis, which can be seen as the hyperechoic U-shaped structure seen posteriorly and laterally (*arrows*) in this image.
FIGURE 7-11. The characteristic appearance of the mid-anal canal. The circular hypoechoic structure represents the internal anal sphincter **A**, surrounded by the thicker hyperechoic circumferential external anal sphincter **B**.

FIGURE 7-12. The technique used to measure the anterior perineal body in a female patient. The examiner's finger is placed in the vagina, and the hyperechoic curvilinear structure **A** seen anteriorly delineates the examiner's finger. The two cross-hatches between the examiner's finger and the transducer measure the thickness of the perineal body in this intact sphincter at the mid-anal canal level.

landmark delineating the upper anal canal. The puborectalis is imaged as a horseshoe-shaped mixed echogenic structure forming the lateral and posterior portion of the upper anal canal.

The mid-anal canal is illustrated in Figure 7-11. Within the mid-anal canal, the internal anal sphincter is represented by a hypoechoic band surrounded by the hyperechoic external anal sphincter. Between the transducer and the internal anal sphincter is an additional hyperechoic ring of variable thickness representing the epithelial, hemorrhoidal, and submucosal tissue. Perineal body measurements can be made at the level of the mid-anal canal (Figure 7-12). With the probe positioned within the mid-anal canal, the right index finger is placed within the vagina against the rectovaginal septum and ultrasound probe. The distance between the hyperechoic ultrasound reflection of the finger and the inner aspect of the internal anal sphincter may be measured and represents the perineal body thickness. Normal measurements for perineal body thickness range from 10 to 15 mm, with a lower limit of normal considered to be approximately 8 mm. This measurement is useful in the evaluation of women with fecal incontinence from anterior sphincter defects. The examining index finger not only better defines the perineal body but may accentuate an anterior sphincter defect that may otherwise appear intact.

The distal anal canal is illustrated in Figure 7-13. The distal anal canal is defined as the point where the internal anal sphincter is no longer seen. Only the hyperechoic external anal sphincter and surrounding soft tissues are visualized.

FIGURE 7-13. The distal anal canal below the inferior level of the internal sphincter, where only the hyperechoic circumferential fibers of the superficial external anal sphincter **A** are imaged.

Evaluation of Fecal Incontinence

EAUS has an important role in the evaluation of fecal incontinence, accurately delineating anal sphincter anatomy.[63–65] Causes of anal sphincter defects include obstetric injuries, anorectal surgeries, traumatic injuries, and congenital abnormalities.

Fecal incontinence is eight times more frequent in women,[66] the most common cause being obstetric trauma leading to injury of the anal sphincter muscles or traction neuropathy involving the pudendal nerve.[66–68] Although anal sphincter injury identified during delivery does not lead to significant deterioration in sphincter function immediately, it is suspected to lead to fecal incontinence in approximately 40% of women in long-term follow-up despite primary sphincter repair.[69–71] Anal incontinence is not restricted to patients with recognized third- or fourth-degree obstetric tears. Patients may also develop delayed symptoms of incontinence several years after an unrecognized sphincter injury.[72] The introduction of EAUS has led to the recognition of unsuspected sphincter defects in asymptomatic, continent women thought to have normal perineums.[73–76] Traumatic sphincter disruption can frequently be associated with a subsequent rectovaginal fistula. These patients may be anally continent but have symptoms of fecal incontinence associated with the fistula. Because these patients may have an unrecognized anal sphincter defect, all patients with rectovaginal fistula should undergo preoperative evaluation for occult sphincter defects by EAUS.[77] Local tissues are inadequate for endorectal advancement flap repairs in patients with anal sphincter defects and these patients should be treated by sphincteroplasty with levatoroplasty.[77] EAUS has become an accurate method to image the anal sphincters identifying anal sphincter defects that result in fecal incontinence.[68,78–80]

EAUS has become the best modality to accurately demonstrate the anatomy of the anal canal as well as anal sphincter defects that contribute to fecal incontinence.[65] Defects in the external anal sphincter usually appear hypoechoic, although some may appear hyperechoic or demonstrate mixed echogenicity. Defects of the internal anal sphincter are represented by the lack of segment of the hypoechoic band of internal sphincter muscle. There is usually associated contralateral thickening of the hypoechoic internal anal sphincter. With complete sphincter disruption, EAUS demonstrates the ends of the internal and external anal sphincter widely separated and bridged with intervening scar tissue of variable echogenicity (Figure 7-14). Many times, complete sphincter disruption is not seen, but attenuation of the sphincter mechanism is noted anteriorly, indicating a significant partial sphincter defect. An examining digit[81,82] or vaginal balloon[81] used to measure the perineal body distance in the mid-anal canal can accentuate an anterior sphincter defect, helping to identify a sphincter injury (Figure 7-15).

Other causes of anatomic anal sphincter defects include anorectal trauma or surgery and congenital anomalies.

FIGURE 7-14. A complete anterior sphincter disruption in a female patient. The hypoechoic internal anal sphincter can be seen completely disrupted in its anterior location (**A** *arrows*). Similarly, the hyperechoic external anal sphincter is completely disrupted anteriorly (**B** *arrows*).

FIGURE 7-15. The measurement of the anterior perineal body in this patient with an anterior sphincter disruption. The curvilinear hyperechoic structure **A** is the examiner's finger in the vagina. This technique can often accentuate the defect **B** seen in the internal anal sphincter and the external anal sphincter, and documents the decreased thickness of the anterior sphincter and perineal body.

Blunt or penetrating trauma to the perineum may involve the sphincter mechanism. Management often includes fecal diversion, and debridement of the associated perineal soft tissues. After the perineal wound has healed, EAUS may be used to assess anal sphincter anatomy to determine if sphincter reconstruction is necessary before colostomy closure.

Patients undergoing anorectal surgery may experience transient minor incontinence in the early postoperative period, which usually resolves spontaneously. Patients who have persistent symptoms of incontinence may warrant evaluation. EAUS provides an objective means to evaluate the anal sphincter mechanism in patients with postoperative fecal incontinence after anorectal surgery such as hemorrhoidectomy, fistulotomy, lateral internal sphincterotomy, or sphincteroplasty.

The surgical correction of congenital anorectal anomalies is based on reconstituting the anatomy of the anorectum. The goal of posterior sagittal anorectoplasty (PSARP) is to place the bowel within the striated muscle complex of the levator ani and external anal sphincter.[83] EAUS has been used to accurately confirm the position of the neo-anus within the anal sphincter complex comparing favorably with MRI.[84] EAUS in fact provided greater detail of the anal muscles than MRI and had better correlation with direct perineal muscle stimulation.[84] Adult patients who present with severe fecal incontinence after previous surgical repair of a congenital anorectal malformation can undergo successful PSARP.[85] Usually, the existing anus is anterior to the sphincteric muscle complex.[85] An EAUS can be performed to help define the relationship of the anus to the sphincteric mechanism. In a recent study, Emblem et al.[86] correlated the endosonographic appearance of the anal sphincter with functional results after operative treatment of anorectal malformations demonstrating EAUS may be used to study the results after different surgical techniques for anorectal malformations.

The identification of localized sphincter defects is important in the evaluation of the incontinent patient, because these defects may be amenable to surgical repair. EAUS can clearly and objectively image the anal sphincter mechanism and has replaced needle electromyography as the procedure of choice for anal sphincter mapping.[65] EAUS is better tolerated and less painful than needle electromyography sphincter mapping. Anorectal manometry and pudendal nerve terminal motor latency testing are complementary but do not definitively correlate with a surgically correctable defect.[68,75,76,87,88] EAUS remains the definitive test that can identify a surgically correctable defect in a symptomatic patient with fecal incontinence.

Evaluation of Perianal Sepsis and Fistula-In-Ano

Typically, the diagnosis of a perianal or perirectal abscess is quite apparent on physical examination and only requires proper identification and prompt drainage. Occasionally,

an abscess is strongly suspected on clinical grounds but is not readily identified on physical examination. In these situations, an EAUS may be useful in the evaluation of perianal or perirectal abscesses. EAUS can be helpful to localize an obscure abscess to plan the appropriate surgical intervention.

Often, clinical examination of perianal or perirectal abscesses is quite painful and examination under anesthesia is required. Because the ultrasound equipment is portable, the EAUS examination can be performed in the operating room while the patient is anesthetized. Abscesses appear as hypoechoic areas often surrounded by a hyperechoic border. In patients with perianal Crohn's disease, EAUS may be useful in distinguishing discrete abscesses that require surgical drainage from inflammation that requires medical treatment. The use of EAUS has also been evaluated in patients with ileoanal pouch anastomosis and can be helpful in demonstrating pouch pathology including inflammation, abscesses, and fistulas.[89]

The natural history of a drained perianal/rectal abscess is either complete resolution or fistula formation. The majority of fistulas that occur are simple intersphincteric fistulas that are easily identified and treated by simple unroofing. However, occasionally fistula tracts develop that are extensive and highly complex. These complex fistulas present a diagnostic challenge to even the most experienced colon and rectal surgeon. Use of EAUS can be helpful in identification of fistulous communications in patients with complex and recurrent fistula-in-ano.[90–92] Fistula tracts are generally hypoechoic defects that can be followed to identify direction and extent. The anatomic details of the fistula tract can be delineated in relation to the anal sphincter. The EAUS examination should include the anal canal and distal rectum to search for the presence of high blind tracts. Hydrogen peroxide has been used to enhance the imaging of complex fistula.[93–96] Hydrogen peroxide causes a release of oxygen, accentuating the fistula and appears as a brightly hyperechoic image on the ultrasound image. With the instillation of hydrogen peroxide the internal opening is identified in 62.5–94% of patients.[93,96–99] Lack of the use of hydrogen peroxide result in suboptimal results as is reflected in a recent meta-analysis.[100] An example of a fistula-in-ano with hydrogen peroxide enhancement is demonstrated in Figure 7-16. When evaluating an anal fistula with ERUS, it is important to use both the balloon-covered transducer to evaluate the perirectal region to assess for any supralevator extension as well as the plastic cap for evaluation of the anus and surrounding anatomy.

Anal Canal Neoplasms

Endoanal ultrasonography images the normal anal canal and associated pathologies quite well. EAUS can have an important role in the evaluation of benign and malignant anal canal neoplasms. The normal anatomic structures are clearly defined and any changes in the normal anatomy and their
FIGURE 7-16. A fistula-in-ano that has been enhanced by the introduction of hydrogen peroxide. The hyperechoic features posteriorly represent the hydrogen peroxide within the fistula tract (*short arrows*). There is an obvious hypoechoic defect in the internal anal sphincter in the midline posteriorly **A**, representing the internal fistula opening. The hypoechoic horseshoe tract can be seen extending toward the patient's left.

relationships with specific anatomic structures are clearly defined. Benign neoplasms such as lipomas and leiomyomas can be demonstrated along with their relationship to adjacent anal canal structures. Lesions within the anal canal appear as hypoechoic areas. Tissue diagnosis may be obtained with ultrasound-directed needle biopsies when desired.

Anal canal malignancies are an uncommon cancer in the gastrointestinal tract. Diagnosis requires appropriate clinical evaluation and histologic confirmation by tissue biopsy. Anal canal malignancies evaluated by EAUS include leiomyosarcomas, malignant melanomas, anal canal adenocarcinomas, and squamous cell carcinomas. Squamous cell or epidermoid carcinomas of the anal canal are the most common anal canal malignancy. EAUS can be used in the initial evaluation to stage the lesion as well as in follow-up for patients with squamous cell carcinoma of the anal canal.[101–104] Because squamous cell carcinomas of the anus are primarily treated nonoperatively with combined chemoradiation therapy; it is desirable to have an accurate method of staging to assess response to multimodality therapy. EAUS accurately stages the initial tumor and can be used in follow-up to detect residual tumors as well as early recurrences after treatment. Surgical treatment in the form of abdominoperineal resection is reserved as salvage surgery for those patients who fail standard chemoradiation therapy.

Although clinical (digital) examination is important in the assessment of squamous cell carcinoma of the anus, EAUS is more precise in accurately measuring the actual size and

TABLE 7-3. Ultrasound staging classification (uTNM) for anal canal cancer

Primary tumor (T)	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor 2 cm or less in greatest dimension
T2	Tumor more than 2 cm but no more than 5 cm in greatest dimension
T3	Tumor more than 5 cm in greatest dimension
T4	Tumor of any size that invades an adjacent organ(s), e.g., vagina, urethra, bladder (involvement of the sphincter muscle(s) alone is not classified as T4)
Regional lymph nodes (N)	
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in perirectal lymph node(s)
N2	Metastasis in unilateral internal iliac and/or inguinal lymph node(s)
N3	Metastasis in perirectal and inguinal lymph nodes and/or bilateral internal iliac and/or inguinal lymph nodes
Distant metastasis	
Mx	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

TABLE 7-4. Ultrasound staging classification by depth of invasion (uTNM) for anal canal cancer

uT1	Tumor confined to the submucosa
uT2a	Tumor invades only the internal anal sphincter
uT2b	Tumor penetrates into the external anal sphincter
uT3	Tumor invades through the sphincter complex and into the perianal tissues
uT4	Tumor invades adjacent structures

circumferential involvement of the lesion. EAUS staging (uTNM) of anal cancers corresponds to the TNM [UICC (International Union Against Cancer)] staging (Table 7-3).[105] Tumor staging for anal cancer depends primarily on the maximal tumor diameter, which is accurately measured by EAUS. Additionally, the depth of invasion of the lesion can be measured in relationship to the sphincter mechanism. The extent of sphincter involvement can be determined and other staging systems stage these lesions based on depth of invasion.[104,106] One such staging system is depicted in Table 7-4.[106] The evaluation of squamous cell carcinomas of the anus should include an evaluation of the rectum with ERUS to determine the presence of metastatic lymph nodes within the mesorectum. The mesorectum as well as the anal canal can also be evaluated in follow-up after treatment. Any suspicious areas detected during follow-up may be biopsied if necessary.

Three-Dimensional Ultrasound

Three-dimensional ultrasound allows for multiplanar imaging of both the rectum and the anal canal. This new technology is currently being evaluated to compare its efficacy
FIGURE 7-17. This three-dimensional ultrasound image of an anteriorly based rectal cancer that extends full thickness through the rectal wall (uT3). However, a clear hyperechoic plane can be seen between the prostate gland and the rectal tumor, as depicted by the *arrows*.

relative to conventional two-dimensional ultrasound as well as to other modalities such as MRI. Three-dimensional ultrasound can be used to assess anal fistulous tracts, to evaluate anal sphincter injury, as well as to stage both rectal and anal tumors. An example of a three-dimensional ERUS image (3D-ERUS) of a rectal cancer is shown in Figure 7-17.

Hunerbein et al.[107] compared standard two-dimensional ultrasound with 3D-ERUS and endorectal MRI and reported accuracy rates for depth of penetration by rectal cancer of 84, 88, and 91%, respectively. Because of the small sample size, these differences were not statistically significant. However, they believed that the additional scan planes improved the understanding of three-dimensional imaging and facilitated interpretation of the findings. In a recent study, Kim et al.[108] reported that 3D ERUS showed greater accuracy than 2D ERUS or CT in rectal cancer staging and lymph node metastases. The accuracy for T-staging was 78% for 3D ERUS vs. 69% for 2D ERUS and 57% for CT ($P < 0.001$–0.002). Accuracy for lymph node metastases was 65, 56, and 53%, respectively ($P < 0.0001$–0.006).

Three-dimensional EAUS has also been applied to benign anal disorders such as anal sphincter injury and anal fistula assessment. Several comparative studies have been reported evaluating its efficacy and comparing 3D-EAUS with MRI. West et al.[109] reported that 3D-EAUS and endoanal MRI were comparable for detecting external sphincter defects.

Gold et al.[110] determined that 3D-EAUS revealed a direct relationship between the length of a sphincter tear and its radial extent. In addition, they demonstrated marked gender differences in anal sphincter configuration using three-dimensional ultrasound imaging. In the evaluation of anal fistula tracts, West et al.[111] reported equivalency between 3D-EAUS and endoanal MRI for the evaluation of anal fistula tracts. In a study by Buchanan et al.[112] 3D-EAUS was found to be very accurate in the assessment of both the internal opening and the primary tract of an anal fistula. They reported an accuracy of 90% in identifying the internal opening and an accuracy of 81% in delineating the primary tract. Three-dimensional EAUS was less accurate (68%) in identifying secondary tracts or extensions. In their study, the use of hydrogen peroxide did not increase the accuracy but in some instances it did make the tract and internal opening more conspicuous.

Summary

Endoluminal ultrasound has been shown to be extremely useful in the evaluation and management of many benign and malignant anorectal conditions. ERUS has become the best imaging technique to accurately stage rectal cancers and anal canal tumors preoperatively. Moreover, ERUS can have a role in the follow-up evaluation of these patients. EAUS is the diagnostic test of choice in the evaluation of fecal incontinence and is used routinely. The EAUS has also been used to help define complex anal fistulas to facilitate their management. The accuracy of diagnosis is operator dependent and improves with experience. Endoluminal ultrasound has made a major contribution to the understanding and management of many anorectal conditions. Three-dimensional ultrasound may prove to be advantageous but requires further study.

Preoperative Management

Janice F. Rafferty

Risk Assessment and Management

Preoperative management of a patient who requires surgery of the colon, rectum, or anus mandates thoughtful consideration of associated conditions that may result in perioperative morbidity and mortality. Understanding risks associated with certain comorbid conditions and disease processes allows the surgeon to stratify patients into risk categories, manage them appropriately, and improve short- and long-term outcomes.

Ambulatory Surgery

"Ambulatory surgery" is defined as surgical procedures requiring at least local anesthesia, which are more complex than office-based procedures but less complex than operations requiring at least an overnight stay.[1] Approximately 90% of anorectal surgery to treat fissures, condyloma, fistulas, certain early tumors, hemorrhoids, and pilonidal disease may be suitable for the ambulatory setting.[2,3] The Standards Committee of the American Society of Colon and Rectal Surgeons (ASCRS) has developed a Clinical Practice Guideline about Ambulatory Anorectal Surgery, for practitioners and health care workers, to provide current information from the literature upon which decisions can be made.[4] Data from many nonrandomized trials suggest that most patients with American Society of Anesthesiology (ASA) Classifications I and II, and some Class III are suitable for ambulatory surgery from an anesthesia risk standpoint. However, multiple factors must be considered to determine whether this is appropriate,[5] including the estimation of the magnitude of the operation, type of anesthesia, patient compliance, distance of the patient's home from the surgical center, and availability of support once home.[4]

- In general, the need for bloodwork, electrocardiogram (EKG), and other investigations of the ambulatory surgery patient can be predicted by information obtained with a thorough history and physical exam.[6] In fact routine preoperative testing is rarely helpful except in monitoring of established patient diseases. One study described 5,003 preoperative screening tests that revealed only 225 abnormal results. Slightly more than 100 tests were of potential importance and the plan for surgery was changed in only 17 cases. The authors concluded that only four patients derived true benefit from preoperative screening tests.[7] From studies such as this and others,[8,9] we can conclude that screening tests should be replaced by directed testing, and a thoughtful and thorough history and exam are the most important tools available to the surgeon in determining a patient's risk for outpatient surgery.

Inpatient Surgery

Objective assessment of patient risk for inpatient colorectal surgery is necessary for informed consent and favorable surgical outcome. Scoring systems have been developed to help differentiate those who are at high risk for perioperative complication from those who are not. Scoring systems can be classified as preoperative or physiologic (Table 8-1).[10] Some are specific to colon and rectal surgery.[11–13]

Cardiac Risk

The Goldman risk model determines cardiac risk for surgery.[14] Point scores are assigned to each of nine clinical factors; patients are divided into four risk classes based on the total point score (Table 8-2). Although the system is easy to use and utilizes relative weighting of risk factors, it was designed in the 1970s and has not been updated for modern practice in anesthesia, medicine, or surgery.

Respiratory Risk

The risk for perioperative respiratory complications can be gauged by combining findings on chest examination, chest X-ray, Goldman's cardiac risk index, and the Charlson comorbidity index.[15] Risk reduction strategies initiated preoperatively,

TABLE 8-1. Operative scoring system

Preoperative	Physiologic
ASA grade	APACHE (I and II)
Goldman cardiac risk index	SAPS
Pulmonary complication risk	Sickness score
Prognostic nutritional index	POSSUM
Hospital prognostic index	P-POSSUM
	Sepsis score
	Therapeutic intervention score

APACHE acute physiology and chronic health evaluation, *POSSUM* physiological and operative severity score for enumeration of mortality and morbidity, *SAPS* simplified acute physiology score, and *ASA* American Society of Anesthesia.

Adapted from Kiran RP, Delaney CP, Senagore AJ. Perioperative management. In: Beck DE, editor. Clinics in colon and rectal surgery. 2003;16(2): 75–84.

TABLE 8-2. Goldman cardiac risk index

Cardiac risk event	Points
Myocardial infarction within 6 months	10
Age >70 years	5
S3 gallop or jugular venous distension	11
Important aortic valve stenosis	3
Rhythm other than sinus, or sinus rhythm and atrial premature contractions on last preoperative electrocardiogram	7
More than five premature ventricular contractions per minute anytime before surgery	7
Poor general medical status	3
Intraperitoneal, intrathoracic, or aortic operation	3
Emergency operation	4

Class	Points	Life-threatening complication risk (%)	Cardiac death risk (%)
I	0–5	0.7	0.2
II	6–12	5	2
III	3–25	11	2
IV	≥26	22	56

such as smoking cessation, lung expansion teaching, chronic obstructive pulmonary disease (COPD) treatments, and asthmatic treatments may positively influence outcome after surgery.[16]

American Society of Anesthesiologists Classification

The American Society of Anesthesiologists (ASA) classification system (Table 8-3) was initially developed to alert anesthesiologists to preexisting diseases. It has also been used to estimate operative risk,[17] and correlates directly with perioperative mortality and morbidity. This classification scheme also correlates with perioperative variables such as intraoperative blood loss, duration of postoperative ventilation, and duration of intensive care unit (ICU) stay.[18] The disadvantages to using the ASA score are that it depends on the subjective opinion of the attending anesthesiologist, and because of small numbers of groups available there can be

TABLE 8-3. American Society of Anesthesia classification

I	Normal healthy patient
II	Mild systemic disease
III	Severe, noncapacitating systemic disease
IV	Incapacitating systemic disease, threatening life
V	Moribund, not expected to survive 24 h
E	Emergency

little meaningful comparison between different surgeons or institutions.

Nutritional Assessment

Abdominal surgery induces a catabolic response with stress hormone release and insulin resistance; therefore, nutritional parameters should be evaluated in certain chronically ill patients before surgery. Protein catabolism may be accentuated by prolonged fasting and bowel preparation. Increased nutritional risk can influence postoperative morbidity and mortality[19,20] and anastomotic leak rates.[21] The prognostic nutritional index (PNI) was devised in the 1970s to predict complications such as sepsis and death after surgery.[22] The PNI evaluates four factors to predict complications (serum albumin, transferrin, triceps skinfold thickness, and cutaneous delayed-type hypersensitivity), but only albumin, transferrin, and delayed hypersensitivity are accurate predictors of postoperative morbidity and mortality. This index can theoretically be used to identify patients who may benefit from nutritional support in the perioperative period.

Acute Physiology and Chronic Health Evaluation Scoring Systems

The Acute Physiology and Chronic Health Evaluation (APACHE) scoring system was initially designed to assess risk for ICU patients, but has been extended to assess patients with severe trauma, abdominal sepsis, postoperative enterocutaneous fistulas, and acute pancreatitis and to predict postoperative outcome.[23] Scoring for emergency patients being admitted to the ICU is best performed before surgical intervention.[24] This index does not take into consideration the nutritional status of the patient, extent of surgery, or cardiovascular findings that add to operative risk. Several simpler scoring systems have been developed from the APACHE system, including simplified acute physiology score (SAPS), which uses 14 of the 34 variables, and SAPS II, which also takes into consideration the urgency of the procedure and any associated chronic medical illness.[25]

Physiological and Operative Severity Score for Enumeration of Mortality and Mortality

The Physiological and Operative Severity Score for enUmeration of Mortality and morbidity (POSSUM) calculates expected death and expected morbidity rates based on

TABLE 8-4. Parameters for the calculation of the physiological and operative severity score for enumeration of morbidity and mortality (POSSUM) score

Physiologic parameters	Operative parameters
Age (years)	Operative severity
Cardiac signs/chest X-ray	Multiple procedures
Respiratory signs/chest X-ray	Total blood loss (mL)

Na$^+$ and K$^+$ levels (mmol/L)	
Electrocardiogram	

12 physiologic variables and 6 operative variables (Table 8-4). The advantage of POSSUM is that it predicts both morbidity and mortality and can be used to compare performance among surgical units, hospitals, and countries.[26] It does not, however, take into account primary diagnosis, differences among surgeons, anesthetists, and operating time, all of which may influence outcome. Nevertheless, it has been shown that POSSUM is superior to APACHE in predicting mortality in patients after general surgery.[27] P-POSSUM may be a better predictor of mortality and morbidity for gastrointestinal and laparoscopic colorectal surgery.[28,29] Another modification of this index, the CR-POSSUM score, is advocated to assess the risk for patients undergoing major colorectal cancer surgery.[11,12]

Preoperative Assessment Specific to Colorectal Procedures

Assessment of specific organ systems may be necessary and should be done for patients with identified preexisting dysfunction.[30] In general, age, history of chronic heart disease, renal disease, emergency surgery, and type of operation are predictors of the risk of mortality.[31] Fit, young patients undergoing minor and intermediate procedures do not need routine preoperative investigation and, in the pediatric age group, a thorough clinical examination has been found to be of greater value than routine laboratory screening. A good history and physical examination are more important than laboratory data in the development of a treatment plan for anesthesia. For patients undergoing colorectal surgery, a previous major laparotomy may preclude laparoscopic surgery or indicate an increased risk of conversion to open surgery. Body habitus of the patient, mental status, visual acuity, and the presence of other disorders such as arthritis may determine the decision on whether a stoma is formed and its placement. Assessment of patients' attitudes toward surgery, addressing their concerns, and counseling them regarding what to expect during hospitalization is integral part of the preoperative evaluation.

Current Recommendations

Preoperative tests serve to complement the history and physical exam. They have been used to assess levels of known disease, detect unsuspected but modifiable conditions that may be treated to reduce risk before surgery or detect unsuspected conditions that may not be possible to treat, and therefore simply be baseline results before surgery. Many patients undergoing minor surgery need minimal investigation, even if they have chronic medical conditions. Review of current evidence indicates that routine laboratory tests are rarely helpful except in the monitoring of known disease states. New guidelines have a significant impact on reducing preoperative testing and have not caused an increase in untoward perioperative events.[32,33]

Tests that need to be performed prior to major colorectal surgical procedures include hemoglobin for evidence of anemia and as a baseline level for postoperative management. Renal and liver function tests are not routinely carried out. Preoperative blood glucose determination is obtained in patients 45 years of age or older because current recommendations suggest screening of all over that age. In addition, impaired glucose control increases perioperative risks. A urine pregnancy test should be considered for all women of childbearing age. Coagulation tests are only indicated in patients on anticoagulation, with a family or personal history of bleeding disorder, or those with liver disease. Patients undergoing major surgery with a potential for blood loss should have a type and screen, even if transfusion is not expected. This may help to minimize the risk of later transfusion reaction.

EKG is indicated in male patients older than 40 years, and females older than 50 years. Those with a history suggestive of cardiac disorders, myocardial abnormalities, valvular disorders, conduction disorders, and hypertension may benefit from more intensive investigation prior to elective colorectal surgery.[34] Chest X-rays are performed on the basis of findings from the medical history or physical examination. As part of preoperative risk assessment, patients found to have medical conditions requiring further specific therapy before surgery should also be considered for more intensive medical supervision. This is important while in the hospital for their surgery and also as part of their postdischarge follow-up.

Bowel Preparation

Bowel preparation for colon and rectal surgery has traditionally involved two components: mechanical cleansing and antibiotics. Mechanical bowel preparation (MBP) before elective colorectal surgery has its roots in history and has long been a cornerstone of surgical practice. Today, however, there remains little evidence that it is necessary.

Bacteria represent a third of the dry weight of stool[35]; uncontrolled leak of intestinal contents into the abdominal cavity can, therefore, be life threatening. The accepted rationale

for MBP includes the evacuation of stool to allow visualization of the luminal surfaces as well as to reduce the fecal flora, which is believed to translate into lower risk of infectious and anastomotic complications at surgery. While the removal of stool permitting mucosal inspection at colonoscopy is well established and not controversial, the latter rationale – the reduction of infectious and anastomotic complications by MBP – has not been supported by evidence and has recently been challenged in the medical literature. In the trauma setting (see Chap. 26), repair of the injured colon and anastomosis has been shown to be safe and less complicated than diversion of the fecal stream,[36,37] unless there is severe fecal contamination, or the need for transfusion of more than four units of blood.[38] These reports led to the question that if primary anastomosis was acceptable in the trauma setting, could its success and safety be translated to elective surgery performed under optimal conditions? Subsequent multiple animal studies failed to strongly support or refute the role of MBP.[39]

To better understand the debate and controversy surrounding the role of MBP in colorectal surgery, it is worthwhile first to review the various regimens currently in use today as well as their mechanisms, effectiveness, and potential side effects.[40] Dietary restriction (5 days of clear liquids), cathartics, and enemas formed the original framework of colon preparation. However, patient discomfort, electrolyte problems, and inadequate caloric intake proved cumbersome as well as costly.[41] Transition to a large volume (8–10 L) orthograde gut lavage with saline solutions was then tried.[42,43] The need of a nasogastric tube, requirement for hospitalization, and large fluid shifts with potential for electrolyte instability led to the search for alternatives.

Mannitol was found to be an excellent cathartic with minimal effects compared with saline lavage. A major detriment was the fermentation by colonic bacteria which generated combustible gases (methane and hydrogen). Multiple case reports described explosions occurring during colonoscopy after mannitol preps. These case reports along with the fear of explosion with the addition of electrocautery during surgery prevented universal acceptance.[44–48]

Polyethylene glycol (PEG) lavage solution was first introduced in 1980.[49] PEG solutions are iso-osmotic nonabsorbable electrolyte lavage solutions that cause little to no fluid shifts or electrolyte disturbances. Colyte™ (Schwarz Pharma, Inc., Milwaukee, WI) and GoLYTELY™ (Braintree Laboratories, Inc., Braintree, MA) are the most familiar commercial examples in practice. Multiple studies have proven these lavage solutions to be safe, effective, and well tolerated when compared with traditional bowel preparative regimens.[50–52]

PEG solutions require ingestion of 3–4 L solution. The salty taste and high volume reduce patient compliance. Addition of bisacodyl, senna, or magnesium citrate to traditional 4 L PEG regimens has been shown to improve colonic cleansing for colonoscopy.[53–55] Addition of these adjuncts has also allowed for lower-volume (2 L) PEG solutions to be administered with equivalent or increased efficacy and improved patient tolerability.[56–58] Prokinetic agents and enemas when combined with oral lavage have not been shown to improve efficacy or decrease patient symptoms.[59,60] PEG solutions are contraindicated in patients with any sensitivity to the components of the solution, gastrointestinal obstruction, gastric retention, bowel perforation, toxic colitis, toxic megacolon, or ileus. PEG solutions are considered Category C drugs in pregnancy and have not been well studied in this patient population.[61]

In 1990, sodium phosphate (NaP), a saline laxative, was introduced as a safe, more efficacious, and less costly form of bowel preparation when compared with PEG in initial and subsequent studies.[52,62] NaP solutions (Fleet Phosphosoda™, Fleet laboratories, Lynchburg, VA) are concentrated, low-volume hyperosmotic solutions that exert an osmotic effect to draw fluid into the bowel lumen to assist in transit of contents.[63] These solutions were administered as two 4.5 oz. dispensations that are diluted and ingested by the patient at preset times, the day prior to elective colorectal surgery. Electrolyte alterations that may occur include hyperphosphatemia, hypocalcemia, hypernatremia, and hypokalemia, which in most patients were minimal and/or transient in nature.

A tablet form of NaP was developed in 2000 showing equal or improved efficacy and/or improved tolerance when compared with both liquid NaP, PEG, and PEG plus bisacodyl regimens.[64–66] These tablet preparations (OsmoPrep™ and Visicol™, both Salix Pharmaceuticals, Morrisville, NC) offer an alternative to the solution-type NaP formulation. The tablet preparation regimen consists of 28–40 tablets given the day prior to the elective procedure or in a split dose manner, similar to the fluid formulation.

Patients with impaired renal function, dehydration, hypercalcemia, hyperphosphatemia, congestive heart failure, or advanced liver disease could experience severe complications with NaP administration including phosphate nephropathy.[67,68] This is especially true in hypertensive patients taking certain medications, namely angiotensin-converting enzyme inhibitors or angiotensin receptor blockers. This led the Federal Drug Administration to issue a Black Box warning for the over-the-counter version of this preparation and the manufacturer to voluntarily remove the preparation from the market. As this preparation is hypertonic, significant fluid and electrolyte shifts can occur and it is necessary to maintain adequate hydration while undergoing the preparation.[69,70] Absolute contraindications to any bowel preparation include obstruction, ileus, perforation, diverticulitis, severe colitis, toxic megacolon, gastric retention, and gastric paresis.

Summary of Trials and Meta-Analyses

Over the past few years and as recent as mid-2008, numerous clinical trials and meta-analyses have been performed in an attempt to understand the role of MBP in elective colorectal

TABLE 8-5. Randomized controlled trials and Cochrane report relating to preoperative mechanical bowel preparation [a]

Author/year	No. of patients	Mechanical bowel preparation agent	Anastomotic leaks	Wound infections	Mortality
Brownson (1992)[70]	179	PEG	11.9 vs. 1.5 [b]	5.8 vs. 7.5	0.0 vs. 0.0
Santos (1994)[71]	149	Mineral oil, agar, and phenolphthalein; enema; mannitol (3-day regimen)	10.4 vs. 5.3	23.6 vs. 11.7	0.0 vs. 0.0
Burke (1994)[72]	169	Sodium picosulfate	3.8 vs. 4.6	4.9 vs. 3.4	2.4 vs. 0.0
Fillman (1995)[73]	60	Mannitol	8.7 vs. 4.3	3.3 vs. 6.7	
Miettinen (2000)[74]	267	PEG	4.0 vs. 2.0	4.0 vs. 2.0	0.0 vs. 0.0
Tabusso (2002)[75]	47	Mannitol or PEG	20.8 vs. 0 [b]	8.3 vs. 0	
Bucher (2005)[76]	153	PEG	6.4 vs. 1.3	12.8 vs. 4	
Ram (2005)[77]	329	NaP	0.6 vs. 1.3	9.8 vs. 6.1	
Fa-Si-Oen (2005)[78]	250	PEG	5.6 vs. 4.8	7.2 vs. 5.6	
Zmora (2006)[79]	249	PEG	4.2 vs. 2.3	6.7 vs. 10.1	1.7 vs. 0.8

[b] Significant result.

surgery.[41] These studies are summarized in Table 8-5.[70–82] This issue of MBP vs. no MBP was reviewed in a Cochrane Database review published in 2005.[83] This comprehensive meta-analysis included nine clinical trials and a total of 1,592 patients. The authors reiterated a belief that was raised in other studies, wherein the use of MBP frequently resulted in a "semi prepared" colon full of liquid feces that was difficult to control, often leading to spillage and peritoneal contamination and thus explaining the higher rates of complications found in the MBP group.

The most thorough and current meta-analysis on the subject was recently published by Pineda and colleagues, who completed a systematic review of the literature through early 2008 and found 13 prospective trials available with a total of 4,601 patients, the greatest number of patients available to date.[84] In this meta-analysis, the authors analyzed two primary outcomes – anastomotic leaks and wound infections. They found no statistically significant difference between 2,304 patients receiving MBP compared with 2,297 patients receiving no MBP in either outcome. Anastomotic leaks were reported in 97 patients (4.2%) with MBP and 81 patients (3.5%) without MBP ($p=0.206$). Wound infections occurred in 9.9 vs. 8.8% ($p=0.155$). This lack of any statistically significant difference between the two arms in the largest meta-analysis yet performed prompted the authors to conclude that MBP is of no benefit to patients undergoing elective colorectal resection. Though the authors acknowledge certain scenarios when the use of MBP is warranted, such as the anticipated need for intraoperative colonoscopy, they propose that routine MBP need not be considered a "prerequisite of safe colorectal surgery." Despite these data, a 2003 survey of practicing colorectal surgeons revealed that 99% of respondents continue to employ MBP, though 10% did question its role in elective surgery.[85]

Antibiotics

The use of antibiotic prophylaxis in elective colon surgery is mandatory to minimize infection complications.[86] Unfortunately, the choice of antibiotic and route of administration are less clear. The first principle in prophylactic use of antibiotic administration is to provide coverage for the normal bowel flora [aerobic bacteria (*E. coli*) and anaerobic species (*Bacteroides sp.*)]. Oral antibiotics as used in the traditional Nichols–Condon antibiotic preparation have been shown to reduce intraluminal and mucosal bacterial count, while parenteral antibiotics have been shown to reduce systemic bacterial counts at the tissue level.

Colorectal surgery performed prior to 1970 was fraught with infectious complications which occurred in more than 30–50% of all operations. With a better understanding of bacteriology and the availability of an increasing number of antibiotics, surgeons attempted to improve their outcomes with regards to infections.[87–90] In a 1977 VA cooperative study, Nichols and Condon showed that oral neomycin sulfate and erythromycin base decrease the wound infection rate of elective colon resections from 35 to 9%.[91] They also showed that this regimen led to significant decrease in all septic complications (wound infection, anastomotic leak, and abscess) from 43 to 9%.[91–93] The dosing of 1 g of oral neomycin sulfate and erythromycin base at 2 p.m., 3 p.m., and 10 p.m. for an 8 a.m. case became and remains a standard oral antibiotic regime for elective surgery. Unfortunately, the Nichols prep has its drawbacks. While this antibiotic combination is efficacious, it can cause significant gastrointestinal discomfort severely limiting patient compliance with the remainder of the antibiotic preparation and completion of their mechanical preparation.

These limitations, along with the significant increase in number and spectrum of parenteral antibiotics, led many

investigators to utilize various IV antibiotic combinations to minimize infectious complications.[86–93] In 1998, Song and colleagues codified modern practice and confirmed that parenteral antibiotics alone decrease the rate of wound infection and that no single regimen is superior as long as the antibiotics chosen cover both aerobic and anaerobic bacteria and are given before incision.[94] In 2003, the Surgical Infection Prevention Guideline Writers Workgroup (SIPGWW), a project endorsed by both the American College of Surgeons (ACS) and the ASCRS, submitted consensus positions for surgical antimicrobial prophylaxis.[95] The standard for parenteral antibiotic prophylaxis in elective colon resections should include:

1. *Timing*: Infusion of the first antimicrobial dose should begin within 60 min prior to surgical incision.
2. *Duration*: Prophylactic antimicrobials should be discontinued within 24 h following surgery.
3. *Dosing*: The initial dose should be adequate based on weight, adjusted dosing weight or BMI. An additional dose should be administered, if the operation continues over two half-lives after the initial dose.
4. *Selection (colon surgery)*: Cefotetan, cefoxitin, cefazolin/metronidazole, and ampicillin/sulbactam.

   – Options for β-lactam allergic patients: clindamycin + gentamicin, ciprofloxacin, or aztreonam.
   – Metronidazole + gentamycin or ciprofloxacin.

Deep Venous Thrombosis Prophylaxis

Deep venous thrombosis (DVT) and its embolic corollary, pulmonary embolism (PE) are a significant source of morbidity and mortality in the perioperative period. Due to the predominance of abdominal and pelvic surgery, colorectal surgery confers a higher risk of these postoperative complications than other general surgical procedures.[96] Yet despite so much emphasis, DVT and PE continue to be the most common cause of preventable deaths during in-hospital admission, accounting for one out of every four hospitalized patients' deaths.[97,98] More concerning, over 50% of all DVTs are asymptomatic, while the vast majority of PEs are detected only after death.[99] Since Virchow's original description of stasis, hypercoaguability and endothelial damage as risk factors, large epidemiological studies have found an increase in the development of symptomatic venous thromboembolism in the perioperative period associated with male gender, malignancy, trauma, immobility, COPD, sepsis, low hematocrit, low albumin, and major surgery.[100]

Prophylaxis of venous thrombotic events centers on both mechanical and medical means. Mechanical methods include intermittent pneumatic compression stockings, while the current mainstays for chemical thromboprophylaxis are unfractionated and low-molecular-weight heparin. Unfractionated heparin works through antithrombin III to inactivate thrombin and other factors in the clotting cascade. Concerns about its increased bleeding events as well as its dose–effect relationship have led many to be wary of its use. Low-molecular-weight heparin has enhanced antifactor Xa activity and more predictable dose–effect relationships.[101] A recent Cochrane review concluded that the combined use of mechanical graduated stockings with either unfractionated or low molecular heparin was the optimal prophylaxis to prevent thromboembolic complications.[102] Only three studies meeting the inclusion criteria, in this review, focused specifically on colon and rectal surgery. Two years later, the group evaluated 558 studies, of which 19 met the inclusion criteria, and again found that unfractionated and fractionated heparin were equally effective, and the addition of either to compression stockings was superior to either alone.[102]

Risk stratification is the mainstay for DVT prophylaxis recommendation. Young healthy patients undergoing routine anorectal surgery with minimal patient-specific risk factors do not require any additional therapy other than mechanical means via graduated compression stockings and/or intermittent pneumatic compression boots and early ambulation. Those patients with multiple risk factors and undergoing high-risk surgery such as pelvic operations warrant more aggressive means such as unfractionated or low-molecular-weight heparin in addition to the mechanical devices. Timing has been somewhat controversial with some studies demonstrating higher bleeding without undue increase in thrombotic events when given after the surgery and others stating that dosing should begin preoperatively. Although this question has yet to be definitively answered based on current literature, it is well accepted that some form of perioperative including intraoperative means has become the standard of care. The risk of bleeding with thromboprophylaxis dosing is small, with the majority revolving around injection site ecchymoses or hematoma in up to 7% of cases.[103] More clinically significant bleeding, such as gastrointestinal or intraabdominal bleeding, occurs in <0.5% and is rarely the cause for secession of therapy.

A concern in colorectal surgery is how to manage anticoagulated patients who require colonoscopy. Recent guidelines suggest that aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) do not need to be withheld, with the rate of postpolypectomy bleeding around 2%.[104] Coumadin and other more potent antiplatelet medications (i.e., clopidogrel) are commonly held for 5–7 days prior to the procedure, especially when it is known that a polypectomy or other procedures are likely. There is some evidence that the application of endoclips or detachable loops with polypectomy in anticoagulated patients is safe; however, small sample sizes hinder ability to make broad recommendations.[105] Current recommendations are provided in the

ASCRS Practice Parameters for the prevention of venous thromboembolism (www.fascrs.org).[106]

Beta Blockade

Perioperative treatment with beta-blockers titrated to a heart rate of less than 70 bpm to reduce cardiac risk has been studied in multiple clinical trials.[107] Although some more recent trials have not demonstrated the pronounced benefit of earlier trials on the subject, the aggregate conclusion of the multiple studies suggests benefit with small risk. Preoperative beta blockade is indicated in patients having intermediate risk surgery with one or more clinical risk factors or any patient having vascular surgery. It is not indicated in patients for low risk surgery or intermediate risk surgery without clinical risk factors. Some authors argue that effective beta blockade obviates the need for additional cardiac testing in certain intermediate risk patients.[108] Institution of statin-class medication for patients with one or more clinical risk factors undergoing intermediate risk surgery should be considered.[109]

Transfusion: and Hematologic Evaluation

Most patients with anemia tolerate operations well unless they have associated disease, and therefore anemia rarely changes management unless operative blood losses are expected to be great.[106] Risk of thromboembolism and bleeding disorders can be assessed by a detailed history and by tests that measure coagulation factors (prothrombin and partial thromboplastin time) and that assess platelet count and function (bleeding time). Measures to reduce the risk of thromboembolism have been well documented and are part of the practice parameters available from the ASCRS.[100,101,106]

Blood grouping and cross-matching are obviously critical when planning major surgery in which significant blood losses may occur. An important consideration is to have a routine sample for blood type on file for patients undergoing major surgery, even if transfusion is not expected, and cross-matching would not usually take place. This allows a double level of security when urgent samples are sent if bleeding occurs during surgery. This may help to avoid the risk of transfusion reaction, if there is concern about errors with sample labeling or source at any time.

Anemic patients who are scheduled for elective surgery may be treated preoperatively by allogenic transfusion, but consideration is also given to autologous donation, erythropoietin, intraoperative hemodilution with autotransfusion or consideration of cell salvage techniques which are still being evaluated in colorectal surgery. Preoperative autologous donation (PAD) has been criticized recently because of cost-ineffectiveness, large wastage of PAD units, and the potential for leaving patients more anemic after surgery than without PAD.[102] Techniques including acute normovolemic hemodilution and cell salvage may be more efficient; however, investigations still continue into their use.[103]

Communication with the Patient and Establishing the Expectations for Postoperative Recovery

No preoperative visit is complete without providing information on expected postoperative outcomes. This discussion helps the patient to build confidence and trust in the surgeon. Such discussion is likely to be an important component of any postoperative care pathway, and this may help lead to significant reduction in postoperative stay.

Patients can be advised of the surgery they will undergo, their expected milestones in recovery, and possible complications, including issues such as readmission, which may occur in 10% or more of these patients undergoing major abdominal surgery.

Prophylaxis for Endocarditis and Prosthesis

Patients undergoing invasive colorectal procedures are at varying risk for endocarditis and infection of prosthesis. The ASCRS has published practice parameters to guide surgeons on selecting appropriate measures for at risk patients.[110]

Conclusion

Assessment of the patient undergoing surgery is of extreme importance in providing patients with a safe recovery from their operation. This permits stratification of patients into groups that require intensive, moderate or minimal investigation, or treatment prior to anesthesia. Tests to investigate patients should be used selectively based on increasingly accepted guidelines. Patients who need such evaluation and treatment prior to surgery should also be seen by the relevant medical specialty when in hospital and receive any necessary instructions for appropriate medical follow-up after their surgery.

MBP continues to be used by the majority of colorectal surgeons based on traditional practice patterns. Several randomized controlled trials now suggest that this practice may be unnecessary. Patients undergoing bowel resection should be given antibiotic prophylaxis using one dose of parenteral broad-spectrum agents at the time of induction of anesthesia.

Postoperative Management

Sharon L. Stein and Conor P. Delaney

Postoperative care of the colorectal patient is focused on decreasing morbidity, mortality, and health-care costs. An estimated 161,000 Medicare patients undergo major intestinal surgery in the USA annually at a cost of 1.75 billion dollars.[1] The average patient remains in the hospital 10.3 days after colorectal surgery, costing approximately $1,055 per day.[2]

Advances and standardization of postoperative care have reduced perioperative morbidity and mortality. Estimates of overall morbidity are 24.3% following colorectal surgery, with the incidence of serious morbidity including organ space surgical site infection, pulmonary embolism, and septic shock at up to 11.4%.[3] Recent NSQIP data estimates mortality at 1.4% for elective procedures and 15.8% for emergency colon and rectal surgery.[4] Although some costs and complications are unavoidable in postoperative care, a substantial percentage result from prolonged hospitalization, complications including surgical site infections, postoperative ileus, and venous thromboembolic events.

Numerous studies demonstrate that most patients can safely leave the hospital within 3–5 days following colon and rectal surgery without increasing rates of complications or readmission.[5–7] By decreasing the length of hospital stay, postoperative complications, and postoperative ileus, clinicians have the potential to save millions of health-care dollars annually, as well as accelerate the recovery of patients after major surgery. An expanding field of literature focuses on optimizing postoperative care and reducing length of stay. Comprehensive enhanced recovery or fast track protocols include several important elements to ensure success: appropriate antibiotic dosing, perioperative fluid optimization, early enteric nutrition, prevention of ileus, early ambulation, venous thromboembolic prophylaxis, and optimized postoperative analgesia.[8] Research has focused on evaluating available treatments and creating a comprehensive postoperative care plan to expedite hospital stay.

This chapter will review the available data for comprehensive enhanced recovery pathways and individual aspects of perioperative care including recommendations for prevention of postoperative complications and optimal treatment of colon and rectal surgery patients.

Standardized Fast Track Protocols or Enhanced Recovery Pathways

Standardized fast track or enhanced recovery protocols have the ability to substantially reduce length of stay. Generally, patients with stable vital signs are deemed ready for discharge when ambulating, tolerating enteric nutrition, and pain is well controlled with oral analgesia, and adequate discharge care (home or transitional facility) is available. In 2005, average length of stay following colectomy was 10.6 days.[1] Using multimodal, enhanced recovery, or fast track protocols, length of stay has dropped to a mean of 4–5 days in many series and as short as 2.5 days in the hands of some authors.[7,9] A truly efficacious postoperative care protocol combines many elements including regulation of postoperative fluids, early ambulation, early feeding and gastric stimulation, postoperative pain control, and pharmacologic treatment of ileus. Multiples studies have demonstrated the feasibility, safety, and success of enhanced recovery protocols.

Initial data on two small series of multimodal recovery protocols incorporated 48 h of epidural analgesia, immediate postoperative ambulation, and early postoperative feeding. Median length of stay after open sigmoid colectomy was 2 days, with a mean of approximately 4.4 days.[9,10] Simultaneously, Bradshaw et al. randomized 72 patients to early removal of nasogastric tubes, oral diet, and early ambulation and found protocol patients had earlier return of bowel function and were discharged on average 1 day prior to controls.[11] In 2001, Delaney et al. applied these premises to 58 patients undergoing reoperative or complex pelvic and rectal surgery.[5] Ambulation, early oral intake, and pain control were important elements of the protocol. Prompt removal of tubes and drains and enterostomal teaching prepared patients for earlier discharge. Patients without significant comorbidities

(DRG 149) left the hospital at 3.5 days, compared with 5.1 days for complicated patients. Eight patients (14%), who were poorly compliant with the protocol, had a mean length of stay of 5.1 days. Readmissions occurred in four patients (7%). A second study on 118 patients undergoing laparoscopic colectomy with standardized postoperative and discharge protocols, found median stay of 3 days.[7] Seventy percent of patients were discharged within 72 h of surgery, with a readmission rate of 8.5%. Patients discharged on days 1–3 were slightly less likely to have complications, but this did not reach statistical significance.

A systematic review of perioperative clinical care pathways found 13 articles incorporating standardized protocols after gastrointestinal surgery.[12] Articles include preoperative (11), intraoperative (7), and postoperative (13) interventions. Postoperative inventions included nutritional management, pain management, early mobilization, education of family and patient, and discharge planning. Overall, 11 of 13 programs demonstrated a significant decrease in length of stay when compared to conventional care; three also found a decrease in complication rates. None of the studies documented an increased risk of negative outcomes in the clinical pathway group when compared to standardized protocol patients. This was supported by several other meta-analyses in which length of stay was significantly decreased in fast track protocols (1.56–2.35 days shorter), and overall morbidity rates favored fast track protocols.[13,14]

Concern over increased readmission rates after early discharge appears to be unfounded. Three individual studies had notably high readmission rates from 22 to 27%[15–17] but meta-analysis has failed to show a significantly higher rate of readmission for fast track protocols (RR = 1.17, 95% CI 0.73–1.86).[16] In addition, total hospital stay was analyzed including readmission in several studies and was still found to be approximately 2.5 days shorter than patients on conventional protocols.[14,16,17]

Data on increased use of posthospital services at time of discharge is scant. None of the meta-analyses of enhanced recovery protocols analyzed use of services, and few individual papers have described the use of home nursing or skilled nursing facilities.[15–17] Patients discharged within 1–2 days after surgery were less likely to require postdischarge services.[7,18] Need for posthospital services should be an individualized decision. Patients with new ostomies may require visiting nurse care following discharge for continued education and emotion adjustment.[19] Deconditioned or nonambulatory patients may require evaluation by physical therapy for in-patient or home services. A number of papers have demonstrated the importance of predischarge planning to ensure patient and caregiver comfort and satisfaction after discharge from hospital.[20,21] Laparoscopic surgery tends to be associated with less use of postdischarge care facilities than open surgery.[7]

Implementing a fast track protocol is not simple. Most fast track protocols incorporate 8–12 elements, with ranges varying

TABLE 9-1. University Hospital–Case Medical Center enhanced recovery protocol guidelines

Day before surgery
1. Protein/glucose drink
2. Bowel prep as directed
3. Diclofenac 100 mg po

Preoperative holding area
1. Gabapentin 600 mg po 1–2 h prior to induction
2. Alvimopam 12 mg po 1–2 h prior to induction
3. Thromboprophylaxis low-dose unfractionated heparin 5,000 U SC
4. Antibiotics prior to induction 30–60 min prior to induction

Postanesthesia recovery unit
1. Morphine PCA for all patients
2. DC antibiotics unless therapeutic indication

Nursing floor – General orders
1. CBC, BMP POD #1, 3 unless otherwise indicated
2. Ambulate in hallway 5 times per day
3. Sit out of bed 4–6 h per day
4. Foley removed POD#1 if laparoscopic, POD#2 if open
5. Heplock IVF POD#1 if laparoscopic, POD#2 if open

Nursing floor – Dietary orders
1. Clear liquids as tolerated
2. Protein/glucose drink 1 can BID
3. Soft diet POD#1 if laparoscopic, POD#2 if open
4. Chewing gum 1 stick TID × 60 min

Nursing floor medication orders
1. Gabapentin 300 mg po TID while in hospital
2. Alvimopam 12 mg po BID × 7 days while in hospital
3. Ketoroloac 15 mg IV Q6 h × 72 h while in hospital
4. Diclofenac 50 mg TID while in hospital
5. Heparin 5,000 U SC TID while in hospital *may be continued following discharge in high risk patients
6. Lactulose 10 mL po BID

Nursing floor – Oral analgesia
1. Transition to oral analgesia – POD#1 if laparoscopic, POD#2 if open
   a. DC PCA
   b. Acetaminophen #3 1–2 pills po q4–6 h, first dose 30 min prior to stopping PCA
   c. Hold morphine except break through pain

The above guidelines should be modified as clinically appropriate and do not replace clinical evaluation and experience.
POD postoperative day, *PCA* patient controlled analgesia.

from 4 to 20 elements.[12,14,16] An example of the University Hospital, Case Medical Center standardized protocol is listed in Table 9-1. Virtually all studies incorporate accelerated mobilization and early postoperative feeding. Other elements include preoperative bowel preparation, prevention of intraoperative hypothermia, early removal of lines and tubes, perioperative fluid management, opioid sparing techniques and pharmacologic treatment of ileus.[22] A key to the success in implementing a fast track program is the involvement of a multidisciplinary team. The team should consist of anesthetists, nurses, physical therapists, social workers and enterostomal therapists all trained, experienced, and committed to the success of the program.

Some studies have looked at the difficulties implementing a fast track protocol. Ionescu et al. randomized 96 patients to standardized protocol versus fast track implemented for

the first time at a single institution.[23] The average length of stay was reduced to 6.43 from 9.16 days. Difficulties faced in implementation included maintaining patients in a higher acuity unit to incorporate all elements of the protocol and convincing patients of the safety of accelerated hospital stay. Although patients tolerated oral diet at a mean of 42 h, mean length of stay was 6.43 days ($p < 0.001$). Maessen et al. also found that implementation of postoperative care plan and discharge criteria were not sufficient to significantly reduce hospital stay in a multicenter European trial.[24] Although the majority of patients met discharge criteria at 3 days, the median time to discharge was 5 days after surgery. In a study center familiar with the fast track protocol, the percentage of patients discharged upon meeting criteria was 66% versus less familiar centers where only 26% of patients were immediately discharged ($p < 0.001$).

Provider hesitancy may also play a role in the slow implementation of fast track programs. Kehlet and colleagues performed a survey in the USA and Europe of 295 hospitals and 1,082 colon surgery patients.[25] Despite evidence demonstrating a lack of efficacy,[26–28] they found that nasogastric tubes were left in situ for an average of 3 days in 40% of US patients and 66% of European patients. After surgery, 50% of patients tolerated their first liquids at 3–4 days and first meals at 4–5 days. However, patients remained in the hospital for a mean length of stay of 7 days in the USA and over 10 days in Europe. Polle et al. compared 55 fast track and 52 conventional patients on two gastrointestinal units at a single hospital using 13 fast track elements.[18] On average only 7.4 elements were applied per patient within the fast track group. Despite this, length of stay was reduced from 8 to 4.5 days for patients undergoing open colorectal surgery ($p = 0.02$) but no reduction was noted in laparoscopic patients. Although readmission rates were higher in the fast track group (6% vs. 3%), overall total hospital stay was still decreased by 2.5 days on average ($p = 0.03$). Patient satisfaction was not significantly different between the two groups.

Many studies have now analyzed the cost effectiveness of fast track protocols. Pritts et al. used pre-fast track historic and concurrent standard protocol patients to evaluate cost savings of an enhanced recovery protocol.[29] The mean cost per hospital stay was $19,997.35 ± $1,244.61 for patients in the historical control group, $20,835.28 ± $2,286.26 for those in the simultaneous control group, and $13,908.53 ± $1,113.01 for those in the enhanced recovery group ($p < 0.05$ vs. other groups). Length of stay was reduced by approximately 2 days when compared to historical and nonpathway groups ($p < 0.05$ vs. other groups). Stephen and Berger compared pre- and post-fast track implementation costs and length of stay.[30] After implementation of a fast track protocol, length of stay was reduced from 6.6 to 3.7 days ($p < 0.001$) and costs were reduced from $9,310 ± $5,170 to $7,070 ± $3,670 ($p = 0.002$). Kariv et al. looked exclusively at patients undergoing ileal pouch anal anastomosis and found shorter hospital stays (4 days vs. 5 days) ($p = 0.012$) and lower direct 30-day costs reduced from $6,672 to $5,692 ($p = 0.001$).[31]

Clearly, development of an enhanced recovery protocol has potential benefits, including the potential for substantial financial savings. Risk of readmission and complications do not appear to be increased in accelerated patient pathways. Provider and patient comfort is an important element to success and is benefitted by a team committed to a comprehensive protocol.

Fluid Management

Postoperative fluid management is complicated by perioperative changes in homeostasis and appropriate fluid management is essential to optimizing postoperative care. Basic fluid requirements are approximately 2,500 cc/day in a 70 kg adult. This allows for both insensible losses from respiration, perspiration, and feces as well as the 1,500 cc of urine necessary to excrete waste products including urea, potassium, and sodium. A basic formula for calculating fluid needs is 1,500 cc for the first 20 kg and 20 cc/kg for the rest of the weight.

After surgical stress, there is an increase in renin, aldosterone, and antidiuretic hormone release and activation of the sympathetic system resulting in sequestration of fluid (third spacing) and increased volume requirements. Additional losses may occur from evaporation from exposed abdominal cavity, blood loss, diarrhea, nasogastric tubes, and abdominal drains; each of these must be accounted for. In recovering patients, fluid retention begins to resolve with a return of the hormones and sympathetic nervous system toward normal in approximately 72 h.

Data have shown that insufficient perioperative fluid resuscitation increases the risk of hypotension, inadequate tissue perfusion, and renal failure.[32,33] Shires historically advocated aggressive fluid resuscitation in trauma patients to compensate for perioperative third spacing, and the concept was quickly applied to elective surgery.[34] In this regimen, patients were resuscitated in excess of expected or actual intraoperative fluid losses, receiving between 3.5 and 7 L of fluid on the day of surgery. Following surgery, patients might receive 3 L per day for 48 h with weight gains of 3–6 kg postoperatively rendering them hypervolemic.[35,36] However, over-resuscitation is associated with hypoalbuminemia, delayed gastrointestinal recovery, pulmonary complications, and increased cardiac demand.[37,38]

Initial attempts to moderate resuscitation fluids were compared with standard resuscitation. Lobo et al. restricted fluids in ten patients to 2 L per day and noted reductions in complication rates ($p = 0.01$), earlier return of gastrointestinal function (4.0 vs. 3.0, $p = 0.001$) and reduced length of stay (9.0 vs. 6.0, $p = 0.001$).[35] These findings were supported by some studies;[39–41] others failed to show decreases in wound infection rates (11.3% vs. 5.5%, NS)[42] or length of stay (7.2 days vs. 7.2 days).[43] A meta-analysis of seven trials not only demonstrated

no evidence of increased rates of serious complications such as anastomotic leaks but also failed to reach definitive recommendations.[44] This body of literature has been criticized for including a heterogeneous mix of resuscitation patterns, definitions, and goals. Postoperative care regimens, time to oral intake, use of colloid supplements, and anesthetic regiments varied greatly between studies. "Restricted" resuscitation rates ranged from 998 to 2,740 mL, and overlapped with liberal fluid resuscitation in other studies. Varied analgesia regimens led to changes in resuscitation; patients with epidural catheters had hypotension associated with sympathetic blockade and vasodilation and required additional fluids.[39] In addition, many studies excluded high-risk patients, who might benefit most from restrictive or goal-directed therapies.[44] Further studies with standardized definitions, perioperative protocols, and more rigorous outcomes are necessary to define optimal management.

More recently, transesophageal Doppler monitoring has been used to guide resuscitation. Monitoring of ejection fraction and stroke volume aid in assessing oxygen tissue delivery.[45,46] Optimization of stroke volume as determined by Doppler is compared with typical postoperative hemodynamic parameters such as urine output, heart rate, and blood pressure. Several studies have shown reduced postoperative gastrointestinal and overall complications[47–50] and earlier return of bowel function.[50] Resuscitation with colloid versus crystalloid did not further improve length of stay.[51] The rate of anastomotic leaks was not increased in the study groups.[52,53] Three studies demonstrated a statistically reduced postoperative length of stay by 1.5 to 2 days[49,50] confirmed in two separate meta-analysis in favor of Doppler-guided resuscitation.[52]

While general trends support restricted perioperative fluids[44,52,53] the ideal resuscitation goals are still being debated. Doppler guidance is available only intraoperatively, and although this can reduce early over resuscitation, postoperative fluids are still based on a variety of subjective hemodynamic parameters. Further studies in the setting of standardized perioperative care module will be helpful in determining best goals for postoperative intravenous fluid administration. In addition, as trends toward earlier enteric intake continue, reducing intravenous fluids in exchange for oral fluids may further change practice parameters.

Postoperative Gastrointestinal Recovery: Nausea, Vomiting, Feeding, Gum Chewing, and Ileus

Postoperative Nausea and Vomiting

Postoperative nausea and vomiting (PONV) is a common early complication after gastrointestinal surgery. Approximately 25% of patients experience PONV within 24 h. Among high-risk patients, the incidence may be as high as 70–80%.[54,55] PONV delays recovery of patients after in-patient surgery

TABLE 9-2. Risk factors for postoperative nausea and vomiting

Patient-specific risk factors
1. Female sex
2. Nonsmoking status
3. History of PONV/motion sickness
Anesthetic risk factors
1. Use of volatile anesthetics
2. Nitrous oxide
3. Use of intraoperative or postoperative narcotics
Surgical risk factors
1. Duration of surgery
2. Type of surgery

PONV postoperative nausea and vomiting.

TABLE 9-3. Koivuranta score II for evaluation of postoperative nausea and vomiting

SCORING: Patient risk is calculated based on cumulative number of risk factors:
Risk factors:
    Female gender
    Previous PONV
    Duration of surgery over 60 min
    History of motion sickness
    Nonsmoker

# of risk factors	Risk of nausea (%)	Risk of vomiting (%)
0-1 factor:	17–18	7
2 factors:	42	17
3 factors:	54	25
4 factors:	74	38
5 factors:	87	61

PONV postoperative nausea and vomiting.

and accounts for a significant proportion of unanticipated hospitalizations following ambulatory surgery. PONV leads to patient discomfort and satisfaction but is largely avoidable when properly addressed.

Risk factors and risk assessment for postoperative nausea have been well studied. Consensus guidelines for managing PONV highlight patient, anesthetic, and surgical risk factors as listed in Table 9-2.[56] Instruments that predict PONV have been validated with a high level of correlation to patient outcome.[57,58] Among the simplest is the Koivuranta score (Table 9-3) which uses only the five strongest risk factors – female gender, previous PONV, duration of surgery, history of motion sickness, and nonsmoking status – as predictors of PONV.[59]

Prevention of PONV is centered on reducing anesthetic and surgical risks, while appropriately adding pharmacologic prophylaxis. Use of regional anesthesia, minimization of narcotics, and avoidance of nitrous oxide and volatile anesthetics have efficacy in reducing PONV.[51,60,61] Propofol induction, increasing hydration, and use of supplemental

oxygen are associated with reduction in risk in patients undergoing colorectal surgery.[62]

Many pharmacologic therapies for PONV are familiar to the colorectal surgeon. 5-HT$_3$A agents such as ondansetron, granisetron, and tropisetron are often chosen as first line treatment. They are generally effective (NNT 5–7) with a favorable side effect profile which includes headaches, increased liver enzymes, and constipation.[63,64] Typical dose of ondansetron is 4 mg IV every 8 h, but this may be doubled for increased efficacy. Steroids have also been shown to be effective, particularly if administered prior to induction.[65] Dexamethasone is generally administered as a single dose intravenous of 8–10 mg, although doses as low as 2.5 have been found to be effective (NNT=4).[66] Side effect profile is more concerning to surgeons and includes wound infection and adrenal suppression, but these effects have not been reported after a single bolus dose. Droperidol was commonly administered at the end of surgery in doses of 1 mg IV with good effect (NNT=5) but a FDA "black box" warning recently issued has diminished enthusiasm for this antiemetic.[67] Reports of prolonged QTc intervals, arrhythmias and cardiac death, have been reported after use of droperidol but not following a single prophylactic dose.[68]

Other medications are used less frequently secondary to side effect profiles or questionable efficacy. Promethazine, a phenothiazine, has been shown in a single study to be more effective than ondansetron in preventing nausea (OR=3.4, 95% CI 1.2–9.4) but was not equally effective in preventing vomiting.[69] Additionally, the study was criticized for having a higher proportion of high-risk patients in the ondansetron arm (40% vs. 27%). Phenothiazines are also limited by their significant side effect profile, which include extrapyramidal symptoms, dystonia, tardive dyskinesia and akathisia. Scopalamine is a transdermal anticholinergic agent effective in preventing PONV in a single study (NNR 3.8).[70] However, use of scopalamine is limited by 2–4 h delay in onset of action as well as uncommon hallucinations, disorientation, and memory disturbances. Metoclopramide is a relatively cost effective treatment, which has mixed results in over 54 studies.[71] In a meta-analysis, metoclopramide had higher efficacy than ondansetron for nausea (59% vs. 48%, NS) but was less efficacious at preventing vomiting (35% vs. 50%, $p < 0.001$).[72] In addition, side effects affect in up to 20% of patients include somnolence, reduced mental acuity, anxiety, and depression.[73] Despite FDA approval for PONV, metoclopramide is not routinely recommended.[56]

Unconventional treatments may also reduce the incidence of PONV. Acupuncture has been demonstrated to reduce the incidence of PONV when compared to placebo (23% vs. 41%, $p = 0.0058$).[74] White et al. found that acupuncture and ondanestron were better than ondanestron alone for both nausea (40% vs. 70%, $p = 0.006$) and vomiting (22.5% vs. 50% $p = 0.070$).[75] Ernst et al. found that the use of 1 g of ginger was equivalent to the use of metoclopramide in preventing PONV.[76] Other studies demonstrated that ginger was no better than placebo

in preventing PONV in women undergoing gynecologic surgery.[77] Aromatherapy including peppermint oil, isopropyl alcohol, or placebo decreased nausea from baseline, but there was no difference between scents in a single study.[78]

Economic and emotional costs of nausea and vomiting are often weighed against the cost of therapy. PONV prophylaxis was not found to be cost effective in patients whose risk of nausea or vomiting are less than 20%.[79] Hill found that prophylactic therapy was cost effective only in higher risk groups when compared to placebo.[80] In high-risk patients, two antiemetic agents were more cost effective than no prophylaxis and rescue therapy.[81] Treating vomiting is typically three times more expensive than treating nausea.[82]

Algorithms for management of PONV are well established.[56,71] Patients should be assessed preoperatively for risk of PONV and if found to be low risk, no prophylactic dosage is generally given. A rescue dose of 5-HT$_3$A, such as ondansetron, may be given if the patient experiences PONV after emersion. Patients are deemed to be at moderate to high risk of PONV are generally treated empirically. Monotherapy agents such as use of dexamethasone, droperidol, or ondansetron may be used or combination therapy of multiple agents can be employed when deemed appropriate.

Early Refeeding and Use of Nasogastric Tubes

Historically, patients were advised to refrain from postoperative nutrition for several days and nasogastric tubes were left in place to protect patients from nausea and vomiting following abdominal surgery.[83,84] Although nasogastric tubes relieved some symptoms of postoperative ileus, there is no evidence that they decreased duration of ileus or PONV.[26,85,86] In 1995, a meta-analysis determined that nasogastric tubes are associated with increased atelectasis and pneumonia.[87] Other studies demonstrated increased gastroesophageal reflux with nasogastric intubation,[28] and a recent meta-analysis demonstrated earlier return of bowel function after colonic surgery without a routine use of nasogastric tube.[26]

Early refeeding is believed to stimulate propulsive activity, decrease intestinal gut mucosal permeability, and induce secretions of gastrointestinal hormones to promote bowel motility. Early feeding was first proposed with laparoscopic surgery and early studies demonstrated that 80–90% of patients tolerated liquids within 24 h of surgery.[88,89] After success in laparoscopic surgery, studies expanded to patients undergoing open surgery.[90,91] A meta-analysis found feeding patients promptly after surgery is associated with decreased rate of infections (RR=0.72, $p = 0.036$), and shorter length of stay (RR=0.84, $p = 0.001$), but an increased risk of vomiting after surgery (RR=1.27, $p = 0.046$).[92] A 2009 Cochrane data review suggested that earlier refeeding was safe and may reduce the risk of postoperative complications but data failed to reach statistical significance.[93]

Accelerated recovery programs uniformly include early refeeding for patients undergoing both open and laparoscopic

surgery.[7,13,14] Approximately 5–15% of patients will develop substantial postoperative ileus requiring return to NPO status or nasogastric decompression, but most patients tolerate early feeding without complications.[5,90] Additionally, for the majority of patients who tolerate early refeeding, decreased complications, earlier discharge, and patient comfort are significant benefits.

Preoperative fasting has also been questioned as a routine part of clinical care. Postoperative hyperglycemia and insulin resistance have been proposed as independent factors increasing hospital stay.[94] Preoperative fasting of 8–12 h can deplete available carbohydrate reserves and promote a fasting metabolism. Data have demonstrated administration of a preoperative carbohydrate drink does not increase risk of aspiration or complications on induction.[95,96] A carbohydrate rich drink, given the evening before surgery and 2–3 h prior to surgery, has been shown to significantly reduce patient thirst, hunger, and improve well-being,[97] while also decreasing the loss of muscle mass postoperatively[98] and significantly reducing length of stay by 1.2 days ($p < 0.02$).[99,100]

Treatment and Prevention of Ileus

Postoperative ileus is defined as the "transient cessation of coordinated bowel motility after surgical intervention, which prevents effective transit of intestinal contents and/or tolerance of oral intake."[101] The average time until recovery of bowel function after major abdominal surgery is less than 24 h for the small intestine, 24–48 h for the stomach and 48–120 h for the colon.[102,103] In general, ileus should resolve within the fifth postoperative day after open surgery and by the third postoperative day after laparoscopic surgery. Failure to resume gastrointestinal function has many adverse effects including increased postoperative pain, nausea and vomiting, poor wound healing, delay in postoperative mobilization, increase in deconditioning, pulmonary complications and nosocomial infections, prolonged hospitalization, decreased patient satisfaction, and increased health-care costs.

Health Care Financing Administration data estimates that postoperative ileus occurs in approximately 14.9% of patients following large bowel resection and up to 19.2% after small bowel resection.[1] It is estimated that the total health-care cost of postoperative ileus are approximately $1.14 billion dollars annually, or 6.24% of all health-care costs in the USA. The average length of stay of patients with postoperative ileus is almost doubled to 11.5 from 6.5 days for patients without postoperative ileus.[104]

To reduce the incidence and duration of postoperative ileus, multiple pharmacologic interventions have been attempted.[105,106] Beta blockade of adrenergic receptors in the gut might be expected to decrease the incidence of postoperative ileus. A single small study of propanolol in 1983 demonstrated promising results with decreased time to bowel movement of 18 h ($p \leq 0.01$), but patients experienced a significant decrease in blood pressure and heart rate.[107] Further studies on propanolol failed to validate results or utility.[108] Neostigamine is an acetylcholinesterase inhibitor, which increases parasympathetic activity in the gut wall and has been used extensively in the treatment of acute colonic obstruction. However, its usefulness in postoperative ileus is limited by side effects which includes abdominal cramps, vomiting, and profound bradycardia.[109] Cisapride is a serotonin receptor antagonist that promotes acetylcholine receptor release from peripheral nerve endings and was demonstrated to have significant utility in decreasing postoperative ileus. However, cardiovascular events resulted in the drug's withdrawal from the market in 2000.[110] Metoclopramide is believed to increase gastrointestinal motility through stimulation of smooth muscle contractions. Although some studies demonstrated decreased nausea and vomiting with its routine use, there are no convincing data establishing a reduction in postoperative ileus.[111–115]

Newer drugs have been designed to selectively block peripheral (mu) μ-opioid receptors that contribute to postoperative ileus (POI). The ideal POI treatment is a peripheral opioid receptor antagonist that reverses GI side effects without crossing the blood–brain barrier, and therefore is unable to compromise postoperative analgesia. Two novel peripheral (mu) μ-opioid receptor antagonists have been studied in patients undergoing abdominal and pelvic surgery.

Methylnaltrexone is a quaternary derivative of naltrexone, which acts selectively on peripheral opioid receptors as a competitive antagonist. Because methylnaltrexone does not cross the blood–brain barrier it does not reverse analgesia or precipitate opioid withdrawal.[101,116] Methylnatrexone was approved in 2008 for treatment of opioid-induced constipation and significantly improved postoperative ileus in a Phase 2 study.[117] A randomized double-blind placebo-controlled trial of 0.3 mg/kg of intravenous methylnaltrexone demonstrated reduced time to first bowel movement (97 h vs. 120 h, $p = 0.01$) and time to discharge eligibility (119 h vs. 149 h, $p = 0.03$). Side effects included abdominal cramps and flatulence, as well as transient orthostatic hypotension when administered intravenously. Data from Phase III trials failed to show clinical improvement in postoperative ileus, and methylnaltrexone is currently approved only for opioid-induced constipation.

Alvimopan is also a peripherally active (mu) μ-opioid antagonist, but has higher affinity for human (mu) μ-opioid receptors and an active metabolite that appears to be absorbed systemically. Taguchi published the first results on postoperative use of alvimopan in 78 patients showing a dose-related response with significantly decreased time to passage of first flatus (70 h vs. 49 h) first bowel movement (111 h vs. 70 h and ready for discharge (91 h vs. 68 h).[118] Results were validated in a randomized double-blind multicenter trial demonstrating reduced time to GI-3 recovery consisting of two of the following: time to tolerating solid food, time to first flatus, or time to bowel movement. GI-3 recovery was reduced by 86.2 h versus 100.3 h in placebo.[119] Of note, patients

undergoing hysterectomy did not have significant decrease in GI recovery time. A second multicenter trial demonstrated a GI-3, dose–response curve to alvimopan with recovery 15 h faster for 6 mg of alvimopan and 22 h faster for 12 mg of alvimopan when compared with placebo.[120] Buchler et al. published a RCT double-blind study in Europe; however, this study varied from the other studies by having much lower use of opioids and some patients who did not receive any opioids.[121] GI-3 bowel function was reduced by 8.5 h in the 6 mg group and 4.8 h in the 12 mg group, but this was not statistically significant. Pooled data analysis of the three US trials showed that alvimopan speeded overall GI-2 (tolerance of solid food and first bowel movement) recovery by 12 h and accelerated time to discharge order (HR = 1.35, $p < 0.01$).[122,123] A second meta-analysis of five studies demonstrated similar findings.[124,125] In these studies, alvimopan has not been shown to have an increase in adverse event rates or complications.[104,123,124]

Alvimopan (Entereg®; Adolor and GlaxoSmithKline, Exton, PA) is currently approved for perioperative use only for hospitalized patients in the setting of Entereg Access Support and Education Programs (EASE). The first dose of 12 mg should be given orally prior to surgery, and continued 12 mg BID for 7 days, or until discharge. Alvimopan is contraindicated for patients on chronic opioids, with bowel obstruction, or severe hepatic or renal disease.[126] A cost analysis of alvimopan from the North American studies found mean hospital length of stay to be 1 full day shorter with a mean savings of $879–977 per patient, given an estimated cost of $558 dollars (8.9 × 12 mg doses).[127] Further analysis of the benefits of alvimopan on patients receiving laparoscopic surgery is ongoing, as all of the trials to date have been in patients undergoing open surgery.

Use of Gum Chewing

Gum chewing has also been proposed to decrease the incidence of postoperative ileus. Chewing stimulates the cephalic phase of digestion and serves as a form of sham feeding stimulating neural and hormonal pathways.[128] Mastication and salivation increase vagal cholinergic stimulation and promote the release of gastrointestinal hormones such as gastrin, neurotensin, and pancreatic polypeptide.[129] Cephalic stimulation is accomplished without oral intake, thereby theoretically avoiding complications of food intolerance, which may occur in up to 20% of patients after early oral intake.[130]

Asao et al. first proposed gum chewing to enhance recovery after colectomy in 2002.[131] Nineteen patients randomized to chewing gum three times daily following laparoscopic colectomy were noted to have earlier return of flatus (1.1 days, $p < 0.01$), time to defecation (2.7 days, $p < 0.01$) and time to discharge (1 days, NS). This data was supported by a multicenter trial by McCormick et al.[132] Patients who chewed gum four times daily after laparoscopic surgery

had shorter duration of postoperative ileus (2.6 days vs. 3.3 days, $p = 0.0047$) and hospital stay (4.0 days vs. 5.3 days, $p = 0.029$).

Data is less compelling on the efficacy of gum chewing following open colectomy. Schuster et al. randomized 34 patients undergoing sigmoid colectomy to gum chewing and noted statistically decreased time to flatus (65.4 h vs. 80.2 h, $p = 0.05$), defecation (63.2 h vs. 89.4 h, $p = 0.04$), and length of stay (4.3 h vs. 6.8 day, $p = 0.01$).[133] But other studies demonstrated no significant difference between groups undergoing open colectomy.[134,135] In a study of 38 open colectomy patients, Quah et al.[134] found slight reductions in passage of flatus (2.7 days vs. 2.4 days), time to defecation (3.9 days vs. 3.2 days), and length of stay (11.1 days vs. 9.4 days), none of which were significant. Matros et al. randomized 66 patients to gum chewing, acupressure wrist bracelets and control groups and demonstrated no significant differences in time to flatus, bowel movement, or discharge.[135] McCormick also found no reduction in time to bowel recovery (3.6 days vs. 3.9 days, $p = 0.50$) or discharge (5.6 days vs. 5.3 days, $p = 0.5$) in the open arm of their study.[132]

At least five meta-analyses on gum chewing exist in the literature, all of which demonstrate a statistically significant reduction in time to flatus and defecation.[136–140] Cumulative time to flatus and defecation were reduced by as much as 20 and 29 h, respectively.[136] Only Noble et al. demonstrated a significant reduction in length of stay (1.1 days, $p = 0.0016$), after including a study of nonrandomized patients undergoing cystectomy.[138,141] Meta-analyses highlight the heterogenicity of trials including frequency and duration of gum chewing, which varied from TID to QID and 5–30 min in duration. Use of epidural anesthesia was varied in open trials; epidurals were used in over 85% of patients in trials by Matros and Quah[134,135] but less than half in the trial by Schuster et al.[133] Thoracic epidural analgesia provides a sympathetic blockade that may negate the parasympathetic stimulation of gum chewing. Most trials were small, and blinding was difficult to perform.

The economic and social costs of gum chewing are minimal. Schuster et al. estimated a cost of gum at $.04 per stick three times daily for 5 days per patients.[133] With over 350,000 colectomies performed annually in the USA, the cost would be under $50,000 per year. An average hospital room was estimated at $1,500 per day, and the cost of ileus is over $750,000,000 annually.[1] In addition, although theoretical complications such as aspiration or small bowel obstruction after gum chewing may exist, no significant complications were reported in any of the trials. Gum chewing appeared well tolerated and probably is a low-risk intervention for patients undergoing colectomy.

Early Ambulation

Early ambulation following abdominal surgery was proposed by Ephraim McDowell as early as 1817, but most surgeons including Sir William Halstead were more cautious,

keeping patients immobilized for up to 21 days following laparotomy.[142,143] In 1941, Leithauser popularized early ambulation, listing decreases in pulmonary, circulatory and digestive system complications as benefits.[144,145]

Direct benefits of ambulation on postoperative gastrointestinal recovery are inconclusive. In 1990, Waldenhausen and Schirmer studied myoelectrical recovery of the gastrointestinal tract following surgery and found no difference in recovery times for patients who ambulated on postoperative day 1 versus day 4.[146] Maessen et al. noted ambulating within 24 h of surgery was associated with early discharge, but not reduction in time to flatus or bowel movement.[147] Lin et al. correlated increased length of ambulation with 36.6% earlier discharge following laparoscopic surgery.[148] However Zutshi et al. found no added benefit for early ambulation in patients who participated in comprehensive enhanced recovery protocols.[149]

Early ambulation appears to be correlated with reduced postoperative respiratory and hematologic complications but may not have a direct effect on recovery of bowel function. Additional benefits include preservation of strength and conditioning.[150] As there are virtually no disadvantages to early ambulation, early ambulation is an established component of virtually all accelerated recovery programs. Ideally, patients ambulate on the evening of surgery. To accommodate early ambulation, lines and tubes are minimized after surgery. Foley catheters are removed by postoperative day 1 for laparoscopic surgery or day 2 after open surgery. Drainage catheters are not routinely left in place after surgery.[151,152] By postoperative day 1, patients are encouraged to walk a minimum of 60 m and spend 5 or more hours out of bed.[153]

Prevention of Pulmonary Complications

Pulmonary complications are well established after surgery. Churchill described reductions of up to 80% of vital lung capacity following surgery in 1928; lung volumes are diminished after both general anesthesia and abdominal surgery.[154,155] Interventions including early ambulation, minimally invasive surgery, and smoking cessation have been evaluated to reduce risk of postoperative pulmonary complications.

Delayed ambulation has been directly correlated with worsening pulmonary function. Pain appears to be a factor in both ability to ambulate and pulmonary toilet. Kanat et al. demonstrated increased respiratory complications in patients who failed to ambulate within 48 h.[156] Appropriate pain control can be essential in moderating diminished lung capacity.[157]

Earlier return of forced expiratory volumes was one of the first benefits demonstrated from laparoscopic surgery.[158,159] Several studies have demonstrated early recovery of pulmonary function as evidenced by incentive spirometry.[160] Vignali et al. demonstrated nonsignificant but lower rates of pneumonia in patients undergoing laparoscopy.[161] A retrospective review by Guller found a decreased incidence of postoperative respiratory complications in laparoscopic patients (2.5% vs. 6%, $p < 0.001$).[162] A meta-analysis performed by Abraham et al. demonstrated achieving 80% preoperative peak expiratory flow was delayed in 44.3% patients having open surgery, but FEV1 and FVC were not significantly different when compared to laparoscopic groups.[163] These studies have been criticized for a lack of prospective data, disparities between groups, and more importantly the relevance of clinical end points, such as spirometry parameters and radiographic atelectasis.[164]

Although all patients are at risk for pulmonary complications, there appear to be groups who are particularly susceptible. A 2006 review evaluated risk factors and interventions in an attempt to reduce postoperative pulmonary complications.[165] Qaseem et al. determined that patients at high risk included patients with chronic obstructive pulmonary disease, age greater than 60, American Society of Anesthesiologist (ASA) class II or greater, and cardiac failure. Emergency surgery, general anesthesia, abdominal surgery, and procedures longer than 3 h in length all further increase risk. Patients deemed high risk of complications benefit from deep breathing exercises or incentive spirometry, and the selective use of nasogastric tubes, though no single intervention was statistically superior.[165]

Preoperative smoking cessation may not be advantageous. Data regarding postoperative benefits of preoperative smoking cessation is generally inconclusive[166] but appears to be most beneficial for patients who quit 4–6 weeks before surgery.[157] Patients who quit smoking within 2 months of surgery may have a paradoxical increased risk of postoperative pulmonary complications, possibly from increased mucous production.[167]

Prevention of Venous Thromboembolism

Colon and rectal surgery patients are at risk for deep venous thrombosis (DVT) and pulmonary embolism (PE). Estimates are that between 20 and 40% of patients undergoing abdominal surgery will experience DVT and 2–4% will develop a pulmonary embolism.[168] Fatal pulmonary embolism occurs in up to 1.0% of hospitalized patients, and accounts for 10% of hospital deaths, making it the most common preventable cause of hospital death in the USA.[169,170] Colon and rectal surgery patients often have multiple risk factors for venous thromboembolism (VTE), listed in Table 9-4, including diagnoses such as cancer or inflammatory bowel disease, advanced age, and prolonged surgical procedures.[171]

The rationale for thromboprophylaxis in colorectal patients is simple and scientific.[172,173] Many of these events are clinically silent and screening is neither clinically nor economically effective. Prophylaxis for VTE should be a standard element in the care of the postoperative colorectal surgery patients. There are many highly efficacious methods of preventing VTE. Patient risk should be stratified preoperatively

TABLE 9-4. Risk factors for venous thromboembolism

Surgery
Trauma (major or lower extremity)

TABLE 9-5. Risk classification of deep venous thrombosis and recommended options for prophylaxis for patients undergoing surgery

Level of risk	Approximate risk of DVT without thromboprophy-laxis (%)	Suggested options
Low risk (minor surgery in mobile patients)	<10	Early ambulation
Moderate risk (most general surgery patients)	10–40	Low molecular weight heparin Low dose unfractionated heparin Fondaparinux
High risk	40–80	Low molecular weight heparin Fondaparinux Oral vitamin K antagonist to INR (2–3)

Modified from Geerts WH, Bergqvist D, Pineo GF, et al. Prevention of venous thromboembolism. Chest. 2008;133:381S–453S.[171]
DVT deep vein thrombosis.

and use of prophylactic regiments including elastic stockings, mechanical sequential compression devices (SCDs), and pharmacologic agents should be employed. Risk classification of patients and general guidelines is included in Table 9-5. The American Society of Colon and Rectal Surgeons (ASCRS) has provided practice parameters for the prevention of venous thromoboemoblism.[174]

Elastic Stockings and Sequential Compression Devices

Elastic stockings and SCDs are mechanical methods of increasing venous outflow and reducing stasis in leg veins to decrease the risk of DVT. Graduated compression stockings function purely on a mechanical level to encourage venous return. SCDs are also believed to systemically increase the

fibrinolytic activity by reducing plasminogen activator.[175] For maximal benefit in patients undergoing surgery, elastic stockings or SCDs should be placed before the induction of anesthesia and function throughout the operation.

Data on the effectiveness of elastic stockings and SCDs is limited. Both methods have demonstrated efficacy in reducing the risk of DVT, but neither have been shown to decrease the incidence of PE.[176–178] Several factors limit the effectiveness of SCDs and elastic stockings including poor compliance, poor fit, and arterial insufficiency.[179] In an observational study of patient compliance, Cornwell et al. observed that only 19% of patients were fully compliant with use of SCDs and patients were using SCDs at the time of only 53% of observations in this study.[180] If not fitted properly, elastic stockings may actually be constrictive and paradoxically increase venous pressure below the knees.[181] Compression stockings are not recommended for patients with arterial insufficiency or current DVT.[182]

As sole prophylaxis, compressive stockings and SCDs should be reserved for the low-risk patient or patients at high risk of bleeding who cannot tolerate prophylaxis pharmacotherapy.[171] SCDs and elastic stockings may be used in conjunction with pharmacologic prophylaxis.[183,184] Care should be taken to ensure that devices are applied regularly, fit appropriately, and do not limit ambulation postoperatively.

Aspirin

Although aspirin has significant antiplatelet activities and has been used to prevent major vascular events, current recommendations are that aspirin should not be used as primary treatment to prevent VTE.[171] A number of trials demonstrated no significant benefit from aspirin therapy alone.[185,186]

Low-Dose Unfractionated Heparin

Unfractionated heparin has been used as a form of DVT prophylaxis since the 1970s and has been shown to be safe in the majority of surgical patients. It binds to antithrombin (ATIII) and accelerates the inhibition of thrombin and other coagulation factors, particularly factor X. Typically, pTT will be unchanged despite use of unfractionated mini-dose heparin. Heparin can be reversed with use of protamine. Recommendations are that the initial dose of low-dose unfractionated heparin (LDUH) be given 1–2 h preoperatively. Although the standard dosing regimen is 5,000 U subcutaneously every 8–12 h postoperatively, no study has compared dosing regimens directly.

A meta-analysis of LDUH compared 46 randomized clinical trials of LDUH, no thromboprophylaxis or placebo.[187] The rate of DVT, PE, and fatal PE were each significantly reduced (22% vs. 9%, 2.0% vs. 1.3%, and 0.8% vs. 0.3%). Risks of use of LDUH include the risk of postoperative bleeding and heparin-induced thrombocytopenia (HIT). LDUH is associated with an increased rate of bleeding events (5.9% vs. 3.5%),

but subsequent analysis demonstrated bleeding was generally associated with wound hematomas and not major bleeding.[188] HIT may occur in 5–15% of patients but is less common than in patients on full anticoagulation. HIT may cause a paradoxical hypercoagulable state with arterial and venous thrombosis. The platelet count typically reduces to less than 50% of baseline levels and should be followed in patients receiving routine heparin and discontinued immediately if diminishing significantly.

Low Molecular Weight Heparin

Low molecular weight heparin (LMWH) consists of heparin molecules in a smaller range and size than LDUH. The mechanism is similar to LDUH in accelerating ATIII inactivation of Xa, but LMWH does not inactivate thrombin or bind as strongly to plasma moieties. LMWH has greater bioavailability, longer half-life, and more predictable plasma levels than LDUH. Because of this, partial thromboplastin time is not affected and does not need to be monitored.[189] Over time, accumulation of antifactor Xa activity and fibrinolysis may accumulate in patients on LMWH, especially in patients with renal failure. Compared to LDUH, LMWH has a longer half-life and may not be reversed with protamine infusion. The incidence of HIT is also lower than LDUH (2.7% vs. 0%).[190,191] Dosing regiments for LMWH are varied. In Europe, LMWH (enoxaparin) is typically dosed 20–40 mg daily. Americans tend to prefer a 30 mg BID dosing.

LMWH is at least as effective as LDUH in preventing DVT in postoperative general surgery and colorectal surgery patients. A large European trial randomized 1,351 patients undergoing abdominal surgery to LDUH or LMWH.[192] The incidence of thromboembolic complications was equal (4.7% vs. 4.3%), but patients in the LMWH group experienced fewer bleeding complications (8.3% vs. 11.8%, $p=0.03$). A meta-analysis of prospective randomized trials including over 5,000 patients confirmed these results.

Despite equal incidence of VTE, cost currently limits the use of LMWH. The Canadian Multicentre Colorectal Deep Vein Thrombosis Prophylaxis Trial attempted a cost analysis in both Canadian and US dollars for the use of LDUH and LMWH in a randomized prospective trial of 936 colorectal surgery patients.[193] Based on their findings of equal efficacy, and a trend toward more bleeding in the LMWH group, they concluded that LDUH was more cost effective. LMWH was twice as expensive as LDUH therapy. This was further supported by the National Institute of Health and Clinical Excellence who failed to note economic benefits of LMWH when compared to LDUH.[194]

Fondaparinux

Fondaparinux is a selective Factor Xa inhibitor that has been successfully used for thromboprophylaxis. A randomized controlled study comparing LMWH and fondaparinux 2.5 mg SC QD demonstrated equivalent rates of VTE, major bleeding, and death.[195] A second trial compared fondaparinux to placebo and SCD's and found that rates of VTE and DVT were significantly lower when using fondaparinux (1.7% vs. 5.3%, $p=0.004$).[196] Fondaparinux has a longer half-life than LMWH and may result in bioaccumulation in patients with altered creatinine clearance. Because of daily dosing, fondaparinux has been noted to be cost effective when compared to LMWH.[197]

VTE Prophylaxis and the Use of Epidural Analgesia

A rare but potential complication of spinal or epidural analgesia is the risk of bleeding into the spinal canal or epidural space. This may result in spinal cord ischemia and paraplegia in patients. Risk factors for the development of hematoma include high level of anticoagulation and continuous use of epidural.[198] Tryba et al.[199] estimated the overall incidence of spinal hematoma to be approximately 1:150,000 after epidural anesthesia and, in the presence of anticoagulation, it is estimated to increase to approximately 1:1,000 to 1:32,500 patients.[200,257]

Initial data in patients receiving neuroaxial anesthesia while receiving prophylactic doses of unfractionated heparin failed to show an increase in the incidence of complications in 5,528 patients.[201] However, the use of LMWH has been correlated with an increase in incidence of hematoma.[202,203] In 1998, after 40 cases of spinal hematoma were reported in 5 years, the Food and Drug Administration (FDA) released a public health advisory that anticoagulation with LMWH or heparinoids for thromboprophylaxis increases risk of developing spinal hematomas.[204] Interestingly, the increased incidence of spinal complications is noted in US patients, but not in European patients. In Europe, patients typically receive a dose of enoxaparin of 20–40 mg once per day, as opposed to US dosing of 30 mg twice per day.[205]

Current recommendations are that LDUH or LMWH and neuroaxial anesthesia can be used concurrently with appropriate caution.[171,206] Dosing guidelines, consideration and precautions are listed in Table 9-6. Currently, the American Society of Regional Anesthesia and Pain Medicine RA do not recommend dosing of fondaparinux with neuraxial anesthesia.

Duration

Although thromoboprophylaxis is traditionally terminated at the time of discharge from the hospital, the risk of DVT and PE continues. Several studies have shown a significant rate of DVT 4–6 weeks after surgery.[207,208] White et al. noted up to 66% of thrombotic events occurred following discharge[209] and Agnelli et al. found that 40% of DVT/PE events occurred more than 21 days after surgery.[210] Bergqvist demonstrated prolonged administration of LMWH significantly reduced the

TABLE 9-6. Anticoagulation and epidural analgesia

Low dose unfractionated heparin
1. Avoid in patients with underlying intrinsic or acquired coagulopathy
2. Heparin administration should be delayed for 1 h following needle/catheter placement
3. Indwelling catheters should be removed 2–4 h after last heparin dose and after evaluation of coagulation status
4. Resumption of heparin should be delayed 1 h after catheter removal
5. Monitoring of patient postoperatively for early detection of motor block

Additional recommendations for patients treated with low molecular weight heparin
1. Patients on LMWH preoperatively should wait 10–12 h from last dose before needle/catheter insertion
2. Presence of blood during needle or catheter placement does not necessitate postponement of surgery, but LMWH should be delayed for 24 h postoperatively
3. For patients on twice-daily dosing of LMWH, in-dwelling catheter should be removed prior to first dose of LMWH. First dose may be administered 2 h after catheter removal
4. For patients on once daily dosing of LMWH, first dose of LMWH may be administered 6–8 h postoperatively. The catheter should be removed 10–12 h after a dose of LMWH and subsequent dosing should occur minimum of 2 h after removal

incidence of DVT at 3 weeks and 3 months (12.0 vs. 4.8, $p = 0.02$ and 13.8% vs. 5.5% $p = 0.01$).[211] A 2009 Cochrane review of four eligible studies noted a decrease in VTE from 1.7 to 0.2% in patients receiving prolonged thromboprophylaxis; the incidence of bleeding complications was slightly but not significantly higher in the treatment groups (3.7 vs. 4.1, $p = 0.73$).[212] Based on this data, reviewers concluded that patients should undergo extended thromboprophylaxis for 1 month following surgery. Determination of which patients should receive prolonged therapy and duration of therapy will require further evaluation.

Prophylactic Perioperative Antibiotics

Significant literature has focused on the use of perioperative antibiotics for colorectal surgery. Surgical site infections account for 14–16% of all hospital acquired infection.[213] Although all antibiotics should be based on the presence of infection, culture data, and patient disease, recommendations for type and duration of antibiotics for prophylaxis of infections can now be made.

Prophylaxis is centered on the prevention of surgical wound infections. A 2009 Cochrane review evaluated 50 antibiotics used in over 180 trials and 30,000 patients.[214] Although patients who received antibiotics were less likely to develop surgical wound infections when compared to placebo (RR = 0.30, 95% CI 0.22–0.41), there was no difference for short term versus long term prophylaxis (RR = 1.06, 95%

CI 0.89–1.27) or single versus multiple doses (1.17%, 95% CI 0.67–2.05). Additional aerobic and anaerobic coverage reduced the risk of surgical wound infections (RR 0.41 and 0.55) and the use of both oral and intravenous antibiotics was superior to intravenous or oral antibiotics alone. Using these parameters, there was a 75% reduction in surgical wound infections. Further trials to establish timing and dosing were recommended.

Guidelines for perioperative antibiotics have been formalized by the Surgical Care Improvement Project, a partnership of organizations including the Centers of Medicare and Medicaid services (CMS) and US Centers for Disease Control.[215,216] Currently, there are five recommendations relevant to prevention of surgical site infections in colorectal patients (see Table 9-7).[215,216] Antibiotics should be given within a 60 min window of incision and within 2 h when using vancomycin or fluoroquinoles. Ideally, this ensures that antibiotics will be in adequate tissue concentration at the time of incision. Antibiotics given too soon may be eliminated, whereas those given too late will not be therapeutic at time of incision. An increase in preoperative timing intervals was allowed for vancomycin and fluroroquinoles secondary to longer infusion times. Prophylactic antibiotics should be discontinued within 24 h of surgery. Prolongation is costly, promotes bacterial resistance, and is without evidence of benefit to patients. Patients with documented preoperative infections should be treated appropriately and do not fall under these recommendations.

Antibiotic recommendations have been standardized and are listed in Table 9-7. Additional measures to prevent

postoperative surgical site infections include appropriate preoperative hair removal, prompt removal of urinary catheters, and immediate postoperative maintenance of normothermia (greater than 96.8°F/36°C) for colorectal patients.[217]

Postoperative Treatment of Adrenal Insufficiency

Glucocorticoids and mineralocorticoids are important in the control of hemostasis including maintenance of blood volume and normal cardiovascular function. In addition to hemodynamic changes, use of chronic steroids may have other perioperative side such as water retention, delayed wound healing, and diabetes.[218] After stress of trauma or surgery, endogenous steroids are increased up to six times from baseline to over 150 mg daily.[219] Patients with adrenal suppression or insufficiency are unable to secrete sufficient corticosteroids.

There are many causes of adrenal insufficiency including primary causes: Addison's disease, tuberculosis, and HIV; or secondary causes such as chronic exogenous administration. In addition to underlying medical illness, patients undergoing colorectal surgery may use steroids chronically as a component of treatment for their primary colorectal disorder; patients with inflammatory bowel disease are often treated acutely with steroids and steroids may be a component of oncologic treatment as well. Patients treated with steroids chronically or with primary steroid deficiencies may suffer from adrenal insufficiency during times of stress, such as surgical intervention. Any patient on doses of 5 mg prednisone for any prolonged period up to 1 year prior to surgery have traditionally been believed to be at risk of postoperative adrenal insufficiency.

In actuality, the occurrence of adrenal insufficiency in the surgical population is quite rare. Current postoperative repletion is based on two anecdotal reports in 1952 and 1953 that led to recommendations that became the standard of care.[220,221] World literature reviews by Salem and Kehlet revealed only three cases of death or hypotension attributable to perioperative adrenal crisis.[222,223] Only two randomized controlled trials, each with small numbers of patients, have results reported. Glowniak and Loriax performed a randomized control trial of 100 mg hydrocortisone versus normal daily dose of glucocorticoids plus placebo in 18 patients with an average baseline daily dose of 7.5 mg of hydrocortisone.[224] One patient in each group experienced hypotension treated with fluid resuscitation. The authors concluded that there were no significant differences between the groups and basal glucorticoid levels were sufficient to counterbalance perioperative stress. The second trial was a randomized crossover study of 20 patients undergoing dental surgery.[225] Patients were randomized to regular dose versus 100 mg hydrocortisone and the authors found no difference in hemodynamic parameters. However, both trials were criticized for limited power and sample size, and the second study was questioned in terms of stress impact of dental surgery in terms of severity of physiologic stress.

Recent systematic reviews of the literature including a 2009 Cochrane review failed to find definitive evidence that preemptive perioperative supraphysiologic dosing of steroids is necessary.[226] The Cochrane review evaluated 37 patients in the two randomized clinical trials and concluded that studies were insufficiently powered to determine whether supplemental steroids were needed. deLange and Kars determined that current perioperative steroids supplementation is not validated by review of the medical literature and recommended continuation of baseline steroids without supplementation until further trials establish further evidence.[227] Marik and Varon concluded that while most patients on exogenous steroids do not require supplementation, there was sufficient evidence to supplement patients with primary hypothalamic pituitary adrenocortical axis failure such as Addison's disease and congenital adrenal hyperplasia.[228] These patients cannot increase steroid hormone production and require 48–72 h of treatment postoperatively following major surgery.

It is important to recognize the signs of adrenal insufficiency because they may occur both in the immediate postoperative period and beyond in the event of a complication. Symptoms may include hypoglycemia, cardiovascular collapse, fatigue, abdominal pain, nausea, and vomiting. In the postoperative patient presenting with a change in intestinal function, steroid withdrawal should be considered in the at-risk population. Stelzer et al. reviewed their 60 steroid-dependent patients who underwent pouch surgery and developed signs and symptoms of a bowel obstruction.[229] They found that 43 had no objective signs of mechanical obstruction and promptly resolved their symptoms within 4 h of steroid administration. At the other extreme of intestinal function, Rai and Hemingway reported on a patient presenting with high ileostomy output responsive to steroids.[230]

Postoperative Analgesia

Analgesia following colon and rectal surgery is of paramount importance in improving patient satisfaction, early ambulation and minimizing sympathetic inhibition postoperatively. Narcotics are used to decrease pain after surgery by crossing the blood–brain barrier and binding to (mu) μ-opioid receptors within the central nervous system. However, a secondary effect of narcotics is stimulation of (mu) μ receptors in the gastrointestinal tract that contribute to inhibition of bowel function postoperatively. Narcotics have been shown to decrease peristaltic activity, delay gastric emptying and play an important role in prolonging postoperative ileus.[231] Cali et al. demonstrated a positive correlation between the amount of morphine used postoperatively and prolonged return of bowel sounds ($r=0.74$, $p=0.001$), time

to flatus ($r=0.47$, $p=0.003$) and time to bowel movement ($r=0.48$, $p=0.002$).[232]

The use of epidural analgesia was proposed to minimize systemic narcotics, decrease inflammation, and create sympathetic blockade leading to earlier return of bowel function and decreasing need for narcotics. A randomized trial of epidural analgesia by Liu et al. initially demonstrated that patients receiving local anesthetic plus opioid postoperatively had the best balance of analgesia and return of gastrointestinal function.[233] In 2000, a Cochrane review of eight studies comparing local epidural versus opioid-based regiments concluded patients receiving local anesthetic without narcotic accelerated return of gastrointestinal function with comparable postoperative pain.[234]

More recent data demonstrates equivalency in length of stay and gastrointestinal recovery for patients receiving thoracic epidural analgesia versus intravenous patient controlled analgesia (PCA). A 2001 large multicenter VA study of 1,021 patients demonstrated reduced postoperative pain scores ($p>0.01$) with thoracic epidural but no reduction in length of stay or complications rates.[235] Senagore performed a randomized trial of epidural versus PCA, using identical dietary regimens, and demonstrated similar hospital stays in both groups, 2.3 versus 2.4 days in laparoscopic cases.[236] A 2005 Cochrane review concluded pain scale ratings were higher in the PCA groups, but there was no difference in return of bowel function or length of stay.[237] This is further supported by a recent meta-analysis of 16 studies demonstrating reduced pain scores in the epidural group, slightly decreased time to return of bowel function (weighted mean difference – 1.55 days) but no change in the length of stay.[238]

Notwithstanding the lack of evidence supporting use of epidurals, many centers still use them, particularly in European enhanced recovery pathways. Zutshi noted improved epidural pain scores were not durable; pain scores were reduced at 48 h, but equivocal at discharge.[239] Patients with thoracic epidurals were more likely to experience urinary retention, pruritis, and arterial hypotension postoperatively.[238] Although costs may be lower in patients with thoracic epidurals,[239] difficulty inserting epidurals has been reported in up to 40% of patients.[240] Postoperative reduction of ileus and earlier return of bowel function are effective only with thoracic epidurals using local anesthetic alone without fentanyl,[241,242] and several studies have demonstrated that epidurals should remain in place for 48 h to maximize benefits.[233,243,244] In these cases, continuation of the epidural may prolong hospitalization, especially after laparoscopic resection.[240]

Multiple studies have investigated the use of alternative analgesic regiments to avoid the use of narcotics including ketorolac, diclofenac, and gabapentin. Nonsteroidal anti-inflammatory drugs (NSAIDs) have been shown to reduce interruption of gut motility postoperatively.[245] Ketorolac, at doses of 15–30 mg, has been demonstrated to decrease postoperative pain, the need for narcotics and time to recovery of bowel function after abdominal surgery.[246–248] Schlachta et al. performed a randomized study of patients receiving PCA versus PCA with ketorolac and found patients receiving ketorolac used less narcotics (33 mg vs. 66 mg, $p=0.011$) with improved pain control and were more likely to ambulate, and have earlier return bowel function (2.0 days vs. 3.0 days, $p<0.001$).[249] However, these improvements did not translate into a shorter postoperative length of stay. Chen et al. demonstrated similar improvements in time to bowel movement (1.8 days vs. 2.4 days, $p=0.001$), and patients receiving ketorolac were 5.25 times less likely to have postoperative ileus.[250] Cyclooxygenase-2 inhibitors have been used in postoperative pain management and to promote earlier return of bowel function but cardiac and safety concerns have limited their use in the USA.[251,253] Patients receiving a nonspecific NSAID, diclofenac, have also been shown to have lower use of narcotics postoperatively and may have earlier return of bowel function.[254] Gabapentin is an antiepileptic drug with efficacy in neuropathy, neuralgia, and neuropathic pain has been studied in multiple randomized trials. Although evidence is limited in gastrointestinal surgery, patients undergoing abdominal hysterectomy and mini cholecystectomy had reduced pain scores, opioid consumption, and incidence of nausea after receiving 600 mg of gabapentin 2 h preoperatively.[254–256]

Reducing the use of postoperative narcotics has a role in recovery of bowel function, avoiding postoperative ileus, and reduced length of stay. The use of thoracic epidural appears to reduce postoperative pain but not length of stay. Use of narcotic sparing analgesia such as ketorolac and gabapentin may help improve pain control and reduce the incidence of postoperative ileus.

Conclusion

The care of the postoperative colon and rectal surgery patient has undergone significant changes over the past 20 years. Optimization of perioperative fluids, early ambulation, timing of oral nutrition and gastric stimulation, prophylaxis for VTE, minimization of narcotics, and avoidance of postoperative ileus have led to substantial reductions in length of postoperative stay and improvements in postoperative care. A significant body of literature evaluating and testing various care options is now available. By combining care elements into standardized fast track or enhanced recovery protocols, average length of stay can be reduced without compromising complication or readmission rates. Implementing a fast track protocol requires multidisciplinary teams, with patient and provider education to be truly successful. However, patient care benefits as well as health cost savings may be substantial.[252]

Postoperative Complications

David W. Dietz

Whether practicing in a small rural hospital or a large tertiary referral center, colorectal surgeons will encounter a variety of postoperative complications. The ability to minimize, recognize, and effectively treat these problems is paramount to achieving quality outcomes for our patients. This chapter focuses on those surgical complications most often encountered by colorectal surgeons: injuries to the bowel and genitourinary structures, pelvic hemorrhage, small bowel obstruction, wound infections, abscesses, and anastomotic leaks, strictures, and bleeding.

Unrecognized Enterotomies and Enterocutaneous Fistulae

Patients undergoing extensive adhesiolysis are at the highest risk for enterotomies. An enterotomy, while a complication, can be easily and promptly managed. In cases in which any significant degree of adhesiolysis is performed, the entire bowel should be carefully inspected at the end of the procedure. Although the natural history of serosal tears is unknown, they should be repaired when recognized with imbricating seromuscular sutures. Full-thickness enterotomies can be repaired using a number of different and equally effective techniques: one common method is a two-layer closure using an inner layer of absorbable seromuscular sutures and an outer layer of permanent Lembert sutures. In cases in which multiple enterotomies have occurred within a short segment of bowel, resection of the involved segment with primary anastomosis is performed. If the mesentery has also been injured during the course of adhesiolysis, the viability of the bowel ends should be confirmed before anastomosis. Imbrication of excessive amounts of mucosa and submucosa may cause excessive luminal narrowing with subsequent obstructive symptoms. Thus, long longitudinal seromyotomies may be treated by converting them to full-thickness lacerations and closing them in a strictureplasty fashion.

Failure to recognize an enterotomy at the time of surgery will lead to one of several postoperative complications. The patient may develop peritonitis within the first 24–48 h after surgery. This problem may be difficult to detect in the background of narcotic analgesia and the surgeon and patient's expectation of postoperative incisional pain. The diagnosis is purely based on patient's appearance and examination. The usual markers of bowel perforation (leukocytosis, fever, and pneumoperitoneum) are not reliable, because they are normal findings in the early postoperative patient. A high index of suspicion should be maintained with a low threshold for reexploration. Reoperation within the first several days is usually not difficult because significant adhesions have not yet formed. Most enterotomies found in this situation can be primarily repaired, provided that the bowel edges are viable. If conditions are not favorable for primary repair, a diverting stoma should be created proximal to the repair. An especially difficult situation is that in which bilious fluid is encountered at reexploration but no enterotomy can be found. After running both the small and large bowel at least twice and excluding a duodenal, gastric, or gallbladder injury, the only remaining option may be to place drains in both paracolic gutters and the pelvis in hopes of creating a controlled enterocutaneous fistula. Insufflation of the small bowel with carbon dioxide gas through a nasogastric tube has also been described as a method for localizing small enterotomies. Gas bubbles may be seen emanating from the site of injury after the abdomen has been filled with saline.

An unrecognized enterotomy may also present as an enterocutaneous fistula, with enteric drainage emanating from the incision or wound later in the postoperative course. If there are no signs of sepsis, a nonoperative approach may be considered, especially if the patient is more than 1 week removed from surgery. Laparotomy after the first postoperative week is often extremely difficult. Dense, vascular adhesions may be encountered and there is significant risk of making the situation worse with further enterotomies or

mesenteric vascular injury. Instead, the patient is placed on complete bowel rest, a nasogastric tube is inserted, broad-spectrum antibiotic coverage is initiated, and a computed tomography (CT) scan is obtained to assess for an associated abscess or fluid collection. If a fluid collection greater than 4 cm in diameter is present, percutaneous, radiologically guided drainage should be used. If available, an enterostomal therapist should be involved to assist with pouching the fistula in order to protect the skin from irritating enteric contents. In most cases, parenteral nutrition will be started to meet the patient's caloric and protein requirements in anticipation of a prolonged period of fasting. H2 antagonists should be added to decrease gastric secretions. Somatostatin analogs may also be used to decrease the volume of fistula output, although they do not seem to increase the rate of spontaneous fistula closure.[1] The rate of spontaneous small bowel fistula closure varies but is typically less than 50%. Chances of spontaneous closure are thought to be reduced by high output because of proximal location, distal obstruction, local sepsis, radiation exposure, a short or epithelialized tract, malignancy, a foreign body in the tract such as mesh and/or sutures, Crohn's disease, and malnutrition.[2,3]

Most enterocutaneous fistulas that spontaneously close will do so within the first month. If the fistula persists, fibrin glue injection can be attempted. Several reports have been published describing this technique and successful closure has been achieved in some cases.[4–6] Although no large series exists to define the success rate, little progress is lost in making the attempt. Surgical intervention should be delayed until all sepsis has resolved, adequate nutrition has been restored, and intraabdominal adhesions have softened to the point of allowing safe reoperation. Most authors recommend a delay of at least 6 weeks since the last laparotomy, but 3–6 months may be more appropriate.[7,8] Experience has dictated that the longer one can wait until reoperation, the better. This must, of course, be balanced against the patient's medical and social condition, and their degree of patience. Appropriate management of the often highly caustic effluent including pouching by an enterostomal therapist is a very important measure.

The outcome from our department regarding the surgical management of over 200 patients with small bowel enterocutaneous fistulas was recently reported. Following the principles outlined above, the ultimate healing rate was approximately 80% with a median follow-up of 9.5 months. Most fistulas that recurred did so within the first 3 months. The only statistically significant predictor of recurrence identified was surgical technique. Fistulas that were primarily repaired recurred in 36% of cases, whereas the recurrence rate in those treated with segmental bowel resection was only 16%. There was a trend toward better outcomes with a longer interval between the index surgery and the operation for fistula repair (<3 months, recurrence rate 28%; 3–6 months, recurrence rate 15%; >6 months, recurrence rate 10%). Ninety-day operative mortality was 3.5%.[8]

Anastomotic Complications

Anastomotic complications are among the most feared in colorectal surgery. They can lead to emergent reoperation and/or a prolonged, complicated, and costly postoperative hospitalization. If the patient recovers from the acute event, chronic sequelae may develop because of stricture or pelvic fibrosis leading to poor bowel function and the possibility of further revisionary surgery or permanent fecal diversion.

Anastomotic complications are usually related to technical factors such as ischemia, tension, poor technique, stapler malfunction, or preexisting conditions such as local sepsis, poor nutrition, immunosuppression, morbid obesity, and radiation exposure. The contribution of the former set of variables may be minimized by a careful, methodical approach to construction of the anastomosis (Table 10-1). For colorectal anastomoses, a tension-free anastomosis may be achieved by full division of the lateral attachments of the descending colon, complete mobilization of the splenic flexure, high ligation of the inferior mesenteric artery (IMA), separation of the omentum from the distal transverse colon and mesocolon, and division of the inferior mesenteric vein (IMV) at the lower edge of the pancreas. Adequate blood supply should be confirmed by cutting across the marginal artery or bowel wall with anything less than pulsatile bleeding considered unacceptable. Further colon resection should be performed until adequate bleeding is encountered. If necessary, anastomoses between the hepatic flexure or distal ascending colon and rectum are easily achieved by passing the colon through a window in the mesentery of the terminal ileum.

Nutritional status, degree of immunosuppression, and general medical condition should be considered when deciding whether or not to perform a primary anastomosis. If severe malnutrition (albumin <2.0 or weight loss >15%) or significant immunosuppression (chemotherapy, high-dose steroids, antitumor necrosis factor drugs) are present, either an endcolostomy and Hartmann stump or a proximal loop ileostomy will minimize the risk of complications. Stoma takedown can then be performed if and when these factors have been corrected. A 3-month waiting period is advised for closure of a

TABLE 10-1. Steps to minimize risk of leak from colorectal or coloanal anastomoses

1. Ensure good blood supply (pulsatile bleeding from marginal artery at level of anastomosis)
2. Ensure tension-free anastomosis by complete mobilization of splenic flexure (includes high ligation of inferior mesenteric artery and ligation of inferior mesenteric vein at lower border of pancreas)
3. Avoid use of sigmoid colon in creation of anastomoses
4. Inspection of anastomotic donuts for completeness after circular stapled anastomoses
5. Air or fluid insufflation test to rule out anastomotic leak immediately after construction in the operating room

loop ileostomy. Laparotomy for takedown of an end stoma is generally deferred for 6 months. Preoperative weight loss, if able to be accomplished by the morbidly obese patient, will make the construction of deep pelvic anastomoses easier. When operating in the radiated pelvis, one end of the bowel used to construct the anastomosis should come from outside the field of radiation.[9] The double-stapled technique and other intersecting staple lines may have a higher predisposition to leak than a single stapled or hand sutured anastomosis.

Bleeding

Anastomotic bleeding is common and varies greatly in severity. In most cases, bleeding is minor and is manifested by the passage of dark blood with the patient's first bowel movements after surgery. In rare instances, bleeding can be significant and require transfusion and active intervention.

Bleeding can occur after either stapled or hand-sewn anastomoses, but is probably more common with the former. This complication can be reduced by careful inspection of the staple line, particularly in the case of side-to-side/functional end-to-end anastomoses. Before closing the enterotomy through which the stapler was introduced, the linear staple line can be everted and inspected. Routine intraoperative endoscopy after the construction of coloanal or colorectal anastomoses may allow intraoperative rather than postoperative control of bleeding.[10] Bleeding points should be controlled with sutures rather than cautery to prevent a deep burn injury which may lead to delayed leak. The incidence of bleeding from the linear staple line can be minimized by using the antimesenteric borders of each limb to construct the anastomosis, thus avoiding inclusion of the mesentery in the staple line. Alternatively, full-thickness staple line reinforcement may be undertaken with interrupted sutures to ensure optimal hemostasis.

Bleeding from circular stapled anastomoses or from the staple lines of ileal or colonic J pouches is usually not diagnosed until after the patient has left the operating room. After performing proctoscopy to evacuate clot from the rectum or neorectum, a rectal tube is inserted and a 1:100,000 solution of saline and epinephrine is instilled. The tube is then clamped for 15 min. If bleeding persists after the solution is allowed to drain, the procedure may be repeated. If bleeding continues or hypotension develops, the patient should be returned to the operating room for transanal examination of the anastomosis or pouch under anesthesia. Bleeding from anastomoses that are not accessible using these techniques, such as ileocolic or enteroenteric, may be managed with supportive care and correction of any underlying coagulopathy. If bleeding is severe, angiography may be required to localize the site and allow selective infusion of vasopressin. Alternatively, colonoscopy may be used. If the anastomosis can be visualized, the bleeding site can be treated with either cautery, injection of epinephrine, or endoscopic clips. In rare cases, reoperation with oversewing or resection of the bleeding anastomosis may be required.

Leaks

The incidence of anastomotic leak varies widely and is related to the factors listed above as well as the type of anastomosis. The lowest leak rates are seen after small bowel or ileocolic anastomosis (1–3%), whereas the highest occur after coloanal anastomosis (10–20%). Vignali et al. reported on 1,014 colorectal anastomoses.[11] The overall clinical leak rate was 2.9%. The incidence of leak was strongly associated with the distance of the anastomosis from the anal verge. Eight percent of low anastomoses (<7 cm from anal verge) leaked compared with only 1% of high anastomoses (>7 cm from anal verge). Although diabetes mellitus, use of a pelvic drain, and duration of surgery were each related to anastomotic leak in the univariate analysis, only low anastomosis was predictive in the multivariate model. Again, this higher leak rate may be related to the double stapling technique.

Another high-risk anastomosis is the ileal pouch-anal anastomosis. Leak rates of 5–10% have been reported.[12–14] Data from series of ileal pouch-anal anastomosis in patients with ulcerative colitis identify immunosuppressive drug therapy as a significant risk factor. Prednisone >40 mg/day and antitumor necrosis factor alpha agents have both been shown to increase the risk of ileal pouch-anal anastomotic leaks and pelvic sepsis in some studies.[15,16]

Role of Fecal Diversion

The creation of a proximal diverting stoma minimizes the severe consequences of an anastomotic leak but it does not reduce the incidence of leak itself.[17–19] A diverting stoma should be considered for any high-risk anastomosis [coloanal, low colorectal (<6 cm from anal verge), ileoanal]. In addition, patient factors such as severe malnutrition, significant immunosuppression, hemodynamic instability, excessive intraoperative blood loss, and purulent peritonitis or pelvic sepsis should be considered as indications for diversion (Table 10-2). Consideration should also be given to the patient's comorbidities and general condition; in cases in which the "physiologic reserve" necessary to tolerate an anastomotic leak does not exist, the use of a proximal stoma should be strongly entertained even if other risk factors are not present. Neoadjuvant radiation therapy does not seem to increase the incidence of anastomotic leak in patients undergoing restorative proctectomy for rectal cancer[20,21] but this may be because of the tendency for surgeons to cover these anastomoses with a proximal stoma, thus reducing the clinical manifestations of a leak. In fact, recent data from a large randomized trial assessing the efficacy of short-course neoadjuvant radiation therapy in rectal cancer found that a protecting stoma reduces the need for surgical intervention

TABLE 10-2. Indications for a diverting loop ileostomy

1. Coloanal or low colorectal anastomosis (<6 cm from anal verge)
2. Ileoanal anastomosis
3. Severe malnutrition
4. Significant immunosuppression (i.e., prednisone >40 mg/day, anti-TNF agents)
5. Hemodynamic instability
6. Excessive intraoperative blood loss
7. Purulent peritonitis
8. Pelvic sepsis
9. Neoadjuvant therapy

should an anastomotic leak occur.[22] When in doubt it is definitely safer to divert than to avoid diversion.

Role of Pelvic Drains

The use of pelvic drains is controversial. Whereas surgeons have long believed that preventing the collection of fluid or hematoma in the pelvis minimizes the risk of anastomotic leak, the use of drains has not been shown to be of benefit or harm in a recent, large randomized study[23] and in a metaanalysis.[24] However, examination of the data from the Dutch TME trial showed that the use of pelvic drains reduced the incidence of clinical anastomotic leak after short-course neoadjuvant radiation therapy from 23 to 9%. In the absence of data suggesting harm, the author routinely drains low colorectal or coloanal anastomoses, especially after neoadjuvant therapy.

Diagnosis and Management of Anastomotic Leak

Anastomotic leaks can be divided into "free" and "contained" varieties. Free leaks are those in which fecal contents leak from the anastomosis and spread throughout the abdominal cavity. Patients usually present with fever, tachycardia, leukocytosis, and diffuse peritonitis. Feculent fluid may present itself through the surgical incision or via the pelvic drains. Hypotension and other signs of systemic sepsis may ensue. If the patient is stable, radiologic investigation may be helpful to localize the leak and to determine its size and severity, although this is usually readily apparent at laparotomy. Radiographic studies, however, should not be allowed to delay reoperation.

Patients with "free" leaks should be taken to the operating room after fluid resuscitation and administration of broad-spectrum intravenous antibiotics. Surgical treatment will be dictated by the findings at operation. Most leaking colorectal anastomoses will require abdominal washout and takedown of the anastomosis with creation of an end-colostomy and Hartmann stump. If the stump cannot be stapled or sutured closed because of the friability of the tissues, transabdominal pelvic and per-anal drains should be placed. However, leaking ileocolic or small bowel to small bowel anastomoses can occasionally be repaired primarily in carefully selected circumstances, i.e., small defect with viable edges. However, resection of the anastomosis with either reconstruction or creation of a stoma is the most conservative option. Placing the repaired anastomosis directly under the midline incision will usually result in an enterocutaneous fistula rather than a second bout of peritonitis should the repair fail. If the viability of the bowel ends is questionable, takedown of the anastomosis and creation of a stoma is mandatory. Small defects in colorectal anastomoses may also, under ideal circumstances, be repaired primarily and covered with a proximal ileostomy. This is contraindicated, however, if there is a significant fecal load present between the ileostomy and the site of repair. Despite recent trends, mechanical bowel preparation for left-sided colorectal resections may still be wise for this reason alone.

Creating a stoma in the setting of an anastomotic leak can be particularly challenging. Severe peritonitis with a thickened and rigid mesentery may make it difficult to create an end-colostomy in the conventional manner. If a stoma does not reach skin level through an aperture away from the midline incision, two options exist. The first is to create a "loop-end" stoma. This often provides extra mesenteric length and also has better blood supply than a traditional end stoma. The second option is to bring the stoma up to the skin through the upper aspect of the midline wound. While this may present pouching difficulties for the patient, it is sometimes the only alternative in cases of intraabdominal catastrophe. Simply wrapping the exteriorized bowel with gauze and then performing delayed maturation of the stoma in 5–7 days will ensure viability of the stoma and insure against complete mucocutaneous separation and retraction.

"Contained" leaks are those in which the extravasation of contrast material is limited to the pelvis and usually result in the development of a pelvic abscess (Figure 10-1). If the abscess cavity is small and contrast flows freely back into the bowel, the patient may be treated with intravenous antibiotics, bowel rest, and observation. If the abscess is larger or somewhat removed from the site of the anastomosis, then percutaneous abscess drainage using CT or ultrasound guidance may avoid laparotomy. Such leaks rarely require immediate operation for fecal diversion, but surgery may eventually be required if the patient is left with a cutaneous fistula, anastomotic stricture, or chronic presacral cavity as a consequence.

Fistulae

Anastomotic leaks may also result in fistulae to the skin, vagina, male genitourinary system, or chronic presacral abscess (presacral sinus). Colocutaneous fistulae will frequently close with conservative management consisting of either bowel rest with total parenteral nutrition or a low residue diet and pouching
FIGURE 10-1. Pelvic abscess resulting from ileocolic anastomotic leak (*white arrow*). Extravasated enteric contrast can be seen in the right pelvis tracking down toward the abscess.

FIGURE 10-2. Gastrografin enema demonstrating chronic presacral sinus in a patient after ileal pouch-anal anastomotic leak.

of the fistula to protect the surrounding skin. If drainage persists, reoperation for fistula takedown and reconstruction of the anastomosis can be performed after a delay of 3–6 months. Patients can usually eat a normal diet during this time period to maintain nutritional status. Fibrin glue injection has been reported as a successful alternative to surgery.[6]

Colovaginal fistulae are usually the consequence of either an anastomotic leak necessitating through the vaginal cuff in a patient who has undergone a prior hysterectomy or the inadvertent inclusion of the vagina during creation of a stapled anastomosis. In either case, spontaneous closure is rare. If the vaginal drainage is copious and intolerable to the patient, proximal fecal diversion may be necessary. An alternative measure to avoid a stoma during the period of fistula maturation is to use a large-volume daily enema to evacuate the colonic contents at a predictable time each day. After a waiting period of 3–6 months, reoperation may be performed. Options include attempts at local repair using advancement flaps (colonic or vaginal)/sleeve advancements, tissue interposition (labus majorum or gracilis), or laparotomy with redo coloanal anastomosis.

Chronic presacral abscess or sinus may result from a posterior leak from a coloanal or ileal pouch-anal anastomosis. Patients may have an occult presentation consisting of vague pelvic pain, fevers, frequency of stool, urgency, and bleeding. A pelvic CT scan usually shows presacral inflammatory changes and a contrast enema confirms the presence of a sinus tract originating from the posterior midline of the anastomosis and extending cephalad into the presacral space (Figure 10-2). Examination under anesthesia can then be performed with careful inspection of the anastomosis. A probe or clamp is placed through the anastomotic defect and the chronic presacral cavity is simply lain open using

cautery and gently curetted of granulation tissue. An alternative to using cautery is to open the sinus with a laparoscopic linear cutting stapler to divide the luminal-cavity septum. Either method allows free drainage of the presacral abscess and healing by secondary intention. This may result in a chronic posterior sinus or "pseudo-diverticulum." Successful management of an anastomotic sinus or chronic cavity has been described in Europe with an endoscopically placed vacuum-sponge device. A Dutch multicenter experience included 16 patients with early and late sinuses.[25] Closure was obtained in 11 of the 16 patients at a mean of 40 days and a median of 13 sponge replacements. If these approaches fail, then a redo coloanal anastomosis may be considered.

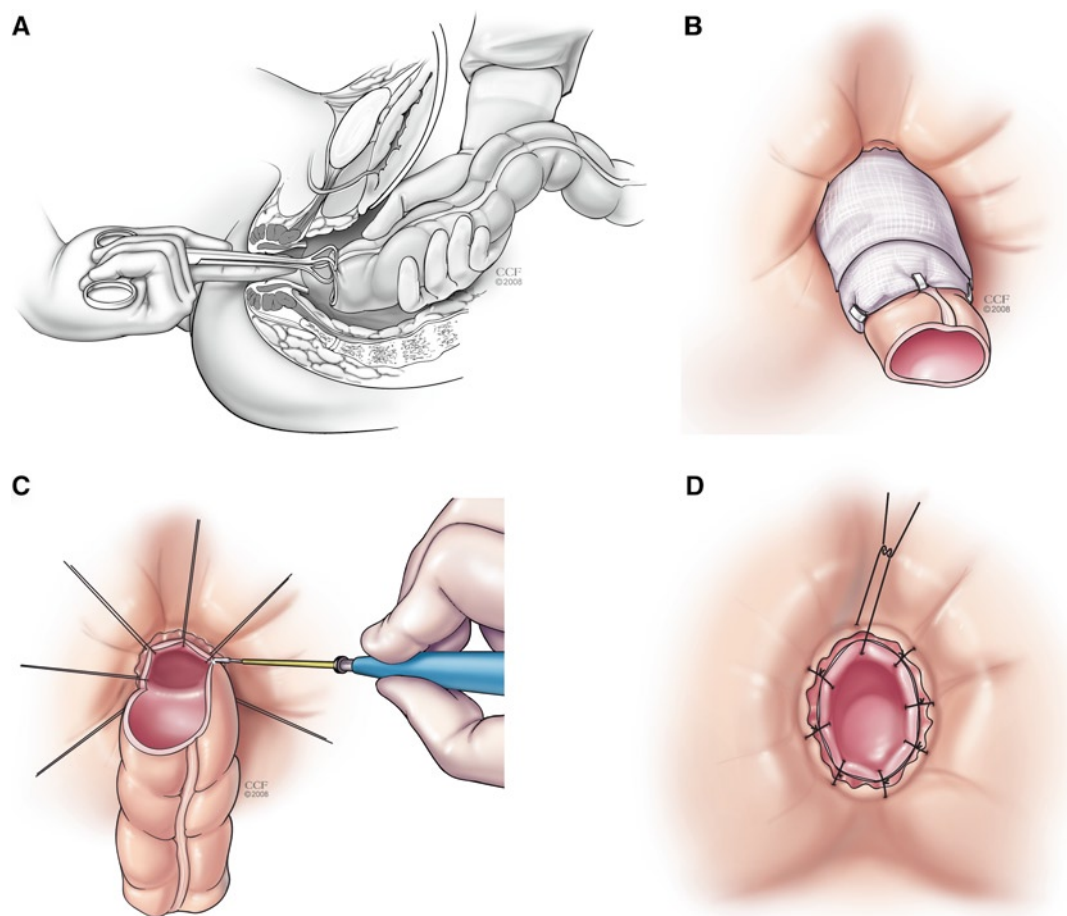
An especially useful, but not widely known, operation that can be employed in these situations is the "Turnbull–Cutait" abdominoperineal pull-through procedure. This operation was devised and reported on by Turnbull, Cutait, and Bacon, among others.[26–28] The technique involves two stages. In the first stage, after the failed coloanal anastomosis has been resected and pelvic sepsis debrided, the mobilized descending colon is brought through the anal canal and exteriorized to the extent that it can be wrapped with gauze to secure it in place. Five to ten days later, the patient is returned to the operating room for the second phase where the exteriorized portion of colon is excised and the delayed coloanal anastomosis is performed by a perineal approach (Figure 10-3A–D). Remzi et al.[29] have recently reported our experience with this procedure in 67 patients, mostly for salvage of pelvic anastomotic


FIGURE 10-3. **A–D** Turnbull–Cutait abdominoperineal pull-through procedure.

complications (recto-vaginal and -urethral fistulas, strictures, presacral abscess, etc.). The procedure was successful in 75% of patients. Bowel function was felt to be satisfactory by most patients and was comparable to a matched group undergoing primary coloanal anastomosis for rectal cancer.

Stricture

Anastomotic stricture may be the end result of anastomotic leak or ischemia. It typically presents 2–12 months after surgery with increasing constipation and difficulty evacuating. If the initial resection was done for malignancy, recurrence as a cause of the stricture must be excluded with a combination of CT scan and fluorodeoxyglucose–positron emission tomography (PET) scan. Biopsy is mandated if a mass or abnormality is identified. Low colorectal, coloanal, or ileal pouch-anal anastomotic strictures may be successfully treated with repeated dilatations using an examining finger or rubber dilators. Dilatation is more successful if initiated within the first few weeks after surgery. In fact, almost all coloanal or ileoanal anastomoses stricture to some degree during the early

postoperative period, especially if a diverting stoma is present. All such anastomoses should undergo digital examination at 4–6 weeks after surgery and just before stoma closure (usually at 2–3 months). Strictures are usually soft and easily dilated during these examinations. Higher colorectal, colocolic, or ileocolic strictures may be approached using endoscopic balloon dilatation (Figure 10-4). If these measures fail, or if the stricture is extremely tight or long, revisionary surgery may be required. These are difficult operations, however, because of the pelvic fibrosis that develops after anastomotic leak and complications are common. In some cases, permanent fecal diversion is the only option.[30,31]

Genitourinary Complications

Ureteral Injuries

Injury to the ureters typically occurs at one of four specific points during pelvic intestinal surgery. The first is during high ligation of the IMA where the junction between the upper and middle thirds of the left ureter lies in close
FIGURE 10-4. Endoscopic balloon dilatation of a colorectal anastomotic stricture: **A** 5-mm colorectal anastomotic stricture, **B** balloon dilator inflated, **C** result.

proximity to the vessels. Failure to mobilize the ureter laterally before ligation of the IMA may result in its inclusion with the vascular pedicle when clamped and subsequent division. It is good practice to always confirm the position of the left ureter before and after applying clamps to the IMA and before division of the vessel. Injury at this level is usually limited to transection and can be repaired primarily using an end-to-end, spatulated anastomosis performed over a stent. The second point of danger is during mobilization of the upper mesorectum near the level of the sacral promontory. It is at this point that the ureters cross over the bifurcation of the iliac artery and course medially as they enter the pelvis. The left ureter may be closely associated with the sigmoid colon and can even be adherent secondary to prior inflammatory processes. The injury may be tangential

and not readily recognized in the setting of a phlegmon or abscess. Ureteral stents in this setting are most beneficial in identifying the injury rather than preventing it. Injury at this level is usually managed by either primary repair or ligation of the distal stump and creation of a ureteroneocystostomy with a Boari flap or psoas hitch repair.

The third point of risk is during the deepest portion of the abdominal phase of the operation. Anterolateral dissection in the plane between the lower rectum, pelvic sidewall, and bladder base can result in ureter injury at the ureterovesical junction. The ureter may also be injured at this level during division of the lateral stalks. The final area of risk is during the most cephalad portion of the perineal phase of the operation. If exposure is limited (obese patient, android pelvis), the ureter may be unknowingly divided near the ureterovesical

junction. In either of these circumstances, the injury can be managed by creating a ureteroneocystostomy. The ureter is reimplanted into the bladder by tunneling the ureter through the bladder wall and creating a mucosa to mucosa anastomosis.

Should ureteral injury occur, the key to minimizing its consequence is immediate (intraoperative) recognition and repair of the injury. In cases in which a difficult pelvic dissection is anticipated, because of prior pelvic surgery, inflammation, or a locally advanced tumor, the preoperative placement of ureteral stents can be invaluable. Although the literature does not demonstrate that stents prevent ureteral injuries, palpation of the stents can aid in localization of the ureters and can also facilitate identification and repair should injury occur. In cases in which the surgeon is suspicious of occult injury, indigo carmine can be administered intravenously. After several minutes, the urine turns blue-green and the operative field can then be inspected for staining. Unfortunately, the literature suggests that less than 50% of ureteral injuries are identified intraoperatively, usually because the injury is not suspected. Ureteral stents should be used selectively, however, because their use can lead to complications such as obstruction secondary to hematoma, perforation, or acute renal failure. As is the case with all complications, it is far better to avoid them than to treat them; Specifically in this instance, if there is a premonition of significant anatomic distortion at one or more of the points of potential ureteric injury then intraoperative ureteric catheterization should be undertaken. These settings typically include patients with recurrent Crohn's disease, chronic diverticulitis, leaked pelvic anastomoses, and pelvic irradiation.

Urethral Injuries

Iatrogenic injury to the urethra occur during abdominoperineal resection (APR) or total proctocolectomy. The injury typically occurs during the perineal portion of the procedure and usually involves the membranous or prostatic portion. Intraoperatively, urethral injury may be recognized by visualization of the bladder catheter through the defect. These injuries may be difficult to avoid in the presence of a large, deeply penetrating anterior tumor in which the involvement of the prostate gland can occur. Desmoplastic reaction to the tumor or edema from neoadjuvant radiation therapy may also obscure anatomic planes. Small injuries can be repaired at the time of surgery using 5-0 chromic sutures with the Foley catheter left in place to stent the repair for 2–4 weeks. Larger injuries or those not presenting until the postoperative period (urine draining from the perineal wound) require proximal urinary diversion via suprapubic catheter and delayed repair. This should be performed by a skilled urologist with experience in urethral reconstruction and typically utilizes a gracilis muscle flap. If the patient is deemed at high risk for a urethral injury the intraoperative placement of a large diameter bladder catheter may be useful to avoid the injury.

Bladder Injury

Bladder injuries are relatively frequent and are, in most cases, related to resection of an adherent rectosigmoid tumor or diverticular phlegmon. When created purposefully or recognized immediately, defects in the bladder dome are easily repaired in two layers with a Foley catheter then left in place for 7–10 days postoperatively. Before removal, a cystogram may be obtained to confirm healing. Injuries to the base of the bladder are more problematic. The major risk of repair in this situation is occlusion of the ureteral orifice at the trigone. Most urologists advocate opening of the bladder dome to gain access to the bladder lumen with subsequent repair of the trigone injury under direct vision from the interior. Ureteral patency is confirmed at the conclusion of the repair before closing the cystotomy. Injuries not recognized at the time of surgery will present in the postoperative period with urine in the abdominal cavity, pneumaturia, or fecaluria. Initially, fecal and urinary diversion may be necessary to temporize the situation until reoperation can be safely performed. At that time, takedown of the colovesical fistula can be performed with primary repair of the bladder. If available, omentum may be interposed between the bladder repair and any bowel anastomosis. Regardless of whether or not a repair was undertaken, catheter drainage of the bladder is maintained for 1–2 weeks after which a cystogram is performed to confirm integrity of the repair prior to catheter removal.

Urinary Dysfunction

Urinary dysfunction is one of the most common urinary complications of APR.[32] Some degree of voiding difficulty occurs in up to 70% of patients after APR, but it is usually confined to the early postoperative period. In most instances, urinary retention is the result of denervation of the detrusor muscle causing partial paralysis. Bladder contractility is under parasympathetic control via pelvic nerve branches originating from the inferior hypogastric plexus. These nerves can be injured if the endopelvic fascia is breached, especially during blunt dissection of the rectum. Temporary dysfunction of these nerves is nearly universal after APR, even when a meticulous sharp dissection is used. Most patients, however, only require maintenance of a bladder catheter for 5–7 days postoperatively. In a small percentage of patients, the problem persists beyond several months and urologic consultation is required. A small percentage of these patients may require prostatectomy or even intermittent self-catheterization on a long-term basis.

Sexual Dysfunction

Recent series report an incidence of sexual dysfunction of 15–50% in male patients undergoing APR for rectal cancer.[33–35]

This wide range is likely attributable to several factors such as patient age, preoperative libido, use of adjuvant radiation therapy, varying definitions of dysfunction, time point of follow-up, and social barriers preventing a frank discussion of the problem. The type of dysfunction is dependent on the pattern of nerve injury. Damage to the superior hypogastric (sympathetic) plexus during high ligation of the IMA or to the hypogastric nerves at the sacral promontory during mobilization of the upper mesorectum results in ejaculatory problems such as retrograde ejaculation. This is the most common type of sexual dysfunction seen in male patients after APR and is also the type most likely to resolve with time (6–12 months). Damage to the pelvic plexus during the lateral dissection or to the nervi erigentes or cavernous nerves while dissecting the anterior plane (abdominal or perineal phase) may result in erectile dysfunction. The cavernous nerves arise from branches of the pelvic plexus and course anterior to Denonvillier's fascia at the lateral border of the seminal vesicles. Parasympathetic innervation from these routes controls the inflow to and retention of blood within the corpora cavernosa. The important anatomic relations of the pelvic nerves are illustrated in Figure 10-5.

Risk of injury to these nerves may be reduced by tailoring the anterior dissection based on the location of the tumor. The highest risk of parasympathetic nerve injury occurs when dissection is performed in the plane anterior

to Denonvillier's fascia and flush with the posterior aspect of the seminal vesicles and prostate. Whereas some believe that this plane is a vital part of total mesorectal excision for any low rectal cancer, others will only include Denonvillier's fascia in the resection specimen for an anterior tumor where it may help obtain a clear radial margin.[36] For posterior tumors, Denonvillier's fascia is preserved by dissecting between it and the fascia propria of the rectum in order to protect the small cavernous nerves. Using a "nerve sparing" approach to total mesorectal excision, several authors have reported an incidence of erectile dysfunction of 5–15% after proctectomy for rectal cancer. Factors shown to increase risk are older age, poor preoperative libido, and low rectal tumor requiring APR (two- to threefold increase compared with low anterior resection).

Sildenafil has been shown to be an effective treatment for male patients suffering from erectile dysfunction after proctectomy. A randomized, double-blind, placebo-controlled trial by Lindsey and Mortensen[37] found that the treatment with sildenafil completely reversed or satisfactorily improved erectile dysfunction in 79% of patients, compared with 17% in the placebo group. Side effects were mild and well tolerated.

Although harder to quantify, sexual dysfunction also occurs in women after proctectomy. It is characterized by dyspareunia and inability to produce vaginal lubricant and achieve orgasm. The incidence is lower than that seen in males and varies between 10 and 20%.[35,38,39]
Female Infertility

Several recent studies have documented decreased fertility in women who have undergone restorative proctocolectomy for ulcerative colitis or familial adenomatous polyposis.[40,41] The postoperative infertility rate exceeds 50% in this group when defined as "one year of unprotected intercourse without conception." This has important implications in both preoperative patient counseling and in the modification of operative technique to minimize the effect of pelvic adhesions on fertility. Women of childbearing age should be informed of this potential complication before elective restorative proctocolectomy because it may influence the timing of surgery. In addition, because pelvic adhesions are thought to interfere with egg transit from the ovary to the fallopian tube, measures to minimize their occurrence may be of benefit. Tacking the ovaries to the anterior abdominal wall outside of the pelvis and wrapping the adnexa with an antiadhesion barrier sheet are frequently used techniques but there are no data to support their efficacy.

Trapped Ovary Syndrome

Trapped ovary syndrome is a fairly common complication after restorative proctocolectomy in young women (Figure 10-6).

FIGURE 10-5. Anatomic relations of the pelvic nerves. Damage to the superior hypogastric plexus during high ligation of the inferior mesenteric artery (IMA) or to the hypogastric nerves at the sacral promontory during mobilization of the upper mesorectum results in retrograde ejaculation. Damage to the pelvic plexus during the lateral dissection or to the nervi erigentes or cavernous nerves while dissecting the anterior plane may result in erectile dysfunction.

FIGURE 10-6. CT scan demonstrating "trapped" ovary in the right pelvis.

The adhesions that form after ileal pouch-anal anastomosis trap the ovaries in the pelvis and cover the fallopian tubes. With each ovulatory cycle, there is release of fluid into the pelvic cavity defined by these adhesions. As fluid accumulates and the cavity expands, patients will complain of pelvic or lower abdominal pain relevant to the side of the trapped ovary. A CT scan or ultrasound reveals a cystic lesion in the pelvis containing no air and with no surrounding inflammatory reaction. Operative findings are a cyst containing clear or tan fluid, surrounded by adhesions and with the ovary attached. Treatment consists of unroofing and evacuation of the cyst, pelvic adhesiolysis, and suspension of the ovary to the pelvic brim or iliac fossa with sutures. Trapped ovary syndrome may be prevented by suspending the ovaries at the time of restorative proctocolectomy and by placing an adhesion barrier film in the pelvis.

Small Bowel Obstruction

Perhaps the most critical components in the management of patients with bowel obstruction are the recognition and prevention of the disastrous effects of bowel ischemia. Timely surgical intervention, before the development of transmural necrosis, will limit complications and improve outcome. In one recently published series of more than 1,000 patients undergoing surgery for small bowel obstruction, nonviable strangulated bowel was present at laparotomy in only 16% of cases but the risk of death in this group was increased fourfold.[42] It is also important to distinguish between early (<30 days) and late postoperative small bowel obstruction.

Presentation and Diagnosis

Nausea and vomiting, colicky pain, abdominal bloating, and obstipation are the hallmark signs of small bowel obstruction. The degree to which each of these contributes to the clinical picture will depend on the location, degree, and duration of the obstruction.

The commonly regarded hallmarks of strangulated bowel are fever, tachycardia, leukocytosis, sepsis, peritoneal signs, and the presence of continuous as opposed to intermittent pain. If any of these are found, the suspicion of ischemia should be high. These signs may also be found in patients without strangulation and are, therefore, nonpathognomonic. In many cases, however, this determination is not made until laparotomy, and timely surgical intervention in symptomatic patients may be the best means of avoiding the progression to bowel ischemia. This fact is underscored by a report from Sarr et al.[43] who found that the traditional clinical parameters frequently used to predict strangulation were neither sensitive nor specific. Nearly one-third of patients with strangulation were not diagnosed until the time of surgery.

Radiographic Studies

Plain Radiographs

An acute abdominal series is the initial imaging study performed in most patients suspected of having small bowel obstruction and consists of both upright and supine abdominal films and an upright chest X-ray. Typical findings include dilated, air-filled loops of small bowel, air-fluid levels, and an absence or paucity of colonic air. These findings may be absent, however, when the obstruction is proximal or the dilated bowel loops are mostly fluid filled. The sensitivity of plain radiographs in detecting small bowel obstruction is approximately 60%. The findings of pneumatosis intestinalis or portal vein gas are worrisome for advanced bowel ischemia.

CT Scan

Abdominopelvic CT scanning is increasingly used as a primary imaging modality in patients suspected of having small bowel obstruction. In addition to establishing the diagnosis, CT may also be able to precisely define a transition point and reveal secondary causes of obstruction such as tumor, hernia, intussusception, volvulus, or inflammatory conditions such as Crohn's disease and radiation enteritis. CT may also reveal closed loop obstructions or signs of progressing ischemia such as bowel wall thickening, pneumatosis, or portal vein gas. Several studies have shown that the sensitivity of CT in diagnosing small bowel obstruction approaches 90–100%.

Contrast Studies

Contrast studies using water-soluble agents are frequently used in patients with acute small bowel obstruction. In patients with distal small bowel obstruction, a contrast enema is an efficient means by which colonic obstruction can be excluded. Antegrade studies of the small bowel can help to differentiate partial from complete obstruction, and may therefore predict the need for surgical intervention. In fact, some authors have used small bowel contrast studies as a "screening test" for patients presenting with adhesive obstructions. Failure of contrast material to reach the colon by 24 h is used as an

indication for prompt surgical exploration. Several studies have also shown that the antegrade administration of contrast agents may speed the resolution of partial small bowel obstruction, presumably through an osmotic effect. However, conflicting data also exist and the therapeutic effects of the small bowel contrast study remain to be defined.

Initial Therapy and Nonoperative Management

Once the diagnosis of small bowel obstruction is made, the patient is admitted to the hospital. Those with peritonitis, perforation, or signs of ischemic bowel are immediately prepared for laparotomy with expeditious correction of fluid and electrolyte deficits. A urinary catheter is inserted to guide resuscitation with the end points being resolution of tachycardia and hypotension and/or achieving a urine output of at least 0.5 cm^3/kg/h. Broad-spectrum antibiotics are initiated. A nasogastric tube is inserted preoperatively to decompress the stomach, because these patients are at risk for aspiration on induction of general anesthesia.

If signs of perforation or ischemia are not present, a trial of expectant management may be undertaken. Patients with partial small bowel obstructions secondary to adhesions will resolve with a nonoperative approach in 80% of cases.[44–46] The success rate for patients initially presenting with complete obstruction is significantly lower. The nonoperative management of small bowel obstruction consists of fluid and electrolyte replacement, bowel rest, and tube decompression. The debate between standard nasogastric tube vs. long nasoenteric tube decompression has mostly settled in favor of the nasogastric tube. This is in part attributable to the fact that long tubes with mercury-weighted tips (Miller-Abbott) are no longer available for use (because of concern about the elemental Mercury) and have been replaced with a balloon-tipped tube (Gowen tube) that requires endoscopic placement. Long tubes are more difficult to place, requiring special expertise, serial radiographic studies, or endoscopy to guide insertion. There has been some recent resurgence in interest in the use of nasoenteric tubes, mostly among radiologists. Indications for long tube management of small bowel obstruction include early postoperative obstruction and recurrent partial obstruction where the transition point is difficult to identify on contrast studies.

Narcotic analgesics may be administered to comfort the patient, but not to the point of diminishing mental status. The practice of withholding pain medication to avoid masking the signs of perforation or ischemia is probably unnecessary. Serial abdominal examinations (ideally just before the next dose of analgesics) should be performed to assess for increasing tenderness or the presence of peritoneal signs. Any change in the patient's condition that suggests developing bowel ischemia mandates exploratory laparotomy. In general, a nonoperative course may be followed for 24–48 h. If the obstruction has not resolved within that time period, it is unlikely to do so and laparotomy is advised.

Decision to Operate

Several studies have attempted to define certain criteria that would reliably predict the presence or absence of strangulated bowel. Unfortunately, none have been shown to be particularly accurate and the best tool remains sound clinical judgment. Certainly, patients with fever, peritonitis, pneumoperitoneum, or overt sepsis should undergo emergent laparotomy because these are hard signs of transmural bowel necrosis. The presence of early ischemia, however, is much more difficult to discern. It is not uncommon for patients with small bowel obstruction to present with tachycardia, relative hypotension, mild acidosis, and leukocytosis, all of which may be secondary to dehydration. These patients should be aggressively rehydrated with isotonic intravenous fluids and the above parameters should be reassessed. Persistence of any of these signs after fluid resuscitation should prompt immediate laparotomy. Adherence to this simple algorithm should minimize the progression to strangulation while limiting the number of unnecessary laparotomies.

Distinguishing between partial and complete obstruction is also a key element in deciding which patients should be taken for early operation. As stated above, the likelihood of resolution of a complete obstruction with expectant management is low (20%). Delaying operative therapy until after a nonviable strangulation or perforation has occurred will substantially increase the mortality rate. Although this distinction may be difficult to make clinically, there are some useful caveats. The passage of stool or flatus cannot be relied on as an accurate predictor because patients with complete obstruction may continue to pass stool and flatus until the bowel distal to the site of obstruction is evacuated. However, if bowel function continues for more than 12 h after the onset of obstructive symptoms, the likelihood of complete obstruction is diminished. The passage of large volumes of nonbloody, watery stool along with vomiting and distension is pathognomonic for partial small bowel obstruction. The onset of flatus, however, usually signals the beginning of resolution of the obstruction because flatus is produced from swallowed air.

Surgical Technique

After the adequacy of resuscitation is confirmed and broad-spectrum antibiotics active against enteric pathogens are administered, the peritoneal cavity is entered through a midline incision. This is a point in the operation where the risk of inadvertent enterotomy is very high because bowel loops are distended and often adherent to the undersurface of the abdominal wall. Once the fascia is encountered, the application of gentle pressure with the bevel of the scalpel blade, rather than a cutting stroke, is used to breach the peritoneal cavity. Using this technique, it is usually possible to recognize an adherent bowel loop before enterotomy occurs.

In the most favorable scenario, a single constricting band will be encountered that can be sharply divided to relieve the obstruction. In the worst cases, the peritoneal cavity will be

totally obliterated by scar tissue. An orderly and systematic approach to adhesiolysis is advised in these instances. First, the underside of the midline scar is cleared so that the entire length of the incision can be opened if necessary. Next, adhesions to the abdominal wall are dissected laterally until both paracolic gutters are reached. This allows the placement of a self-retaining retractor to facilitate exposure. In cases in which bowel distension is severe, needle decompression may be used to gain additional working space. Particularly severe adhesions that defy identification of the bowel and peritoneal surfaces ("frozen abdomen") may be injected with saline through a fine-gage needle to separate the surfaces and thus facilitate adhesiolysis. Attention is then turned to the pelvis where the most difficult adhesions are often encountered. Rather than separating individual bowel loops at this stage, the small bowel residing in the pelvis should be mobilized "en-masse" by lysing adhesions to the pelvic structures in an anterior to posterior manner in order to roll the mass of intestine up and out of the pelvis. The final portion of this stage of the operation involves mobilizing the plane between the small bowel mesentery and the retroperitoneum until the duodenum is encountered. Only at this point are all adhesions between individual bowel loops lysed in order to free the entire length of the small intestine. The bowel is then inspected for any coexisting pathology and for enterotomies or serosal tears created in the course of mobilization.

Assessment of bowel viability is usually possible by using the triad of color, peristalsis, and mesenteric pulsations. In cases in which these signs are questionable, the ischemic segment should be wrapped in warm, wet packs and viability reassessed after 15 min. If viability is still in doubt, use of the Doppler probe or systemic injection of fluorescein dye followed by inspection of the bowel under a Wood's lamp may aid in decision making. If the area in question is a short segment, it may be best to proceed with resection. If an extensive segment of questionable viability is present, then a second-look operation 24 h later should be planned before committing the patient to a massive small bowel resection.

There is some debate as to the need for complete adhesiolysis when the point of obstruction is encountered early in the operation. It is our policy to divide the majority of adhesions if this can be done safely. This facilitates the inspection of the entire length of the small bowel and allows for the placement of anti-adhesion barriers if desired (see below).

Special Situations

Early Postoperative Bowel Obstruction

Early postoperative bowel obstruction is generally defined as mechanical obstruction occurring within 1 month of abdominal or pelvic surgery. This condition is special in that attempts at relaparotomy in the early postoperative period frequently result in disastrous complications. The mantra of "never let the sun rise or set on a patient with bowel obstruction" should not be broadly applied in this group. An intense

inflammatory response usually begins within the abdomen at 7–10 days postoperatively and persists for at least 6 weeks. If forced to operate during this period of time, the surgeon is likely to encounter dense hypervascular adhesions that may obliterate the peritoneal cavity. The risk of enterotomy and subsequent fistulization is extremely high. In addition, vascular or extensive serosal injury of the bowel may lead to massive resections. Therefore, immediate reoperation for early postoperative bowel obstruction is not advised, especially considering the fact that the development of strangulation in this setting is extremely rare. These patients should be managed conservatively with nasogastric or long tube suction and intravenous fluids. If resolution does not occur within the first 5–7 days, a percutaneous gastrostomy tube may be placed for long-term decompression, and the patient is started on hyperalimentation. Patients may be discharged from the hospital on this regimen and laparotomy performed in 6–12 weeks if the obstruction has not resolved. However, if peritonitis or signs of sepsis are present initially or develop during the course of nonoperative therapy, a CT scan should be performed immediately. Any abscess or fluid collection caused by an enteric leak can be percutaneously drained and a controlled enterocutaneous fistula established. Exploration is usually only required in cases of ischemic or necrotic bowel. There is a place for very early exploration within the first 10 days postoperatively if obstruction is recognized promptly. The adhesions encountered during this time period have not usually become severe and can be dealt with safely. There is also a role for laparoscopic enterolysis in the selected settings when performed by appropriately trained skilled surgeons.[34]

Anastomotic "Overhealing"

Anastomotic overhealing is a rare cause of postoperative small bowel obstruction. It is most often attributable to early adhesion and healing of the staple lines of the linear cutter between the limbs of a functional end-to-end/side-to-side anastomosis. This is best prevented by maximally distracting the two staple lines as the transverse staple line is placed to close the enterotomy made to introduce the side-to-side stapler. When this occurs in the early postoperative period, it will be easily diagnosed with a water-soluble contrast study, especially if administered via a long tube near the point of obstruction. The treatment should be conservative initially and may include long tube decompression. In some cases, the balloon-tipped catheter itself has broken through the healing web and relieved the obstruction. In the case of an obstructed ileocolic anastomosis, colonoscopic balloon dilatation may be carefully used. Operative intervention should be a last resort and usually requires resection and reanastomosis.

Prevention of Adhesions

More than 90% of patients undergoing abdominal surgery will develop some degree of intraabdominal adhesions.

Adhesion formation can occur wherever the visceral or parietal peritoneum has been disturbed. Once an area of injury is established, fibrin is deposited and then organizes to form a matrix for collagen deposition. Bowel motility and endogenous lubricants attempt to counteract this process, but in most cases, adhesions will eventually result as the deposited collagen matures. As discussed earlier, the progression from early to mature adhesions usually takes approximately 6 weeks.

Several strategies have been developed to minimize, prevent, or influence adhesion formation. Gentle handling of tissues, avoiding the deposition of talc by wearing powder-free gloves, and copious lavage of the peritoneal cavity at the conclusion of the operative procedure are simple means that should be used in all cases. In instances in which particularly severe adhesion formation can be anticipated, for instance patients with multiple recurrences of small bowel obstruction, the use of long intestinal tubes placed at the conclusion of surgery to "splint" the bowel open during adhesion formation has been advocated. This is usually accomplished by inserting a Baker tube via a proximal jejunostomy.

Recently, several chemoprophylactic agents have been developed in an attempt to reduce or eliminate adhesions through a barrier mechanism. The best studied of these is a bioresorbable membrane of modified sodium hyaluronate and carboxymethylcellulose. A large multicenter study by Becker et al.[47] has shown that this material substantially reduces the extent, incidence, and severity of adhesion formation. Its efficacy in reducing the incidence of adhesive bowel obstruction has recently been reported.[48] However, the decrease in incidence of bowel obstruction requiring reoperation from 3.4% in the control group to 1.8% in the treatment group is of uncertain clinical significance. The use of adhesion barriers in patients at high risk for subsequent reoperation because of disease or previous adhesions may be justified by the likely improvement in the ease and safety of the subsequent abdominal reentry and explorations. One of the problems with the barrier material is that it only prevents adhesions between the surfaces where it is applied.

Pelvic Bleeding

Serious pelvic bleeding may be encountered during proctectomy and is usually caused by injury to the presacral venous plexus or the internal iliac vessels or their branches. Although rare, pelvic bleeding can be a devastating event and is a significant cause of operative mortality. If bleeding is moderate, the best course of action is to complete the proctectomy. Bleeding will often stop, or at least slow significantly, once the rectum has been removed. Presacral venous hemorrhage is especially challenging because the anatomy and fragility of the presacral venous plexus make control of bleeding difficult. Attempts at electrocoagulation or suture ligation of these vessels usually results in an increase in bleeding and

is not advised. Direct finger pressure should be used to gain temporary control of bleeding while allowing the anesthesia team to "catch up" with the resuscitation. Finger pressure can then be replaced with pressure applied by a cotton pledget on a long clamp. This will improve exposure and visualization for the attempt at repair. Once the patient is stabilized, several methods exist for permanent hemostasis. The most common of these is the use of sterile thumbtacks or specially designed "occluder pins" that are driven into the sacrum at right angles and directly over the site of bleeding.[49,50] If this maneuver is unsuccessful, a rectus abdominus muscle flap may be rotated down into the pelvis based on the inferior epigastric pedicle. Heavy sutures are then placed on either side of the sacrum and tied down to compress the rectus flap against the sacrum to tamponade the bleeding.[51] Other methods to control presacral bleeding have also been described,[51-54] such as removing a 2×2 cm square of rectus muscle and tacking this to the sacrum with absorbable sutures placed on either side of the bleeding site and tied tightly to secure the muscle patch. Application of electrocautery to the muscle then produces a secure coagulum on the surface of the bleeding venous plexus. If these measures fail, pelvic bleeding may be controlled by packing several laparotomy sponges tightly into the pelvis with the ends being brought out through the lower portion of the abdominal wound. The abdomen is then closed and the patient is taken to the intensive care unit for blood transfusion, fluid resuscitation, correction of coagulopathy, and general support. After 24–48 h, the patient is returned to the operating room for removal of the packs.[55]

Wound Infection and Intraabdominal Abscess

Wound Infection

Because of the large bacterial content of the colon (10^{10} anaerobes and 10^8 aerobes/g of stool), wound infection rates are high after colorectal surgical procedures.[51,54,62] The introduction of an oral antibiotic preparation before surgery by Nichols and Condon reduced wound infection rates from 40% historically to the present day level of 5–10%. In many centers, a single parenteral dose of antibiotics at induction has replaced the more complicated "Nichol's prep." Several single-agent or combination choices exist, each with adequate gram-negative and anaerobic coverage. Risk factors for wound infection have been identified and include malnutrition, diabetes mellitus, immunosuppression, age >60 years, American Society of Anesthesia score >2, fecal contamination, length of hospitalization before surgery, and extensive surgery.[8,55] Recently, there is a growing body of literature that shows that mechanical bowel preparation does not decrease the incidence of wound infection. Several metaanalyses have examined this question and are in agreement.[56,57] The largest

and most recent also found that the risk of anastomotic leak was actually increased in patients receiving a bowel preparation (odds ratio 1.75).[58]

Wound infections typically present on or around the fifth postoperative day and are characterized by erythema, warmth, tenderness, fever, and purulent drainage. Initial treatment consists of opening a portion of the skin incision over the area of maximal change to allow drainage. Antibiotics are not prescribed unless there is cellulitis present. If a significant amount of necrotic tissue is present, it should be debrided. Once the wound is adequately drained, a packing regimen is begun and the wound is allowed to heal by secondary intention. Large wounds may be treated with the application of a vacuum-assisted wound closure device. After the wound has been debrided by several days of wet to dry dressing changes, the vacuum-assisted closure device is applied (V.A.C.; KCI Therapeutic Services, San Antonio, TX). The advantages of this system are simplification of wound care and quicker closure. The dressing only needs to be changed every 4–5 days and wounds typically close within several weeks.

Several situations require more aggressive treatment. Deep infection involving the rectus muscle and fascia may occur and result in dehiscence. These patients should be taken back to the operating room for debridement of the necrotic fascial edges and repair of the dehiscence. Invasive wound infections with either clostridium perfringens or beta-hemolytic streptococcus is a potentially life-threatening complication. These infections may have an atypical presentation in that they can occur within the first 1–2 days after surgery and may be associated with minimal skin changes. The combination of fever and unusually severe wound pain early in the postoperative course should prompt opening of the skin incision. A necrotizing infection is suggested by the drainage of thin gray fluid. The key to timely diagnosis and treatment of these severe infections is a high level of suspicion. The patient should be taken to the operating room for a thorough wound exploration. All devitalized tissue should be removed and the fascia excised back to healthy, bleeding edges. Broad-spectrum antibiotic coverage should include high-dose penicillin.

Intraabdominal Abscess

Intraabdominal abscesses can result from anastomotic leaks, enterotomies, or spillage of bowel contents at the time of surgery. Patients will usually present with fever, leukocytosis, and abdominal or pelvic pain 5–7 days after surgery. The diagnostic modality of choice is a CT scan of the abdomen and pelvis performed with intravenous and oral contrast (and rectal contrast in the patient with a colorectal anastomosis). The finding of a fluid collection with a thickened, enhancing rim and surrounding inflammatory stranding is diagnostic. Air bubbles may also be present in the collection. Proximity to a staple line and the presence of contrast material in the abscess suggest an anastomotic leak as its cause.

Most intraabdominal or pelvic abscesses can be successfully treated with percutaneous catheter drainage performed under ultrasound or CT guidance. Intravenous antibiotics should also be administered. The CT scan is repeated 48 h after drainage to assess its efficacy. Further follow-up is usually performed by contrast studies obtained by injecting the drainage catheter. Once the abscess cavity has collapsed and no fistula to the bowel is identified, the catheter can be safely removed. Some abscesses cannot be drained percutaneously because of their location and lack of a safe "radiographic window" for drainage. Reported success rates for percutaneous drainage of intraabdominal abscesses range from 65 to 90% and depend on size, complexity, etiology, and microbial flora.[58–61]

Perineal Wound Infection

Perineal wound infection and delayed healing are major causes of morbidity after APR with the incidence ranging from 11 to 50%.[62–65] The rigidity of the lower pelvis combined with wide resection of the perineal soft tissues and levator muscles is mostly to blame, because this results in dead space cephalad to the skin closure which is easily infected.[66] Technical modifications that may help reduce the incidence of perineal wound problems include reapproximation of the subcutaneous tissues, suction drainage of the pelvis (with or without irrigation) to prevent hematoma formation and resultant fibrosis,[67] and filling of the dead space with an omental pedicle graft.[68–72] The area of raw surface deep in the pelvis also frequently fills with small bowel and may lead to small bowel obstruction. The bowel can be excluded from the pelvis by closing the pelvic peritoneum when possible, posteriorly retroverting the uterus to close the defect, or by rotating the cecum into the pelvis. The use of absorbable mesh has also been described, but this has been associated with multiple reports of obstruction and fistulization. In benign disease, a cuff of levator muscle can be left by incising the pelvic floor just outside of the external sphincter muscle. This method should always be possible for small rectal cancers. This technique allows closure of the levator muscles in the midline and prevents dead space formation and perineal hernia. Several risk factors for perineal wound complications have been identified. Foremost among these is the use of neoadjuvant radiation therapy. In one study, the incidence of perineal wound infection increased from 13 to 34% with the addition of preoperative radiation, whereas the rate of nonhealing at 30 days increased from 19 to 51%. Rates of perineal wound complications were even higher if intraoperative radiation was used.[73] Other factors are long operative time (>300 min), intraoperative hypothermia, and fecal contamination during the perineal dissection.[68,74–77] Patients with anorectal Crohn's disease are also at increased risk when undergoing APR for rectal cancer. However, an intersphincteric dissection in patients with inflammatory bowel disease allows closure of the external sphincter and may improve wound healing (Figure 10-7A–C).
FIGURE 10-7. **A** Technique of intersphincteric proctectomy, **B** the mucosa overlying the intersphincteric groove is incised near the dentate line and the dissection is carried cephalad between the internal and external sphincters, **C** this results in retention of the external sphincters and levators which are then able to be closed in the midline.

If infection does occur, the skin should be opened to allow drainage and a program of wet to dry packing begun. A vacuum-assisted closure device can then be placed, as described above. In cases in which a chronic perineal sinus develops, closure of the defect may require wound debridement and myocutaneous flap reconstruction with gracilis, inferior gluteus, or rectus abdominus muscle.

Hemorrhoids

Marc Singer

Anatomy

Hemorrhoids are a normal component of anorectal anatomy. The terms "hemorrhoids" – as used by patients – or "hemorrhoidal disease" refer to the state of symptoms attributed to the vascular cushions present in the anal canal. It is critical for both surgeons and patients alike to consider this fact when evaluating and managing hemorrhoidal symptoms, as patients may desire removal of hemorrhoids, whereas control of symptoms should be the primary treatment goal.

Thomson's classic description introduced the concept of hemorrhoids as anatomically distinct vascular cushions in 1975.[1] The internal hemorrhoids are not merely a thickening of the mucosa or submucosa within the anal canal, rather, discrete specialized structures with specific physiologic functions. Hemorrhoids, also known as piles, are vascular cushions contained within the submucosal space of the anal canal. These cushions are a normal anatomic component of the anus, and serve to maintain closure of the anal canal, thus contributing toward fecal continence. The hemorrhoids are composed of blood vessels, connective tissue, smooth muscle, and elastic tissue. The smooth muscle contained within the submucosal space, and therefore within the hemorrhoids, known as Trietz's muscle, originates from the conjoined longitudinal muscle and the internal sphincter. These fibers support the hemorrhoid, keeping it adherent to the internal sphincter. Hemorrhoids typically exist at three locations: the left lateral, right anterior, and right posterior positions of the anal canal.[1] These positions are often referred by the misnomer "quadrants." Hemorrhoidal tissue is not necessarily limited to these locations, and there is frequently additional hemorrhoidal tissue in between these three specific locations. In fact, less than 20% of cadavers were found to have the specific configuration of hemorrhoids at the three standard positions.[1] Gross inspection of the hemorrhoids reveals a blue hue, which may suggest similarity to veins. However, histologic analysis of hemorrhoids reveals an absent muscular wall, characterizing the cushions as sinusoids, technically not veins or arteries. Furthermore, hemorrhoidal bleeding is typically described as "bright red," suggestive of well-oxygenated arterial blood. A pH analysis of hemorrhoidal blood is most consistent with arterial blood.[2]

The arterial inflow supplying hemorrhoids consists of the terminal blanches of the superior hemorrhoidal artery, with some contribution by the branches of middle hemorrhoidal arteries. The more distal aspects also receive inflow from the inferior hemorrhoidal arteries.[3] The specific locations of the terminal branches of the superior hemorrhoidal artery do not relate to the three common locations of hemorrhoids (left lateral, right anterior, and right posterior). A renewed interest in the anatomy and the number of terminal branches of the arterial inflow has occurred, as directed ligation of these branches has become a popular treatment option. The venous drainage of the hemorrhoidal plexus distal to the dentate line (external hemorrhoids) includes the inferior hemorrhoidal veins, which flow into the pudendal veins, and ultimately the internal iliac veins. The middle hemorrhoidal veins contribute toward venous outflow from the internal hemorrhoids, located proximal to the dentate line, and also drain into the iliac veins.[4]

The anal canal, proximal to the dentate line, is innervated by sympathetic and parasympathetic nerves, as well as noncholinergic/nonadrenergic mediators. The anal canal distal to the dentate line, as well as the anoderm, is innervated by somatic nerves. For this reason, the distal anal canal and the associated external hemorrhoids are sensitive to touch, pain, temperature, and stretch.

There are multiple theories regarding the function of hemorrhoids. The most commonly believed hypothesis is that the hemorrhoids contribute toward maintaining fecal continence. Closure of the sphincter complex does not completely close the anal canal, and the bulkiness of the hemorrhoidal tissue provides closure of the central aspect of the anus. As one strains, sneezes, or exerts themselves, the vascular cushions engorge and distend, which completely closes the anus while at highest risk of fecal leakage. It has been theorized that hemorrhoids contribute up to 20% of the resting pressure of the anus.[5] The anal canal, including the hemorrhoids, is highly sensitive toward the discrimination of an

empty rectum, gas, liquid, or solid stool. The loss of bulk and sensation within the anal canal may put patients with marginal continence at high risk for postoperative incontinence after hemorrhoidectomy. Besides aiding continence, the soft and pliable hemorrhoid tissue may protect the sphincters from trauma related to passing stool.

Internal hemorrhoids are lined by columnar epithelium. Near the dentate line, there may be transitional epithelium. This mucosa is viscerally innervated, which means patients will report sensations such as vague fullness and pressure, but do not perceive touch, pain, stretch, or temperature such as on the skin. This makes office-based treatments possible without anesthesia.

The anoderm is specialized squamous epithelium that lacks skin structures such as hair follicles or sweat glands. The distal most aspects are lined by normal skin, including the appendages. The anoderm and perianal skin are somatically innervated, which means external hemorrhoids are very sensitive to touch, requiring anesthesia for procedures.

Etiology

A long list of conditions, diagnoses, behaviors, and comorbidities have been suggested as possible causes of symptomatic hemorrhoids. Conditions that impair venous drainage, promote prolapse of the vascular cushions, dietary patterns, behavioral factors, and sphincter function are among the features commonly believed to contribute toward the exacerbation of hemorrhoid symptoms.

Venous congestion with subsequent hypertrophy of the internal hemorrhoids is the most common event leading to symptomatic hemorrhoids. During normal straining and defecation, hemorrhoids engorge and then return to normal. If patients strain for prolonged periods, as with chronic constipation, the internal hemorrhoids become congested but do not rapidly decompress because the increased abdominal pressure impairs venous return. This process occurs as a result of constipation as well as pregnancy, chronic cough, pelvic mass, pelvic floor dysfunction, or ascites.

The internal hemorrhoids are normally supported by the fibers of Trietz's muscle and the elastic tissues in the submucosa. These supportive tissues can become attenuated, and therefore the hemorrhoids become progressively more mobile and begin to prolapse. As they prolapse, the venous return becomes obstructed, and the hemorrhoids will become more engorged. The bulk of the hemorrhoid will lead to further weakening of the supporting structures. Thompson described this cycle of progressive prolapse and engorgement as the sliding anal cushion theory.[1] If the prolapse is outside the sphincter, then the pressure of the sphincter further impairs blood return and the hemorrhoids become further congested.

Dietary and behavioral features contribute to symptomatic hemorrhoids. The low fiber diet of Western society creates hard dry stools. Constipation causes excessive straining, which exacerbates the hemorrhoids. The hard stool will also cause local tissue trauma, thus inducing bleeding. Toileting behavior and defecation habits are widely believed to contribute toward the development of hemorrhoid symptoms, but objective evidence is limited. This may be an indirect reflection of constipation. Some patients may spend prolonged time periods sitting on the commode because they are determined to have a bowel movement at a selected time or to move the bowels daily, even if not necessary. Some patients may read while on the toilet, which may subconsciously lead to prolonged straining.

Although constipation is well known to exacerbate hemorrhoid symptoms, diarrhea or frequent bowel movements can have the same effect. Advancing age is a known risk factor, independent of the other comorbidities. There is histologic evidence suggesting that the supporting soft tissues of the hemorrhoids, including Trietz's muscles, become less supportive with age, which leads to prolapse.[6] It has also been suggested that erect posture contributes to hemorrhoids due to the gravitational effects and venous pooling.

Hemorrhoids are not typically due to mucosal abnormalities, such as inflammation or dysplastic changes, or intrinsic sphincter abnormalities. However, there is objective evidence that patients with hemorrhoid symptoms demonstrate elevated manometric sphincter pressures compared to controls.[6–12] It may be possible that elevated sphincter pressures impair venous drainage of the hemorrhoids in some patients. Excisional hemorrhoidectomy has been documented to reverse this finding.[9]

There is sparse objective evidence for any of the purported hypotheses. It is likely that the development of symptoms is multifactorial, including a number of patient-specific anatomic, behavioral, dietary, and possibly genetic influences.

Epidemiology

The true incidence of hemorrhoids is difficult to accurately assess. Many patients do not seek medical attention for their symptoms.[7,10] Patients often self-medicate with any number of the large variety of over-the-counter products that are available. Statistics such as operative procedures may be straightforward to monitor; however, a very small proportion of patients with symptoms actually require operative therapy. In addition, patients seek care from a large number of different specialists including surgeons, gastroenterologists, internists, family practitioners, pediatricians, gynecologists, and practitioners of alternative medicine. Finally, patients self-diagnose many other anorectal diseases as "hemorrhoids."

The prevalence of hemorrhoids in the USA has been estimated at 4.4%[10] or 8.5 million patients.[11] It may be as high as 36% of patients seeking care in a general medical practice.[12] Fortunately, the number of deaths attributed to hemorrhoids is exceedingly small.[13] The prevalence is highest in Caucasian patients between 45 and 65 years of age and of

elevated socioeconomic status. This may represent selection bias and access to care, as this cohort typically would have the greatest access. Johanson and Sonnenberg[14] suggest that the incidence of hemorrhoidal symptoms has decreased in the last 50 years based on self-reporting of patients in the USA and UK. By any measure, this represents a common problem with between 1.9 and 3.5 million physician visits[15,16] and 168,000 hospitalizations, annually.[17] There are nearly two million prescriptions written annually for hemorrhoid therapies,[18] accounting for over $43,000,000. This is independent of over-the-counter, herbal, and homeopathic remedies.[19]

Classification

Hemorrhoids are generally divided into two categories: internal and external. Internal hemorrhoids originate proximal to the dentate line. This can be a source of confusion in the setting of prolapse completely through the anus. Patients perceive the hemorrhoids to be outside of the anorectum, but in fact, the hemorrhoids originate proximal to the dentate line. Internal hemorrhoids are lined by columnar epithelium. External hemorrhoids are located distal to the dentate line, and are lined by anoderm and skin at the distal most aspect. A mixed, or combined, hemorrhoid is a condition in which both internal and external hemorrhoids are present.

In 1985, Banow et al.[20] described a classification system based on clinical prolapse (Table 11-1). This system has become popular among surgeons because it describes the symptoms of prolapse, which is one of the main factors driving treatment decisions. Unfortunately, it does not incorporate size, discomfort, or bleeding, which also commonly direct therapeutic decisions.

Clinical Presentation

Patients with essentially any anorectal pathology may present with the complaint of "hemorrhoids." Patients and physicians unfamiliar with specific anorectal pathology commonly use this label. A number of patients may suffer from other benign anorectal conditions such as fissures, fistulas, pruritis, abscesses, and condylomata. These are pathologies also addressed by a colon and rectal surgeon, making a referral appropriate under any circumstance. More importantly, patients with warning signs, like bleeding, should not be overlooked as colon, rectal, or anal cancer can present with such symptoms.

TABLE 11-1. Classification of hemorrhoids

Grade I – Internal hemorrhoids bulge into the anus without prolapse
Grade II – Internal hemorrhoids prolapse during defecation, spontaneously reduce
Grade III – Internal hemorrhoids prolapse, requiring manual reduction
Grade IV – Hemorrhoids prolapsed and irreducible

Internal Hemorrhoid Symptoms

Patients with symptomatic internal hemorrhoids may complain of bleeding, itching, burning, pain, prolapse, swelling, mucus discharge, and difficulty with perineal hygiene. The edematous hemorrhoids may cause the patient to feel as if they are sitting on a foreign object. Patients with prolapsing hemorrhoids may not always recognize the prolapsing nature of the hemorrhoids, but may report wetness, itching, and soiling of the undergarments. Traditionally, it has been suggested that internal hemorrhoids do not cause somatic pain because they originate proximal to the dentate line. However, patients commonly complain of anal or rectal pain. It may be that patients use the word "pain" as a surrogate for itching, burning, or an overall sense of discomfort or unpleasantness. When patients are specifically queried, patients do report hemorrhoidal pain, even if afforded the opportunity to differentiate pain from burning, wetness, or other symptoms.[21] Although the anatomic location suggests that internal hemorrhoids should not cause pain, such objective evidence should not be entirely discounted, and patient complaints of pain should be addressed. It remains critical to identify and treat alternative causes of pain such as associated fissures or perianal excoriation. A subtle volume of mucus may be discharged at the time of hemorrhoid prolapse, which can cause significant perianal irritation. Severe pain may be indicative of thrombosed or strangulated internal hemorrhoids.

The specific details of the rectal bleeding should be elicited. The classic hemorrhoidal bleeding is bright red blood at the time of bowel movements. Patients may report blood on the toilet paper, blood dripping into the toilet, or even blood squirting into the toilet. Hemorrhoidal bleeding will typically occur at the end of the bowel movement, presumably because the stool itself causes trauma to the engorged hemorrhoids. An attempt should be made to differentiate this from blood mixing into the stool, or melena, which suggests a colorectal malignancy. Patients may not be able to reliably distinguish these patterns, and for that reason, bleeding must be carefully considered and worked up in the appropriate patients. Age, personal history, family history, or other risk factors must weigh into the decision regarding further workup of bleeding. It is not always necessary to complete this workup at the onset of treatment. A mechanical bowel preparation and colonoscopy may exacerbate hemorrhoid symptoms. Deferral until after hemorrhoids have been treated is appropriate, but it must not be postponed indefinitely. Bleeding may occur in microscopic quantities only, resulting in a positive guaiac test. Anemia due to hemorrhoidal bleeding is sufficiently rare that it warrants a full assessment of the gastrointestinal tract.

The internal hemorrhoids may be prolapsing internally, which can cause a sensation of fullness, the urge to defecate, or the sensation of incomplete evacuation after bowel movements. If hemorrhoids prolapse completely through the anus, then patients will perceive a mass or lump, but can also cause wetness or soiling. As the mucosa prolapses, it carries

mucus, blood, or stool from inside the anal canal out to the perineum. This can make hygiene difficult after a bowel movement. Patients may complain that excessive wiping is required, or shortly after a bowel movement they find their undergarments to be soiled. Patients should be asked about spontaneous or manual reduction of prolapsing hemorrhoids. Finally, lifestyle questions should be directed toward uncovering additional precipitating factors such as constant straining due to heavy lifting, chronic coughing due to chronic obstructive pulmonary disease (COPD), and limited bathroom access leading to hard dry stools.

External Hemorrhoid Symptoms

External hemorrhoids may present with redundant tissue around the anus, bleeding, or difficulty in maintaining hygiene after bowel movements. In addition, they may become inflamed. Symptoms are typically less severe than those of internal hemorrhoids, with the exception of acute thrombosis of an external hemorrhoid. Patients will experience the acute onset of mild to excruciating anal pain. This may be precipitated by an episode of diarrhea or constipation, but many times there is no identifiable inciting factor. Patients will also complain of a firm lump at the anus. Patients sometimes undertake unusual maneuvers in order to visualize their own anus, and may report a blue or purple color to the lump. This will be at the level or distal to the dentate line. Bleeding will not usually occur immediately following the onset of pain; however, when the pressure of the thrombus erodes through the skin, then the clot will spontaneously drain. The necrotic skin may become gangrenous and rarely cause surrounding cellulitis. After the external hemorrhoid thrombus drains spontaneously or is surgically evacuated, the expanded external hemorrhoid will reduce in size; however, patients are often left with resultant skin tags. These tags may reduce in size over time, but typically do not completely regress. Tags may cause symptoms in the future, such as itching and difficulty with hygiene, even after the hemorrhoid symptoms have long resolved. Such tags may also be embarrassing for patients. The differential diagnosis of common hemorrhoidal problems based on anorectal symptoms is presented in Table 11-2.

TABLE 11-2. Differential diagnosis based on anal symptoms

Symptom	Differential diagnoses
Pain	Thrombosed hemorrhoids, fissure, abscess, fistula, pruritis, anorectal Crohn's disease, anismus, abscess
Bleeding	Internal or external hemorrhoids, fissure, fistula, hypertrophic papilla, polyps, anal or colorectal cancer, ulcerative colitis, Crohn's disease, infectious colitis, draining thrombosed hemorrhoids, rectal prolapse
Pruritis	Prolapsing hemorrhoids, fistula, incontinence, anal condylomata, rectal prolapse, pruritis ani, anal papilla, dermatitis, dietary causes
Mass	Thrombosed or prolapsed hemorrhoids, abscess, anal cancer, prolapsing polyp or papilla, skin tags, prolapsing tumor, rectal prolapse, condylomata

Evaluation

History

The goal of management of hemorrhoids is control of the symptoms, but not necessarily to extirpate all hemorrhoid tissue. For this reason, a careful ascertainment of specific symptoms is critical toward guiding the evaluation and directing the therapeutic options.

A detailed history, including a complete discussion of the patient's bowel habits, is the starting point in the workup of symptomatic hemorrhoids. Symptoms are intimately related to bowel habits. Constipation, diarrhea, urgency, frequency, and changes in the bowel habit must be documented. For selected patients, a prospectively maintained bowel diary including standardized instruments, such as the Bristol Stool Scale which specifically describes stool types (texture and shape), and includes visuals (see Chap. 32) may be helpful to accurately characterize bowel movements over time.[22]

This bowel history is also useful in eliciting "red flag" symptoms, such as bleeding or changes in bowel habit, which may be indicative of malignancies. Furthermore, the history can help to differentiate hemorrhoids from other benign anorectal pathology. Chronic diarrhea with anal pain may suggest Crohn's disease. A lump that drains pus suggests an abscess or fistula. Chronic itching without bleeding or prolapse suggests pruritis. Extreme pain with bowel movements suggests a fissure.

A dietary history, and the effects on the bowel habit, is also critical toward management of hemorrhoid symptoms. Specific foods or eating patterns that worsen constipation of diarrhea must be addressed at the beginning of the management plan. A common cause of constipation in Western countries is in adequate dietary fiber and/or fluid intake. Although it can be difficult to estimate fiber intake, patients committed to dietary and medical management of hemorrhoid symptoms may benefit from a diet journal. Special attention should be paid to foods that commonly cause diarrhea (fats, caffeine, or alcohol) or constipation (cheese, beef, or bananas). Recent changes in diet or bowel habit due to acute illness or travel should be noted.

Physical Examination

A generalized physical examination may reveal relevant physical signs of liver disease, COPD, or coagulopathy. The abdominal examination should be directed toward the signs of constipation, such as abdominal distension or a palpable fecal impaction in the left colon. Finally, the examination should be directed toward the anorectum. The anorectal examination can be embarrassing for many patients. This may be especially true of younger patients who have never undergone an anorectal examination by their primary care

physician or gynecologist. The patient should be reassured that the examination will be brief and, although uncomfortable, will not be painful. Patients should be offered to have a same-gender chaperone in the room during the examination, if feasible. These steps will relax the patient and facilitate a more complete and thorough examination. If the patient is uncomfortable or uncooperative, then the clinician may inadvertently abbreviate the examination or be reluctant to complete some aspects of the evaluation such as a proctoscopy.

The prone jackknife position on a proctologic table allows for maximal exposure of the perineum and anus. This can be particularly true for obese patients, in whom retraction of the buttocks can be difficult. In addition, if examining the patient without the aid of an assistant, the prone position does not mandate retraction of the buttocks. If a proctologic table is unavailable or impractical because the patient is too obese, pregnant, or orthopedic issues preclude the prone position, then the lateral position (Sims) or lithotomy positions will suffice. Regardless of the position in which the patient is examined, the anatomy and pathology should be described in anatomical terms (left, right, anterior, or posterior), but *not* the positions of a clock. The convention of clock positions can be confusing as different practitioners may examine patients in different positions. Furthermore, vague terms such as above or below should not be used to describe proximal or distal to the dentate line or anal verge.

The examining surgeon gently spreads the buttocks and inspects the perineum, anoderm, and sacrococcygeal regions. The surgeon then identifies external hemorrhoids, skin tags, prolapsing internal hemorrhoids, rectal prolapse, excoriated skin, fissures, fistulas, abscesses, anal cancers, thrombosed external hemorrhoids, rashes, or dermatitites. Careful palpation should also be performed in order to assess for induration, tenderness, masses, or thrombus in the external hemorrhoids. Next, a digital examination of the anal canal should be performed to assess sphincter tone, identify masses, abscesses, and localize pain. Weak resting sphincter tone should be further interrogated by asking the patient to voluntarily squeeze on the examiner's finger in order to grossly assess squeeze pressures.

At a minimum, anoscopy is required to thoroughly assess hemorrhoids. Several types of anoscopes are available (Figure 11-1A and B). A slotted or side viewing anoscope is best for assessing internal hemorrhoids. The slot allows the internal hemorrhoids to prolapse into the scope, giving the examiner a sense of the bulk of the hemorrhoids. Translucent plastic anoscopes are available, which are conveniently disposable. Also, the clear plastic allows for simultaneous visualization of the entire anal canal, especially the relationship between the hemorrhoids and the dentate lane. However, the lack of a slot on some plastic anoscopes can impair rubber band ligation (RBL). Some anoscopes contain multiple slots, which may facilitate RBL of multiple quadrants in a single setting.[23]
FIGURE 11-1. **a** Ives Fansler Anoscope and **b** a clear plastic anoscope.

The degree of prolapse should be assessed by asking the patient to strain or simulate a bowel movement. This may be underestimated in the prone jackknife position. If the degree of prolapse is questionable, then the patient should be moved to a commode or onto a toilet. The examiner should request the patient to push or strain, and then carefully inspect the anus while the patient is in this more physiologic situation.

Patients should also undergo rigid or flexible proctoscopy. The rectum should be evaluated for inflammatory conditions, polyps, or tumors. This is certainly true in patients with red flag symptoms of bleeding, weight loss, anemia, or change in bowel habits. At least at the initial evaluation of a new patient, an effort should be made to understand the status of the rectum. Hemorrhoids in the setting of rectal inflammation may be treated differently than hemorrhoids in a patient with a normal rectum.

The patient should be considered for formal evaluation of the entire colon with either colonoscopy or double contrast enema. Clinical factors such as red flag symptoms, age, personal and family history of colorectal pathology,

duration of symptoms, or the nature of bleeding can be used to determine which patients should undergo additional evaluation. In suitable patients, it is appropriate to treat hemorrhoids first and defer formal evaluation of the colon until a later date. There is reluctance to administer a full cathartic bowel preparation in a patient experiencing significant symptoms already. It would be reasonable to defer evaluation for several weeks to months to allow treatments of the hemorrhoids. The ability of the patient to accurately characterize the blood per rectum may not be reliable enough to sufficiently differentiate benign versus malignant causes of bleeding in many cases. Therefore, the entire clinical scenario must be considered in the decision to evaluate the colon entirely for bleeding.[24–28] Patients fulfilling specific criteria (such as those proposed by the Multi-Society Task Force on Colorectal Cancers) should be considered for additional workup.[26,27]

In addition, patients with risk factors, such as being part of an HNPCC family or those with atypical bleeding, should also undergo colonoscopy.[29,30] Hemorrhoids often present in younger patients, in whom the risk of colorectal malignancy is relatively low. This often raises the question of total colon examination. Simple hemorrhoidal bleeding does not require total colon evaluation in a young patient without other risk factors (family history); however, hemorrhoids rarely cause anemia. Thus, hemorrhoids with anemia warrant colonoscopy or contrast enema.[31,32]

As a general rule, younger patients (<40 years old) with hemorrhoids and symptoms compatible with their disease may undergo office anoscopy and proctoscopy. If treatment immediately ceases bleeding, then no future evaluation is indicated. Patients >40 years of age with a family history or symptoms that seem out of proportion to their exam should undergo total colon evaluations.

Treatment

The treatment of symptomatic hemorrhoids is directed by the symptoms themselves. Patients should be reassured that hemorrhoids are normal components of human anatomy and that it is not necessary to remove all hemorrhoidal tissue. Treatments can be broadly categorized into three groups: (1) medical management, including dietary and behavioral therapies, (2) office-based procedures, and (3) operative therapies.

Dietary and Lifestyle Modification

Hemorrhoid symptoms are frequently related to alteration of the bowel habit. Therefore, initial therapy should be directed at modifying the stool. Constipation is most commonly related to a relative lack of dietary fiber and fluid intake. The recommendation of 25 g/day for women and

TABLE 11-3. Amount of fiber in common foods

Foods	Serving size	Total fiber (g)
Navy beans, cooked	1 Cup	19.1
Lentils, cooked	1 Cup	15.6

38 g/day for men is rarely achieved. The United States Department of Agriculture (USDA) estimates that mean fiber intake for Americans is merely 15 g/day.[33] A high fiber diet (Table 11-3) and 64 oz of water daily should be the initial recommendations. Also, behavioral modifications such as a regular sleep/wake cycle and exercise schedule can be helpful to maintain a regular bowel habit, and therefore reduce hemorrhoid symptoms.

It can be difficult to ingest 25–35 g/day of dietary fiber, making the fiber supplement a necessary option (Table 11-4). Bulk-forming agents such as psyllium are generally well tolerated and cost-effective. The objective data regarding fiber supplements is somewhat conflicting, but available publications do support the use of bulk-forming agents to treat hemorrhoid symptoms. Moesgaard et al.[34] have

TABLE 11-4. Fiber supplements

Fiber supplement	Brand name products
Psyllium	Metamucil, Konsyl Fiberall, Hydrocil, Perdiem, Serutan
Methylcellulose	Citrucel
Calcium Polycarbophil	FiberCon, Fiber-lax, Equalactin, Mitrolan
Wheat Dextrin	Benefiber
Inulin	FiberChoice

demonstrated that a high fiber diet can reduce bleeding and pain as related to hemorrhoids; however, other authors have not been able to document such benefits.[35–37] Alonso-Coello et al.[38] conducted a systematic review of trials examining fiber for the treatment of hemorrhoids. He examined seven trials with nearly 400 patients comparing fiber to a control group. Fiber showed a consistent benefit for the reduction of bleeding and other symptoms.

Bulk-forming agents treat hemorrhoids by modifying the quality of the stool. They work in combination with oral fluids to add moisture and soften the stool. For this reason, supplements are best administered in the morning, so that fluid can be consumed throughout the day. If ingested at bedtime, as some patients prefer to take their other medications, the fiber will remain in the intestinal track overnight, without additional fluid, and may, in fact, dehydrate the stool and worsen constipation. Divided dosing throughout the day is appropriate, but it is imperative that patients drink fluids with the dose and then throughout the day.

The addition of stool softeners (docusate) or lubricants (mineral oil) can be helpful toward treating constipation. Hyperosmolar (plyethylene glycol), saline (magnesium citrate), or stimulate laxatives (senna and bisacodyl) are safe and effective. There is no creditable evidence that long-term use is harmful. Patients may require such laxatives to break a fecal impaction, but should be transitioned to a regimen of fiber and stool softeners as quickly as possible. The goal of the fiber supplement, stool softeners, and increased fluid consumption is create bulky, but soft stools that move regularly. The goal of this therapy, in terms of the quantity and frequency of bowel movements, is determined by the comfort and symptoms of a patient.

Patients with diarrhea may require additional assessment. Patients with loose stools related to a diet, which is low in fiber and high in fats, need only dietary modification. This is often exacerbated by caffeine, alcohol, and an irregular sleep/wake cycle. Profound or bloody diarrhea may require stool cultures, fecal fat analysis, or endoscopy, among others. Loose stools can be treated initially with fiber supplementation. Although 25–35 g/day is the recommended target, patients will require titration of the dose.

Typically, the high fiber diet and fiber supplements and stool softeners should be trialed for 4–6 weeks. Reevaluation should focus on symptom management. The appearance of internal hemorrhoids during anoscopy may be unchanged, but if symptoms are well controlled, this should be considered a successful outcome. Long-term compliance with these measures can be problematic, as many patients will not commit to indefinite treatment. In addition, many fiber supplements carry significant noncompliance due to poor palatability or side effects such as abdominal bloating, excessive flatus, or crampy abdominal pain. Patients should be started on a low dose and titrated up to the desired effect in order to minimize the side effects.

Toileting Behavior

Patients with hemorrhoids commonly exhibit dysfunctional toileting behaviors. It is not clear that this is a result of hemorrhoidal symptoms or a contributing factor toward symptoms. Common issues include excessive straining, pushing, Valsalva maneuver, and prolonged time on the toilet. Patients should be encouraged to spend 3–5 min on the toilet as a general guideline. Patients should refrain from the common practice of reading on the toilet, as this may lead to prolonged periods of straining. Patients requiring excessive time on the toilet (>30 min) or those with multiple unsuccessful attempts should be considered for evaluation of a pelvic floor disorder. In addition, perianal hygiene routines should be addressed. Patient with soft or pasty stool commonly complain of excessive wiping. Some patients become compulsive with cleaning rituals. Patients should be encouraged to wipe only until clean. Excessive wiping can cause local trauma, contributing to inflammation of prolapsing internal hemorrhoids, bleeding of external hemorrhoids, and worsening pruritis. The use of premoistened wipes (baby wipes and witch hazel wipes) is safe and often less traumatic. Patients should be cautioned to dry the perineum afterwards because a wet perineum will lead to further skin maceration and symptoms.

Sitz Baths

Sitz baths are commonly recommended as part of the initial treatment plan and can aid with hygiene, particularly after bowel movements. They often provide symptomatic relief of pain, itching, burning, and may facilitate the manual reduction of prolapsed hemorrhoids. Sitz baths may alleviate sphincter and pelvic floor spasm, which contribute to the discomfort in some patients.

Sitz baths should be warm, as if a patient were taking a normal bath (approximately 40°C) but not scalding hot. In attempt to maximize the therapeutic benefits of sitz baths, patients have been known to scald their perineal skin. Sitz baths are best accomplished in a traditional bathtub, however, older patients may not be able to get in/out of a bathtub due to orthopedic issues and some patients may not have access to a bathtub. In such cases, portable sitz baths are available (Figure 11-2). These are placed on top of the

Figure 11-2. Portable Sitz bath.

toilet and allow patients to soak the perineum only. Soaking time should be limited to approximately 15 min. Prolonged soaking in water may contribute to edema. Patients should be discouraged from adding salts, oils, or lotions to the water. These products may cause further inflammation of prolapsing hemorrhoids.

There is a dearth of objective evidence supporting the use of sitz baths for hemorrhoids or other anorectal disorders.[39] However, many patients subjectively report relief from this practice. Considering the low cost and low risk, it is appropriate to continue to recommend sitz baths.

For a large number of patients, increasing fiber and water, sitz baths, and simple behavioral modifications are adequate to completely treat hemorrhoid symptoms. If dietary and behavioral modifications are unsuccessful, then additional treatment options should be considered.

Medical Therapy

A large number of topical medications, suppositories, and wipes are available to patients. Patients will frequently attempt self-medication with over-the-counter products before seeking treatment from a physician. Objective evidence regarding the effectiveness of these products is sparse. Most available data does not rigorously examine products compared to controls or placebo, or make use of standardized definitions and survey instruments. It is therefore inappropriate to make firm recommendations in support of any of the products. The use of these products is so common that surgeons should be familiar with them so that appropriate discussion can be entertained with patients.

Common over-the-counter products include ointments, creams, gels, suppositories, foams, and wipes. Most products contain a combination of agents including a barrier protectant and another active ingredient. Local anesthetics applied topically may provide temporary relief of pain, itching, and burning. The delivery vehicles may cause local irritation to the anoderm. The active ingredients include benzocaine, benzyl alcohol, dibucaine, dyclonine, lidcaine, pramoxine, and tetracain. Vasoconstricting agents can be used in an effort to reduce swelling and engorgement of hemorrhoids. Available drugs include ephedrine, epinephrine, and phenylephrine. Barrier protectants aim to prevent skin irritation by keeping mucus, stool, or mucosa from directly contacting the perianal skin. Common products include aluminum hydroxide gel, cocoa butter, glycerin, kaolin, lanolin, mineral oil, petrolatum, starch, and zinc oxide. Astringents can be used to clean and dry the perineum. These products include calamine, zinc oxide, and witch hazel. Analgesics aim to sooth the anus. These include camphor, juniper tar, and menthol. Corticosteroids are anti-inflammatory drugs. These serve to reduce perianal inflammation, itching, and pain. Prolonged use may cause thinning of the skin and therefore should not be used for longer than a few weeks.

Patients commonly attempt symptomatic relief with suppositories. Suppositories do not typically remain localized within the anal canal. They are often expelled immediately after insertion, in which case they cannot deliver a sustained dose of medication. Alternatively, they may migrate proximally into the rectum, where the medication will be delivered. However, as these medications are meant to act topically within the anus, they are not affecting the appropriate mucosa. Suppositories may provide indirect benefit by either mechanically stimulating the rectum to evacuate or they may deliver lubrication to the anal canal and rectum, which can provide some benefit by lubricating the anus, and thus mitigating the effects of stool trauma on the hemorrhoids. A variety of soothing creams and ointments are contained within the suppositories. Frequently, steroids and/or local anesthetics will be combined with these agents.

Phlebotonics

Phlebotonics are a heterogeneous collection of substances that are used to treat venous insufficiency, lymphedema, venous stasis ulcers, and certain bleeding conditions, but also to treat hemorrhoids. Some of these products are plant extracts (flavonoids and saponosedes), and some are synthetic compounds (calcium dobesilate and naftazone). These compounds are purported to improve venous blood flow, which may ameliorate conditions such as lower extremity venous insufficiency or engorged hemorrhoids. The specific mechanisms of action are largely unknown, but they are believed to improve venous tone, stabilize capillary permeability, and increase lymphatic drainage.[40–42] Documented benefits are largely

unknown due to the lack of controlled studies. Some compounds have specific safety concerns, such as the flavonoids which can cause GI side effects or calcium dobesilate which can cause agranulocytosis.[43]

The citrus bioflavoinoids, which create pigmentation in fruits, are most often used in Europe. There are multiple alleged health benefits, but most are not substantially documented. The most common compounds include diosmin, hesperidin, rutin, naringin, tangeretin, diosmetin, narirutin, neohesperidin, nobiletin, and quercetin. A commercially available diosmin product has been shown to be effective for the treatment of hemorrhoids, but such products are not available in pharmaceutical grade in the USA.[44–48] They are available as nutritional supplements (Daflon 500® Les Laboratories, Servier, France) and with the increasing incidence of patients ordering international products through the internet, it is critical to be familiar with this and related supplements. Other naturally occurring compounds include "flavonoids," Rutosides,[49,50] buckwheat herb, ruscus aculeastus (butcher's broom), hidrosmin, gingko biloba, saponsides, escin (horse chestnut seed), and Hamamelis Virginiana (Witch Hazel).

Synthetic products include calcium dobesilate, naftazone, aminaftone, chromocarbe, iquinosa, flunarizine, and sulfomucopolysaccharide. Of this group, calcium dobesilate may be the most widely examined. Its function stems from the capacity to stabilize capillary permeability, decrease platelet aggregation, and improve lymphatic transport. Metes et al.[51] sought to determine the clinical efficacy of calcium dobesiliate for hemorrhoids by conducting a randomized clinical trial comparing effects to fiber supplementation alone. Patient symptoms significantly improved after only 2 weeks of treatments.[51]

A recent meta-analysis examining the utility of flavonoids to treat hemorrhoids reviewed 14 trials.[52] There was significant heterogeneity between trials, but there did appear to be a beneficial effect. Patients enjoyed decreased bleeding, pain, and itching. The doses and formulations of the investigated compounds were highly variable.

Office Treatments

A variety of office-based treatments are available as options for patients including RBL, infrared coagulation, bipolar diathermy, direct-current electrotherapy, injection sclerotherapy, dilation, and cryotherapy. The choice of therapies depends on surgeon experience, patient preference, availability of equipment, and medical status of the patient. It should be emphasized that all of these techniques are directed toward treatment of internal hemorrhoids. The lack of somatic innervations proximal to the dentate line permits such treatments, but excludes office-based directed treatments directed specifically toward external hemorrhoids.

Rubber Band Ligation

RBL is one of the most commonly performed office procedures to treat hemorrhoids. It has been widely adopted due to its efficacy, safety, and cost effectiveness. RBL is a technique of internal hemorrhoid fixation. A small rubber band is applied at the apex of the internal hemorrhoid, which creates an inflammatory response. The fibrotic reaction creates fixation of the hemorrhoid high in the anal canal at the normal anatomic position. By correcting the prolapse, the venous drainage improves and the hemorrhoids shrink in size.

Mechanical bowel preparation is not required, although an enema shortly before the procedure can improve visualization. Patients are ideally positioned in the prone jackknife position on a proctology table. The next best option is the left lateral decubitus position. The patient must be able to tolerate a complete anoscopic exam. If the patient cannot tolerate this examination, then this procedure may require sedation in a monitored setting. Fortunately, discomfort is quite rare.

After a formal anoscopic examination, the grasping instrument is used to bring the redundant mucosa at the proximal aspect of the internal hemorrhoids into the barrel of the banding instrument. The grasper is used to gently bring as much tissue as possible into the barrel (Figure 11-3). The band is
FIGURE 11-3. Rubber banding an internal hemorrhoid. **A** The internal hemorrhoid is teased into the barrel of the ligating gun with a McGown suction ligator or **B** a McGivney type ligator. **C** The apex of the banded hemorrhoid is well above the dentate line in order to minimize pain. (Reprinted from Beck D, Wexner S. Fundamentals of Anorectal surgery, 2nd ed. Copyright 1998, with permission from David Beck, MD).

then applied to this redundant mucosa, allowing reduction of the prolapse and fixation of the hemorrhoid. It is critical to place the band proximal to the dentate line (approximately 2 cm proximal). If the band is applied less than 2 cm proximal from the dentate line, the patient may feel significant pain. The band causes relative ischemia to the tissue contained within, which will then slough in 5–7 days. This creates an ulcer at the site, with an inflammatory response surrounding it. As the ulcer develops and subsequently heals, the accompanying fibrosis will secure the internal rectal mucosa to the underlining sphincter. A common misperception is that the rubber band strangulates the entire internal hemorrhoid. It is the ulcer, and subsequent scarring that causes fixation. By returning the internal hemorrhoid to its normal anatomic position, the hemorrhoid will no longer prolapse outside the anus, venous return will improve, and the hemorrhoid will shrink.

There are a variety of banding instruments available for RBL, but all make use of the same basic principles. The categories include variations of the McGivney type of ligators, McGown suction-type ligators, endoscopic, and disposable instruments. The McGivney ligators come in several styles and require the use of an atraumatic Allis-type grasper. A trigger is activated to deploy the rubber band. This requires two hands to operate and typically an assistant to hold the anoscope in place.

The second type of banding instrument is the McGown type suction ligator. (McGown, Pembroke Pines, FL). This instrument makes use of suction to draw the hemorrhoid into the barrel. It is positioned and activated with the same hand, which leaves the other hand free to position the anoscope. This may allow the surgeon to perform the procedure independently.[53] The barrel of the suction ligator is smaller than the more traditional devices, therefore less tissue is banded.

RBL can be safely and effectively performed with an endoscopic variceal ligator in conjunction with a flexible endoscope.[54–56] Gastroenterologists commonly perform banding of esophageal varices with this instrument. The cost and risks of performing flexible endoscopy may not be justified in all patients, but if diagnostic endoscopy is indicated, then combining banding with the procedure may be appropriate.

Finally, two varieties of disposable instrumentation have been developed for banding. The first is a disposable suction ligator (ShortShot® Saeed Hemorrhoidal Multi-Band Ligator, Cook Medical) (Figure 11-4), with four preloaded rubber bands. The device is placed over the site of ligation, a thumb hole is occluded to activate the suction, and a dial rotated to deploy a band. This is similar to the McGown ligators, in that it makes use of suction, and may eliminate the need for an assistant.[57,58]

The second type of disposable ligator (O'Reagan Ligating System) (Figure 11-5A–C) makes use of a syringe type of device. The surgeon can also perform this procedure alone.

FIGURE 11-4. A ShortShot®Saeed Hemorrhoidal Multi-Band Ligator (Cook Medical).

As depicted in the illustration, the ligator is placed at the site, the syringe withdrawn, thus creating negative pressure and drawing tissue into the device, and the band deployed with a thumb trigger. This device has been reported to be safe and effective similar to other devices.[58]

Regardless of the type of banding instrumentation, an anoscope, a bright light, and possibly an assistant are the only requirements for this procedure. It is appropriate for first-, second-, and third-degree hemorrhoids. However, patients with very large and bulky hemorrhoids may require multiple treatments. Typically, the largest or most symptomatic hemorrhoid should be banded first. If the patient experiences a complication or pain and the procedure must be aborted, then the most symptomatic quadrant was already addressed. Some surgeons prefer to place two bands at the hemorrhoidal bundle (by loading two bands onto the ligator) in case one band slips or sloughs early.

Patients should be instructed to resume normal activities immediately after the procedure. The band and some of the internal hemorrhoid will slough approximately 5–7 days after the procedure. Patients may experience blood per rectum and should be informed of this ahead of time to ease anxieties. More importantly, patients should specifically be instructed, if medically possible, to refrain from anticoagulation [including aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs)] for 10 days. There is no evidence supporting this strategy; however, it seems reasonable to avoid anticoagulation in anticipation of a known bleeding event. RBL is relatively contraindicated in patients on systemic anticoagulation with warfarin, antiplatelet therapy, heparin, or low molecular-weight heparin. The procedure itself can usually be performed bloodless fashion, but the bleeding that occurs 1 week after the procedure occurs in an uncontrolled setting and may potentially lead to a massive bleeding episode. Patients should be maintained on the bowel regimen started previously or at that time.
FIGURE 11-5. **A** O'Regan disposable banding system (Medsurge Medical Products Corp., Vancouver, Canada). **B**, **C** Technique of internal hemorrhoidal ligation using the O'Regan ligating system.

Constipation has been specifically correlated with less successful outcomes after banding.[59]

It has been demonstrated that banding multiple hemorrhoids in the same setting is safe and that there are no significant increases in complications.[20,60–64] Although the majority of patients tolerate banding of multiple sites with minimal discomfort or complications, there is data suggesting greater pain (29 vs. 4.5%), vasovagal symptoms (5 vs. 2%), and urinary retention (12 vs. 0%) if multiple hemorrhoids are banded.[63] For this reason, some surgeons will choose to apply one band at the first setting, and depending on the patient response and outcome, apply additional bands at subsequent visits if necessary.

Complications after RBL fortunately are rare and usually minor. The most common complications are pain, thrombosis, bleeding, and urinary hesitation or retention. The most common complication after banding is pain. Because the bands are placed proximal to the dentate line, patients typically experience vague pressure or fullness more commonly than somatic pain. It may also be common to experience

the urgency to evacuate the rectum or the sensation of incomplete evacuation. These sensations typically subside in 24–48 h. Patients may resume sitz baths if their symptoms dictate, and this may relieve the pressure and/or fullness. Pain has been reported some series as low as 5%, but also as high at 60%.[27,58,65–67] Severe pain is rare, and usually due to one of the several clinical situations. Pain immediately after the procedure is related to a band misplaced too close to the dentate line. If the pain becomes unbearable, and the patient can no longer tolerate the anoscopy, then the surgeon can attempt a local anal block in the office setting to facilitate band removal, or even proceed to the operating room where anesthesia providers and sedation are more readily available. The delayed onset of pain may signify the complications of thrombosed internal and/or external hemorrhoids. This is typically treated with analgesics, sitz baths, and observation. If the pain is severe enough, then hemorrhoidectomy may rarely be indicated.

Other complications such as abscess, early band slippage, and urinary dysfunction are reported but rare.[68] The most concerning complication of RBL is pelvic sepsis. This is an extremely rare, but potentially fatal complication. There have been several documented case reports of this situation.[69–72] The clinical picture of worsening pain, fever, and urinary retention mandates immediate attention, including examination under anesthesia if necessary, as this may suggest the diagnosis of pelvic sepsis.[72] CT scan of the pelvis may demonstrate extrarectal air and/or inflammation, which may require exploratory laparotomy and pelvic drainage and/or fecal diversion. This potentially devastating complication may be increasing as the number of immunocompromised patients grows.[73]

Finally, it should be noted that most rubber bands are made with latex. Latex-free bands are available. Patients with true latex hypersensitivity should be advised not to undergo the procedure. Anaphylaxis from this application has not been reported, but a known fatal side effect should be avoided for a minor outpatient procedure.

The large majority of patients will respond to treatment of first- or second-degree hemorrhoids.[54,74,75] It may be common that patients require multiple treatment sessions. Savioz et al.[75] followed a small cohort of patients over 10 years. Thirty-two percent required repeat banding by 10 years. Bayer et al.[76] followed nearly 3,000 patients over 12 years. Eighteen percent required repeat banding and 2% required formal hemorrhoidectomy. This is a fairly durable procedure and can be easily and safely repeated if necessary. Many patients would find banding, and even repeat banding, preferable to the significantly more painful hemorrhoidectomy.

Infrared Photocoagulation, Bipolar Diathermy, and Direct-Current Electrotherapy

Surgeons utilize infrared photocoagulation, bipolar diathermy, and direct-current electrotherapy much less commonly as compared to RBL. These procedures are similar to RBL in that all are techniques of fixation. The difference is only in the method of fixation. The management issues such as patient preparation, positioning, and anticoagulation are similar to RBL.

Infrared photocoagulation employs infrared radiation to generate heat, which coagulates proteins and creates an inflammatory bed (Figure 11-6). The subsequent eschar formation and scarring at the site of application create the point of fixation for the internal hemorrhoid during the 2 weeks following the procedure.[77] A tungsten halogen lamp is used to generate the infrared radiation (Redfield Corp, Montvale, NJ) (Figure 11-7). The applicator tip is placed at the apex of the internal hemorrhoid for a 1.0–1.5 pulse of energy. Typically three or four applications at each hemorrhoid are performed. Up to three internal hemorrhoids may be treated at a single visit.[57] The application of this device will yield a 4 mm^2 focus of coagulation with a 2.5 mm deep ulcer. Complications are minor and rare. If the radiation is applied too close to the dentate line, then postprocedural pain may occur as the tissue ulcerates. Bleeding may be caused by excessive application of the energy. Infrared coagulation is best applied to small first- and second-degree hemorrhoids. There is some evidence that it may be less painful than banding.[78] At least three prospective randomized clinical trials have suggested that infrared coagulation controls bleeding in the majority of patients with first- or second-degree hemorrhoids.[57,71,72] One drawback of this technique is the expense of the device, which is clearly more costly than a rubber band ligator.

Bipolar diathermy is an alternative technique of fixation. Rather than a rubber band or an infrared-induced ulcer creating the point of fixation, bipolar radiofrequency energy is applied to the apex of the hemorrhoid. Bipolar energy does
FIGURE 11-6. **A** Infrared photocoagulation. The infrared photocoagulator creates a small thermal injury. Thus, several applications are required for each hemorrhoidal column. not penetrate as deeply as monopolar electrocautery. The energy is applied in a pulsatile fashion until the tissue coagulates. The depth of coagulation is 2.2 mm. Success rates of treatment have been reported from 88 to 100%, however, up to 20% of patients may ultimately require excisional hemorrhoidectomy for prolapse.[79–81]

Direct-current electrotherapy is an additional method of applying energy to the site, with the intent of creating a scar, and thus securing the internal hemorrhoid in place. An applicator is directed to the apex of the internal hemorrhoids, and a 110-V direct current is delivered at increasing amperage up to the maximum tolerable level, which is approximately 16 mA. The energy is then delivered for 10 min. Patients frequently require multiple treatments at the same hemorrhoid. This technique has not gained popularity, primarily because of the time course required to treat each site and inability to treat larger grade III hemorrhoids.[82–84]

Sclerotherapy

Sclerotherapy is also a technique of internal hemorrhoidal fixation. Unlike the previously described techniques which rely on energy delivery to the site, this office technique employs chemical agents to create fibrosis and fixation of the hemorrhoids. The sclerosing agent obliterates the vascularity of the internal hemorrhoid, reduces the hemorrhoid in size, and secures it at the anatomic position. This is also performed in the office in a manner similar to RBL. A variety of sclerosing agents are available, but commonly used solutions include 5% phenol in an oil base, 5% quinine and urea, or a hypertonic saline solution. A spinal needle can be convenient to prevent the surgeon's hands and syringe from obstructing the anoscopic view. A 25 gauge (or smaller) needle should be used to minimize bleeding; 2–3 ml of the sclerosant is injected 1–2 cm proximal to the dentate line at or near the base of the internal hemorrhoid (Figure 11-8). The injection should go into
the submucosal space, and the surgeon should take caution to avoid injection into the mucosa or intramuscular spaces, which may cause either mucosal sloughing with a large ulcer or significant pain.

Sclerotherapy can be safely used in patients on systemic anticoagulation since it does not induce sloughing, but rather a fibrotic reaction. Multiple repeated attempts at sclerotherapy should be avoided due to the potential complication of stricture. Complications are generally related to injection of the sclerosant into an unintended anatomical space.[85] On rare occasion, the sclerosant or the oil vehicle may cause a significant inflammatory reaction with subsequent abscess, urinary retention, or even impotence.[86] Sclerotherapy is best indicated for first- or second-degree internal hemorrhoids. Success rates are generally reported to be high. A prospective randomized trial comparing single versus multiple injections of phenol yielded similar results, with symptom control in nearly 90% of patients.[87] However, not all data are as impressive, with some series reporting 30% recurrence of symptoms 4 years after injection.[66] One trial even suggests that sclerotherapy plus fiber yields similar bleeding control rates as fiber alone.[88]

In many practices, RBL or infrared coagulation have become the preferred office-based procedures, except in anticoagulated patients, in whom injection sclerotherapy is the safest option.

Anal Dilation

Anal dilation – also known as Lord's procedure – was originally described as dilation to accommodate four fingers of both hands.[89] This essentially creates an uncontrolled stretch injury to the sphincter. Ultrasonographic evidence and postoperative incontinence have precluded this treatment from gaining acceptance in the USA.[90–92]

Cryotherapy

Cryotherapy is an alternative method of fixation of the internal hemorrhoids. This technique makes use of freezing as a method of local tissue destruction. A specialized probe is cooled by nitrous oxide (−70°C) or liquid nitrogen (−196°C). The probe is then applied to the desired location at the apex of the internal hemorrhoids. The procedure can be time-consuming, and the patients can experience pain and a foul smelling discharge per rectum afterwards.[93–95] In addition, the probe is not widely available, and inappropriate applications can lead to anal stenosis, sphincter damage, or even fecal incontinence. This technique is rarely offered and should likely be abandoned.

Operative Hemorrhoidectomy

In broad terms, operative hemorrhoidectomy is indicated for patients who fail nonoperative management techniques, have advanced disease unlikely to be amenable to nonoperative techniques, or significant external hemorrhoids requiring excision. In addition, patients with other anorectal pathology, such as fissures, fistulas, or abscesses requiring operative intervention may elect for concomitant hemorrhoidectomy. Patients unable to tolerate office procedures or coagulopathic patients requiring definitive control of bleeding are also suitable candidates for operative therapies.

A relatively small number of patients, 5–10%,[96,97] require operative hemorrhoidectomy compared to the very large number of patients experiencing hemorrhoidal symptoms. Surgical treatment falls into three categories: excisional hemorrhoidectomy, stapled hemorrhoidopexy, and a relatively newer technique of Doppler-guided transanal devascularization.

Excisional hemorrhoidectomy remains the gold standard treatment to which other operations must be compared. Its safety and efficacy have withstood the test of time for decades. The obvious drawback to this operative approach is the notorious postoperative pain. There are three variations of excisional hemorrhoidectomy: the open technique, the closed technique, and the circumferential (Whitehead) technique.

Closed Hemorrhoidectomy (Ferguson Hemorrhoidectomy)

Described by Ferguson some 40 years ago, the closed hemorrhoidectomy or Ferguson hemorrhoidectomy remains the most common operation for hemorrhoids in the USA.[98]

Patients do not require a formal mechanical bowel preparation or perioperative antibiotics. Enemas prior to surgery are sufficient for evacuation of the rectum. Prone jackknife position with the buttocks taped widely apart allows maximum exposure. Some surgeons prefer the lateral decubitus position. This operation can be performed under general, regional, or local anesthesia with intravenous sedation. Sedation with local anesthesia is safe and can facilitate an expeditious recovery and discharge.[99]

The operation begins with a formal anoscopic examination and a proctoscopic examination if indicated. A deep anchoring suture is placed at the apex of the internal hemorrhoid using absorbable suture material. The ligature should be deep to the submucosa, so as to incorporate the feeding artery and devascularize the pedicle. A diamond-shaped incision is made to plan the dissection, with either scalpel or a cautery device. The incision should begin immediately distal to the anchoring suture, incorporate the bulk of the internal/external hemorrhoid, and extend widely onto the perineum. A long incision will give a smooth contour when the wound is closed. Next, starting at the distal aspect of the diamond-shaped incision, the hemorrhoidectomy is initiated. A hemostatic clamp can be applied to the external hemorrhoids in order to facilitate traction of the specimen; however, the surgeon must be confident that there is not a significant amount of sphincter within the clamp. The skin and subcutaneous tissues are dissected with scalpel, scissors, or cautery. The dissection proceeds to remove the external hemorrhoid, and the base of the wound will now expose the external sphincter. Care should be taken to dissect the mucosa and submucosal away from the underlying sphincter fibers. As long as the submucosal plane is not traversed, the muscle fibers can usually be easily swept downward, away from the hemorrhoid tissue. The dissection proceeds proximally, separating the internal hemorrhoids from the external and finally the internal sphincter. This portion of the dissection, with good visualization of the sphincter, is the critical aspect in preventing injury to the sphincter. The use of cautery, scalpel, scissors, or even an advanced energy device does not change this critical element. The specimen is amputated just distal to the anchoring stitch. The wound is inspected for hemostasis. The suture at the apex stitch is retrieved and used to close the wound. If the mucosal edges are bleeding, a running locked suture can aid hemostasis. If there is significant dead space deep to the closure, then a three-point stitch, incorporating a small amount of sphincter, will obliterate this space.

Another variation of the techniques uses an hourglass-shaped incision around the hemorrhoid bundle. The bundle is dissected carefully off the muscle until the proximal vascular bundle is encountered. This structure is clamped and the hemorrhoidal bundle is excised. The vascular pedical is suture ligated and the stitch is used to approximate the mucosa as described above. This variation ensures that maximal anoderm is retained and there is no suture to obstruct the dissection (Figure 11-9).

Care should be taken with both techniques to match up the anal verge from both sides of the wound. The distal most aspect of the wound (5 mm) should be left open to drain. The wound should be dressed with a nonadherent dressing, or antibiotic ointment and gauze, and mesh panties. Tape on the buttocks should be avoided so as to prevent the painful removal and avoid putting tension on the new suture lines.
FIGURE 11-9. Ferguson closed hemorrhoidectomy. **A** An incision is made in the mucosa and anoderm around the hemorrhoid bundle. **B** The hemorrhoid dissection is carefully continued cephalad by dissecting the sphincter away from the hemorrhoid. **C** After dissection of the hemorrhoid to its pedicle, it is clamped, secured, or excised. The pedicle is suture ligated. **D** The wound is closed with a running stitch. Excessive traction on the suture is avoided to prevent forming dog-ears or displacing the anoderm caudally.

FIGURE 11-10. Open (Milligan–Morgan) hemorrhoidectomy. **A** External hemorrhoids grasped with forceps and retracted outward. **B** Internal hemorrhoids grasped with forceps and retracted outward with external hemorrhoids. **C** External skin and hemorrhoid excised with scissors. **D** Suture placed through proximal internal hemorrhoid and vascular bundle. **E** Ligature tied. **F** Tissue distal to ligature is excised. Inset depicts completed three-bundle hemorrhoidectomy.

Patients can be discharged home in most cases. One, two, or three quadrants may be excised at a single operation. Maintaining bridges of viable skin and mucosa in between each excision will prevent anal stenosis.

The operative specimen does not require routine pathologic examination as the incidence of significant pathology as a clinically normal exam is not justified.

Open Hemorrhoidectomy (Milligan–Morgan)

The open technique, or Milligan–Morgan, is more commonly used in the UK and follows the technique described by Milligan and Morgan.[100] Perioperative management is identical to Ferguson hemorrhoidectomy.

The external hemorrhoids are grasped with a hemostat and retracted in the caudal direction. This exposes the internal hemorrhoids, which are also grasped with hemostats. Traction on the three internal/external bundles exposes the apex of each group. A V-shaped incision is made on the anoderm extending to the mucocutaneous junction.

The sphincter fibers are exposed and gently dissected away from the hemorrhoid with sharp and blunt dissection. As with open hemorrhoidectomy, care is taken to separate the sphincter fibers from the hemorrhoid bundle. The apex of the pedicle is then suture ligated, and the hemorrhoid amputated (Figure 11-10). One, two, or three columns can be excised.[101] The wounds are left open to granulate.

Circumferential Technique (Whitehead Hemorrhoidectomy)

The Whitehead hemorrhoidectomy involves a circumferential excision of the internal hemorrhoids and redundant mucosa just proximal to the dentate line.[102–105] The technique describes total excision of the hemorrhoids and mucosa from the dentate line and progressing proximally (Figure 11-11). It had been used more commonly in the UK, but became much less popular. It was never widely adopted in the USA. Many surgeons would suture the proximal rectal mucosa to the anal
FIGURE 11-11. Whitehead hemorrhoidectomy. **A** Suture placed through proximal internal hemorrhoid for orientation. Excision started at dentate line and continued to proximal bundle. **B** Internal hemorrhoidal tissue excised above ligated bundle. **C** Vascular tissue excised from underside of elevated anoderm. **D** End of anoderm reapproximated with sutures to original location of dentate line. **E** Completed procedure.

skin, which resulted in a significant mucosal ectropion, the so-called Whitehead's deformity. In addition, high rates of stenosis and incontinence have lead to abandonment of this technique at most centers.

Results of Hemorrhoidectomy

The long-term results of excisional hemorrhoidectomy are excellent. There are however, relatively few studies with long-term follow-up on a large number of patients. MacRae et al.[106] reviewed available data and found that the recurrence of symptoms or need for subsequent treatment is low.

The debate regarding open or closed hemorrhoidectomy is longstanding. Multiple clinical trials have examined the relative merits of each technique. In recent years, there have been at least four randomized comparative trials examining open versus closed hemorrhoidectomy.[107–110] These trials revealed similar postoperative pain, analgesic requirement, length of stay, and complications. Some authors suggest complete wound healing was superior in open hemorrhoidectomy,[110] similar between groups,[93,94] or closed hemorrhoidectomy.[108,109]

Ho and Buettner[111] performed a meta-analysis comparing open and closed techniques. Six trials including nearly 700 patients were included. There were no significant differences in cure rates, length of stay, maximum pain score, or complications rates. Open hemorrhoidectomy was faster to perform, but closed hemorrhoidectomy wounds did heal faster. In summary, there were no clear differences between the two techniques. As with any operations in which equivalent results have been documented, the surgeon should offer whichever operation he/she is most comfortable performing.

The greatest patient concern regarding hemorrhoidectomy is postoperative pain. This experience has become a significant deterrent to many patients and often causes delay in seeking surgical care for hemorrhoids. Even relatively recent trials, which incorporate the most modern anesthesia and postoperative analgesic practices, demonstrate the frequent need for narcotic pain medication and the prolonged delay in returning to normal activities for up to a month.[112–115]

Due to the significant postoperative pain, several methods have been examined in an effort to minimize postoperative pain. Alternative methods of tissue dissection have been investigated. The LigaSure™ bipolar energy device (Valleylab, Boulder, CO) as well as the Harmonic® Ultrasonic Device (Ethicon Endosurgery, Cincinnati, OH) have been examined for hemorrhoidectomy. The supposition is that the advanced energy devices may create less thermal injury, less tissue destruction, and therefore less postoperative pain. Multiple randomized trials have examined these devices as compared to diathermy hemorrhoidectomy.[111,116–129]

These trials were all modest size (30–86 patients). The data suggests that advanced energy devices may save operating time, with a lower blood loss. The clinical significance of the difference in blood loss was questionable in most cases (<25 mL). The postoperative pain was similar or less than diathermy in the Ligasure™ and Harmonic® studies. Unfortunately, there is little long-term data regarding the safety and durability of these devices for this application. Furthermore, the cost of these devices is clearly in excess of the traditional instrumentation required for excisional hemorrhoidectomy. The potentially shorter operative time may not offset this cost. A recent Cochrane review of Ligasure™ hemorrhoidectomy compared to excisional hemorrhoidectomy was performed.[111] This review included 12 trials with over 1,100 patients. Ligasure patients experienced less pain on the first postoperative day, and most studies suggested less analgesic requirements. This benefit disappeared by postoperative day 14. Excisional hemorrhoidectomy required nine additional minutes to perform. There were no differences in complications, recurrent

bleeding, or incontinence. Ligasure™ patients returned to work 5 days sooner than control patients.

Both Harmonic® and Ligasure™ hemorrhoidectomy appear to offer patients reduced postoperative pain, but the lack of long-term follow-up precludes a firm recommendation at this time. If the seemingly low rate of recurrence and functional results are sustained during longer-term follow-up, these techniques will likely grow in popularity. The issue will be comparative effectiveness to address the relative cost efficiency of these techniques compared to standard hemorrhoidectomy.

Several trials have examined diathermy versus scissor hemorrhoidectomy. There are not significant differences between the two techniques and this should remain surgeon preference.[130–132] Laser hemorrhoidectomy with NdYAG laser has been evaluated as an alternative technique of excisional hemorrhoidectomy. There were not significant improvements in clinical outcome compare to excisional hemorrhoidectomy.[133–135] This technique suffers from a large cost and may also create compromised wound healing.[135]

Additional techniques or adjuncts to hemorrhoidectomy have been examined in an effort to decrease postoperative pain. Ui[136] proposed hemorrhoidectomy with limited incisions, and Patel and O'Connor[137] described suture ligation of the vascular pedicle alone. Concomitant lateral internal sphincterotomy has been demonstrated to reduce postoperative pain.[138] It may be that sphincterotomy mitigates the painful sphincter spasm experienced after hemorrhoidectomy. The uses of postoperative oral[139] as well as 10% topical metronidazole[140] have been demonstrated to reduce pain. It is unclear whether this represents an anti-inflammatory or an antibacterial effect of the drug. Nitroglycerin ointment, a known smooth muscle relaxant, commonly used to treat spasm associated with fissures has been examined for postoperative pain as well.[141,142] Additional agents, such as local anesthetics, anxiolytics, parasympathomimetics, and other sphincter relaxants have been employed, but none have definitively reduced pain and warrant routine use.[143–147] Routine pathologic examination of hemorrhoidectomy specimens may not be necessary. A recent review suggests that 1.4% of 914 patients contained histologic abnormalities.[100] During a 20-year period at Ferguson Hospital, only 1 of 21,257 specimens made was found to contain carcinoma.[148]

Complications of Hemorrhoidectomy

Bleeding is one of the more common complications after hemorrhoidectomy, although delayed severe hemorrhage occurs less than 5% of cases.[149,150] This may be related to infections at the vascular pedicle, however, it may be more related to technical factors. One large prospective trial documents that male patients (narrow anal canal) and surgeon as independent risks. This suggests technical issues are the cause of bleeding.[151] If patients present with massive postoperative bleeding, then immediate packing of the anal canal

or inflation of a balloon-tipped catheter will adequately tamponade bleeding. If unsuccessful, then proceeding to the operating room for surgical control is appropriate. Patients may accumulate large quantities of old clot within the rectosigmoid, which should be differentiated from ongoing bleeding. Rectal irrigation can help to distinguish these so that selection for operative management can be made.[152]

Other common complications after hemorrhoidectomy include: urinary retention (0.2–36%), infection (0.2–6%), fecal incontinence (2–12%), fecal impaction (0.4%), and anal stenosis (0–6%).[153–158]

Stapled Hemorrhoidopexy

An alternative to excisional hemorrhoidectomy is the stapled hemorrhoidopexy, which was first described, and subsequently modified, by Italian surgeons.[159,160] This operation makes use of modified circular stapler, traditionally used for creating circular end-to-end intestinal anastomoses (Ethicon Endosurgery). The operation is primarily a hemorrhoidopexy, an operative form of hemorrhoid fixation. The transanal stapler circumferentially excises mucosa and submucosa, well proximal to the dentate line. A stapled anastomosis is created, thus lifting and securing the redundant mucosa and internal hemorrhoids in the normal anatomic position, which improves venous outflow. Also, the staple line may divide the arterial inflow contained in the submucosal space, thus devascularizing the hemorrhoids. This procedure offers the convenience of single setting treatment without the painful incisions in the highly sensitive anoderm.

This procedure combines elements of several other procedures. It is an operative technique, like excisional hemorrhoidectomy. It excises a circumferential ring of mucosa, like Whitehead hemorrhoidectomy. It is a technique of fixation, like RBL or sclerotherapy. It also devascularizes the hemorrhoids, like transanal hemorrhoidal devascularization (described below). The main benefit of this procedure as compared to excisional techniques is reduced pain. As all the staples are within the anal canal, proximal to the dentate line, there are no incisions on the highly sensitive anoderm, and therefore does not create the same degree of somatic pain as excisional hemorrhoidectomy.

The procedure has been cited by several names. Stapled hemorrhoidopexy most accurately reflects the nature of this operation as a technique of fixation. It is not a hemorrhoidectomy in that excision of hemorrhoid tissue is only a minor component. Authors have also referred to it as stapled anopexy, stapled prolapsectomy, and stapled mucosectomy. Procedure for prolapse and hemorrhoids (PPH) is a proprietary name coined by the manufacturer (Ethicon Endosurgery).

Stapled hemorrhoidopexy is best considered an alternative to excisional hemorrhoidectomy; therefore, the indications are similar. Indications include second- and third-degree hemorrhoids that either fail nonoperative methods or in patients who desire single setting treatment rather than multiple RBL.

Some exceptions include patients with thrombosed internal or external hemorrhoids, who should undergo excisional hemorrhoidectomy. Fourth-degree hemorrhoids also require excision, as reduction of the hemorrhoids is necessary for the conduct of the procedure. Some limited data does support the use in irreducible fourth-degree hemorrhoids if they can be reduced in the operating room.[114]

Patent preparation, anesthesia, positioning, and management are identical to excisional hemorrhoidectomy. The anal canal is examined per routine. The included disposable circular anoscope inserted. This anoscope is translucent to allow visualization of the dentate line during the procedure. A purse string suture anoscope is placed through the circular anoscope to facilitate the placement of a circumferential pursestring suture (2-0 polypropelene) into the submucosa 2 cm proximal to the apex of the hemorrhoids. The stapler is inserted through the anoscope with the head maximally opened. The head is passed through the pursestring, and the suture is tightened. Gentle traction on the pursestring suture then draws the redundant tissue into the stapler. The stapler is closed and fired, thus creating a circular partial thickness anastomoses proximal to the dentate line, while excising a ring of mucosa/submucosa approximately 1–3 cm wide (Figure 11-12). The staple line should be carefully inspected for bleeding and oversewn, as necessary.

The purse string suture is a critical element as it drives the operation. It determines the height of the staple line relative to the dentate line. If too proximal, inadequate retraction of the hemorrhoids may result in recurrent prolapse. If too distal, the staple line will be near the dentate line and cause pain. If too deep, the patient may experience full thickness anastomoses, which can pose a risk of pelvic abscess, fistula, or stapled rectovaginal fistula. Multiple examinations of the vagina during placement of the suture and before firing the stapler may prevent this complication.

The external hemorrhoids are indirectly treated to a limited extent. They are drawn into the anal canal, and the devascularization does create some resolution of the external hemorrhoids. Significant tags or thrombosed external hemorrhoids can be treated concomitantly if symptomatic or in a deferred fashion as needed. The large majority of patients will not require further treatment of these after stapled hemorrhoidopexy.[146]

A large number of randomized controlled trials have been conducted in the last 10 years. The large majority of these trials demonstrated significantly less postoperative pain compared to excisional hemorrhoidectomy.[21,111,113,114,161–180] In order to help understand this rapid influx of data, there have been several meta-analyses of the results of stapled hemorrhoidopexy.

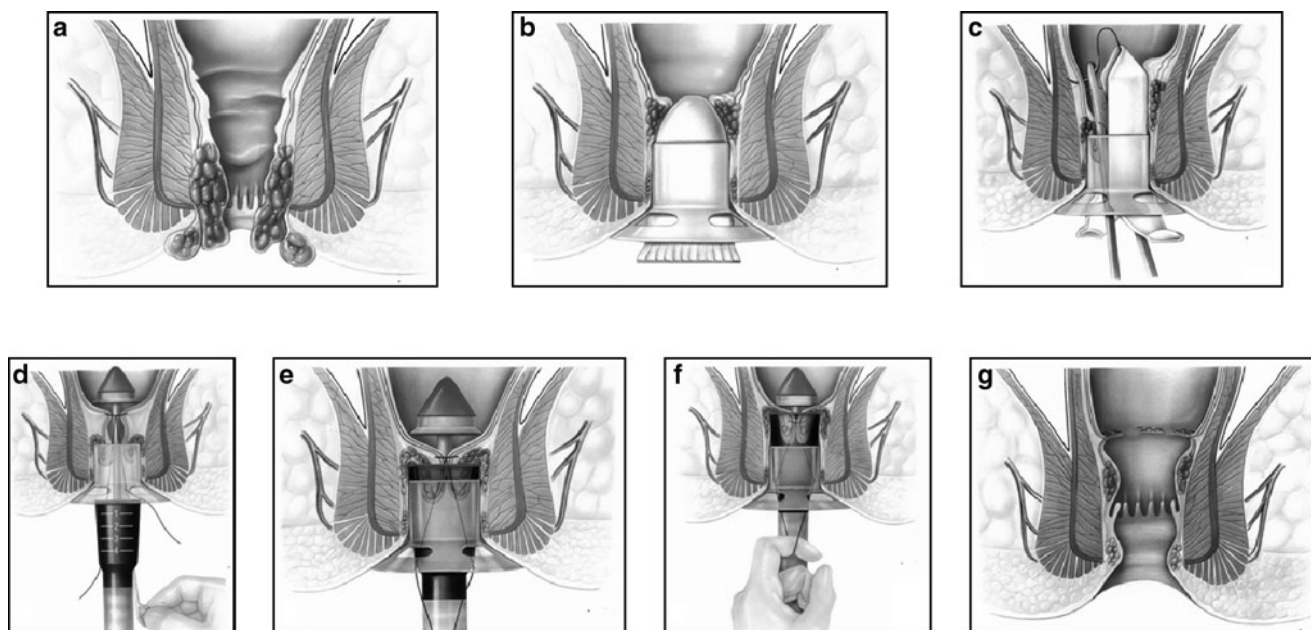
In 2004, Nisar et al.[181] performed a formal systematic review of 15 randomized trials examining the safety and efficacy compared to excisional techniques. The review suggested that there were no difference in total complications and less frequent immediate postoperative bleeding in PPH. There was a shorter hospital stay and return to normal activity. Pain was significantly improved with PPH at 24 h postoperative. Recurrent prolapse at 6 months was higher in PPH, but this was obviously a short follow-up.


FIGURE 11-12. Stapled hemorrhoidopexy. **a** Prolapsing internal hemorrhoids and external hemorrhoids. **b** Circular anoscope is inserted. **c** Purse string anoscope is inserted and circumferential purse string suture is placed proximal to hemorrhoids. **d** The purse strings are drawn through the stapler. **e** Traction on the purse string draws the redundant mucosa into the head of the stapler. **f** The stapler is closed onto the mucosa and fired. **g** The final staple line draws the hemorrhoids into the anatomic positions.

Next, Lan et al.[182] performed a systematic review in 2006. This review included ten prospective RCT comparing PPH to Milligan–Morgan for grades III and IV hemorrhoids. Safety and bleeding was similar up to 3 months postoperative. Complications were similar. Postoperative pain, operative time, length of stay, and patient satisfaction favored stapled hemorrhoidopexy. Postoperative skin tags and recurrent prolapse were more frequent in PPH patients.

A more recent systematic review[183] evaluated PPH compared to excisional techniques for short- and long-term outcomes. Twenty-nine trials were examined including 2,056 patients (20–200 per study). The rate of overall complications was similar between groups. There was a higher rate of bleeding requiring reintervention after PPH. There were similar rates of external thrombosis and urinary retention. PPH caused fewer fecal impactions, required less operating room time, a shorter length of stay, and faster return to normal activities. Postoperative pain was significantly lower in the PPH patients at 24 h postoperative, at the time of first bowel movement, and 1–2 weeks postoperative. Recurrent prolapse was more common after PPH, but the requirement for further operative intervention was similar.

Although the meta-analyses conclude that stapled hemorrhoidopexy is a safe operation with shorter operative time, less postoperative pain, and shorter recovery than excisional hemorrhriodectomy,[181–183] there are several complications important to specifically note. Rectal obstruction, rectal perforation, retroperitoneal sepsis, and pelvic sepsis have all been documented as a result of stapled hemorrhoidopexy.[184–188] There is potential for sphincter injury if the muscle is incorporated into the stapler. Histologic analysis of the resection tissue reveals sphincter muscles fibers.[189,190] The rate of incontinence is not alarming, however, this finding highlights the potential for injury. In addition, rectovaginal fistula has been reported.[167,191,192] This complication is exceedingly rare in excisional hemorrhoidectomy, but is a significant concern in PPH. The actual incidence is very low, however, the nature of the operation puts women at risk due to the demands of precise placement of the purse string suture.

The large majority of data confirms that stapled hemorrhoidopexy is at least as safe at excisional hemorrhoidectomy, with significantly less postoperative pain and faster return to normal activities compared to excisional techniques.

Transanal Hemorrhoidal Dearterialization

The newest addition to surgical armamentarium is Doppler-guided arterial ligation with hemorrhoidopexy. In 1995, Morinaga et al.[193] described a novel surgical treatment for hemorrhoids [Hemorrhoidal Artery Ligation (HAL)]. The specific techniques and commercially available instrumentation have evolved since that time, but the principle remains. The HAL is a nonexcisional operative technique that employs Doppler-guided ligation of the arterial inflow

FIGURE 11-13. Specialized anoscope for the transanal hemorrhoidal dearterialization (AMI Surgical).

to the hemorrhoids. Some years later, suture rectopexy was added to the ligation.

This combined technique was introduced into the USA in 2008. There are currently two available products in the USA: transanal hemorrhoidal dearterialization (THD; America, Ankeny IA) and hemorrhoidal artery ligation and recto anal repair (HAL/RAR; A.M.I. Inc, Natck MA).

This nonexcisional technique relies upon detection of the hemorrhoidal arterial inflow by Doppler-guided identification and ligation of the branches of the superior hemorrhoidal arteries.[193] This reduced inflow facilitates reduction in size of the hemorrhoids. Suturing is well proximal to the dentate line, so as to avoid the highly sensitive anoderm. The suture hemorrhoidopexy addresses the redundant and prolapsing mucosal and internal hemorrhoid.

The procedure is performed in the operating room and requires anesthesia as a hemorrhoidectomy. A specialized anoscope is inserted into the anal canal (Figure 11-13). The anoscope contains within it a removable Doppler ultrasound probe. The anoscope is axially rotated until one of the feeding arteries is precisely identified. At this point, the artery is ligated. A slot in the anoscope that allows for placement of a suture immediately proximal to the ultrasound probe. A "figure of eight" suture ligation of the artery is performed. The adequacy of the ligation may be immediately confirmed by assessing the change in Doppler signal. The anoscope is then rotated axially so as to identify the next artery. Most often, 4–6 arteries are identified and ligated, but this varies depending upon each patient's unique anatomy. Once the ligation is completed, a hemorrhoidopexy or mucopexy is performed. This may be accomplished immediately following the arterial

ligation, using the same suture, or each of the ligations may be performed first, followed by the mucopexies. Although the same specialized anoscope is used, the Doppler feature is not important for this part of the operation. The suture is anchored at the apex of the internal hemorrhoid, and a running suture is then performed from proximal toward distal. With each successive purchase, tension is applied to the suture so as to progressively draw more of the hemorrhoid and redundant into the anoscope, and thus become incorporated into the running suture. This suture line is terminated proximal to the dentate line, so as to minimize pain. The distal tail of the suture is then tied to the proximal tail, which lifts the hemorrhoid and fixes it high within the anal canal. This hemorrhoidopexy may be repeated in association with each artery ligation, or only at locations of redundant and/or prolapsing mucosa. Typically, the procedure is performed 2–4 times.

The operation requires a relatively short operative time. It purports to accomplish the same goals as stapled hemorrhoidopexy in that it devascularizes the hemorrhoids by ligation of the arterial inflow and also creates a hemorrhoidopexy by securing the redundant mucosa high within the anal canal. The benefits of this operation are similar to PPH in that the sutures are proximal to the dentate line, offering patients reduced postoperative pain compared to excisional techniques. This does, however, represent an operative procedure, which includes the anesthesia risks, operating room expense, and usual surgical risks of bleeding, infection, urinary retention, and postoperative pain.

The specialized anoscope and Doppler ultrasound probe are disposable; therefore, add a significant cost when compared with excisional hemorrhoidectomy, but less expensive than a stapled procedure.

Long-term data are lacking, but these procedures are gaining in popularity, and therefore future cost–benefit analyses and long-term follow-up on durability of the repair and need for future treatments are anticipated.

A retrospective review of 330 patients with grades II and III hemorrhoids reported a 7% complication rate. The mean postoperative pain score was 1.32. A total of 219 patients were followed for a mean 43 months; of these 93% experienced complete resolution of symptoms.[194] There are a variety of additional publications documenting the safety of this technique.[195–203]

In order to better understand the limited available data, Giordano et al.[203] performed a systematic review. Seventeen trials were analyzed, but only one was a RCT, which included 1996 patients. A combination of instruments were used [HAL-Doppler instrument, KM-25 device (VaiDan Medical Corp), KM025 Moricorn (Hayashi Denki Co), and the THD Instrument]. The number of arteries ligated were 4–6 in most patients. Early postoperative results were: pain on day 1 in 19%, residual prolapse in 13%, bleeding in 4%, and urinary retention in 0.7%. Normal activities resumed 2–3 days postoperative. Twenty-seven percent required a second THD for persistence prolapse. At 1 year, prolapsed was reported in 11%, bleeding in 10%, and pain in 9%. The addition of mucosopexy alone reduced recurrence to 11%.[194]

TDH is safe and effective for grades II and III hemorrhoids with reduced pain and short recovery, but quality and quantity of data is very limited at this time. It offers surgeons and patients another reliable option.

External Hemorrhoids

Due to the fact that external hemorrhoids are distal to the dentate line, and therefore innervated by somatic nerves, office-based procedures are generally not applicable. Patients requiring specific treatment of the external hemorrhoids are usually treated in two settings, either elective hemorrhoidectomy or the treatment of thrombosed external hemorrhoids.

Acute Thrombosis of External Hemorrhoid

Patients with acute thrombosis will complain of acute onset of severe anal pain. This may be precipitated by an episode of constipation, diarrhea, excessive straining (weightlifting), coughing (COPD exacerbation), or there may not be any precipitating features at all. A firm or hard lump at the anus typically accompanies the pain. The pain rapidly progresses, and the peak of the pain cycle will occur at approximately 48 h and then diminishes by the fourth day. The skin overlying the thrombus may succumb to pressure necrosis and ulcerate. The thrombus will necessitate at this time, resulting in evacuation of thrombus or liquefied hematoma. This may provide relief as a result of the decrease in pressure.

Management of this clinical scenario is directed at pain control. For this reason, the timing of the presentation is critical. If the patient presents in the first 3 or 4 days since the onset of pain, and pain is severe, then excision of the thrombus is warranted. It should be emphasized that this decision is made based not only on timing, but also pain intensity. Some patients may have a large thrombus that does not cause significant pain. This may be safely treated with medical management. Conversely, a small thrombus causing severe pain should sway the surgeon toward operative management (Figure 11-14).

The operative treatment of a thrombosed external hemorrhoid is excision of the thrombus. This procedure can be safely performed in the office setting or the operating room. Local anesthesia, a mixture of 0.5% lidocaine and 0.25% bupivicaine with 1:200,000 epinephrine, should be infiltrated to create a field block at the level of the thrombosed external hemorrhoid. The skin overlying the thrombus is then incised in an elliptical fashion. The entirety of the thrombus should be removed. Bleeding can be controlled with pressure, ferric subsulfate (Monsel's solution), silver nitrate, or topical hemostatic agents such as thrombin or epinephrine soaked gauze. The skin edges may be left open to maximize drainage of residual thrombus and prevent new thrombus from creating pressure. Alternatively, the skin edges may
FIGURE 11-14. Thrombosed hemorrhoid management. Timing of excision of a thrombosed external hemorrhoid.

be sutured closed. Closure provides additional hemostasis and leaves a cosmetically improved wound. After excision, patients should be offered analgesics, and instructed to take frequent sitz baths, and placed on a bowel regimen of bulk-forming agents (psyllium) and a stool softener or lubricant (mineral oil).

If the patient presents in a delayed fashion (>4 days) or has minimal pain, then nonoperative management is appropriate. This includes fiber, a stool softener, analgesics, and sitz baths. Anoscopy should be deferred until pain is controlled, but the anus and rectum should be evaluated at some point. The reason for avoiding excision of thrombus at that time is that the procedure is likely to cause as much discomfort as the patient is already experiencing. The injection of local anesthetic does in fact cause some pain. Therefore, the clinician and patient must decide together which option to choose.

Special Clinical Scenarios

Strangulated Hemorrhoids

Strangulated hemorrhoids are prolapsed internal hemorrhoids that become incarcerated. Patients will present with a history of prolapsing hemorrhoids that became acutely painful and may also experience urinary retention. Physical examination will reveal bulky external hemorrhoids with significant thrombosis and edema. The internal hemorrhoids will be prolapsed, incarcerated, and edematous. The patient will be exquisitely tender and cannot tolerate anoscopy. Depending on the time course, ulceration, necrosis, and gangrene may occur.

Such patients must be urgently treated with excisional hemorrhoidectomy in the operating room. Incisions or excision of thrombus alone is not appropriate for this clinical scenario. A Ferguson or Milligan–Morgan technique can be used,

depending on surgeon preference; however, if devitalized tissue and/or abscess are present, then wounds should be left open to prevent postoperative abscess. This operation is generally safe if all devitalized tissue is debrided.[155] Other than hemorrhoidectomy, or if the operating room is not available, then anther treatment option is to infiltrate a local perianal block, gently reducing internal hemorrhoids, placing multiple RBLs, and performing thrombectomies on the external hemorrhoids. Patients will not typically require future hemorrhoidectomy.[204] Patients must be highly motivated for this technique. A randomized trial suggested both excisional hemorrhoidectomy and this technique were safe options.

Hemorrhoids, Varices, and Portal Hypertension

It should be made clear that rectal varices are a distinct entity from hemorrhoids although often confused. Internal hemorrhoids drain into the middle rectal veins, subsequently the iliac veins and finally the systemic circulation. External hemorrhoids drain into the inferior rectal veins, the internal lilac veins, and the systemic circulation. Rectal varices are a distinct anatomic structure, which provide collateral circulation from the portal system into the systemic venous system.[205] This collateral circulation would seem to exacerbate hemorrhoid symptoms in patients with portal hypertension; however, the incidence of hemorrhoid symptoms is similar in this population to the general populations.[206–208] Rectal varies are very common in patients with portal hypertension (59 and 78%).[207,209] Fortunately, in contrast to esophageal varices, these varies rarely bleed.[210] Treatment of bleeding from rectal varices in this setting ranges widely from medical management of portal pressures, sclerotherapy,[205,211] to suture ligation,[211] stapled anopexy,[212] all the way to TIPS and portosystemic shunts.[213–216]

Hemorrhoids in Pregnancy

Hemorrhoids are not uncommon during pregnancy, likely due to increased circulating blood volume, impaired venous return, straining secondary to constipation, and the prolonged staring associated with labor. While pregnant, most women can be satisfactorily treated with conventional medical and behavioral treatments. If hemorrhoids become severe, or intensify during labor, the large majority will spontaneously resolve in the postpartum period. Like many surgical therapies, operative therapy for pregnancy would be reserved only for severe cases including strangulated hemorrhoids and acute external thrombosis. Operations under local anesthesia while in the left lateral position are preferred. Fortunately, only 0.2% of pregnancy women require emergent hemorrhoidectomy for grave IV hemorrhoids.[217]

Hemorrhoids and Crohn's Disease

Patients with Crohn's disease may be prone to hemorrhoid symptoms, likely related to exacerbations with diarrhea.

Hemorrhoids per say are not part of the anorectal Crohn's picture, but are common, perhaps due to engorgement related to local inflammation. As with other anorectal pathologies such as fissure, skins tags, etc., caution should be exercised with Crohn's patients. Prolonged wound healing and ulceration should be considered when discussing surgical options for hemorrhoids. If anorectal disease is well controlled, and there is little active inflammation, then Crohn's disease is not an absolute contraindication to operative therapy. Jeffery et al.[218] documented a very high complication rate for patients treated for hemorrhoids, with 30% subsequently requiring proctectomy. This was however prior to many of the currently available medical therapies for Crohn's disease. More recently, Wolkomir and Luchtefeld[219] document nearly 90% healing rate in selected patients in whom ileocolic disease was well managed. These results are encouraging for patients in whom hemorrhoidectomy is necessary. However, extreme caution should be exercise in all patient with Crohn's disease.

Hemorrhoids and the Immunocompromised Patient

As the incidence of immunocompromised patients increases due to the long survival of HIV patients, the number of patients treated with immunosuppressants, steroids, and chemotherapy grows, the issues of anorectal surgery in this population become more significant. Commonly, this population has many difficulties healing anorectal surgical wounds and is at increased risk for infectious complications. Similar to Crohn's disease, great caution should be exercised when considering surgical therapies in this population. Neutropenic patients do not suffer a higher rate of mortality due to operative therapy.[220] Nevertheless, nonoperative methods should be exhausted first. Morandi et al.[221] suggested that patients with HIV do suffer a greater degree of complications after hemorrhoidectomy.

As a general rule, all patients in these categories should have their medical conditions optimized, medical and topical therapies exhausted, and hemorrhoidectomy reserved only as needed. Patients with thrombocytopenia should likely have hemorrhoidectomy to provide most definitive control rather than delayed bleeding like in RBL.

Anal Fissure

Rocco Ricciardi, Sharon L. Dykes, and Robert D. Madoff

Introduction

An anal fissure, or fissure-in-ano, is a linear or an oval-shaped tear distal to the dentate line in the anal canal. Patients afflicted with this disorder most commonly complain of severe pain with bowel movements as well as bright red blood per rectum. Anal fissures are assumed to be very common although it is difficult to estimate disease prevalence since diagnosis of anorectal disorders is generally inaccurate. In addition, it is likely that a large proportion of patients with anal fissures never seek medical care and thus the condition is much more prevalent in the general population as compared to what is seen in clinical practice. In one survey, 80% of participants with symptoms attributed to the anorectum did not consult a physician.[1]

Large case series have provided much of the background information regarding fissure epidemiology. Data from these studies should be viewed with the understanding that there may be particular groups of patients who never seek medical counsel. Given this information, it appears that anal fissures occur equally in men and women and tend to occur in younger age groups with a mean age of 39.9 in one large study from Montreal Canada.[2] In almost 75% of cases, fissures are identified in the posterior midline but can be seen in the anterior midline in up to 25% of affected women and 8% of affected men.[2] An additional 3% of patients have both anterior and posterior fissures. When fissures occur in atypical locations or multiple fissures are identified, the clinician should investigate for other potentially complicated disease processes, such as Crohn's disease, trauma, tuberculosis, syphilis, HIV/AIDS, or anal carcinoma (Figure 12-1).

Early, or acute, fissures have the appearance of a simple tear in the anoderm. When symptoms last longer than 8–12 weeks, the fissure generally takes on chronic features, demonstrating evidence of edema and fibrosis. Inflammatory manifestations of chronic fissures include sentinel piles, or skin tags, at the distal fissure margin and a hypertrophied anal papilla proximal to the fissure in the anal canal. In addition

to these changes, fibers of the internal anal sphincter (IAS) are often visible at the fissure base with chronicity.

Etiology

There has been considerable debate regarding the etiology of anal fissures. Most patients report some element of trauma to the anal canal, often after the passage of either hard or loose stool. Yet, many patients pass hard bowel movements or experience episodes of diarrhea without ever developing a fissure; thus, the trauma hypothesis may explain some element of cause, but it is not the complete story. The potential role of constipation has also been debated, but a history of constipation is not universally obtained and as stated, some patients report diarrhea prior to the onset of symptoms.

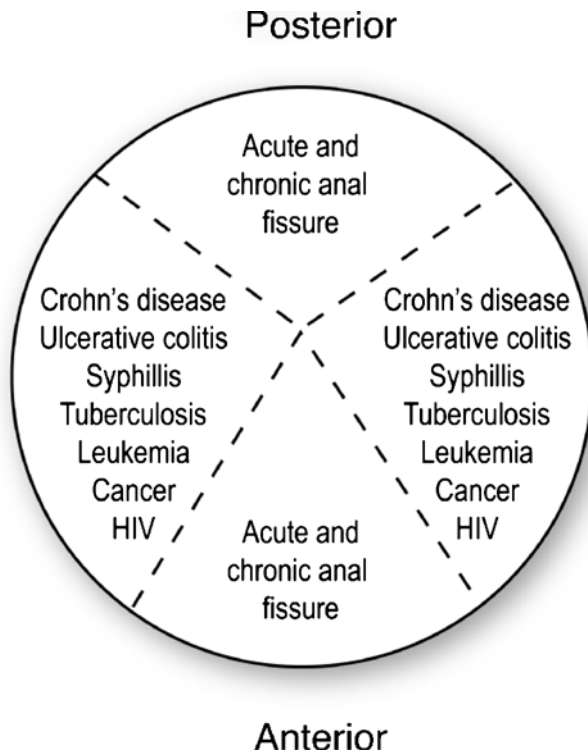
It is likely that many patients develop fissures but most heal within a very short period. However, others develop fissure persistence which is associated with increased resting anal pressure – an observation first reported in the mid-1970s.[3,4] Physiologic studies using ambulatory manometry have confirmed the presence of sustained resting hypertonia in fissure patients.[5] Further observational data have delineated an inverse relationship between anal canal pressure and perfusion of the anoderm. The ischemia hypothesis was initially proposed as an instigator of fissure persistence by Gibbons and Read[6] in 1986. Later support was provided by angiographic studies of the inferior rectal artery in cadavers, which demonstrated a paucity of blood vessels in the posterior midline of the anal canal in 85% of those examined.[7] Schouten et al.[8] measured anodermal blood flow in healthy individuals using Doppler laser flowmetry and found that the posterior midline had the lowest perfusion when compared to the other quadrants. In addition, there was a significant inverse correlation between posterior midline anodermal blood flow and maximum resting anal pressure in a large cohort of patients that included normal controls as well as fissure patients. Those patients with fissures demonstrated the


FIGURE 12-1. The location of anal fissure suggests etiology.

highest resting anal pressures and the lowest posterior blood flow of any group. In addition to these data, improvement in posterior midline blood flow was noted to occur after reduction of anal pressure with anesthesia. These same authors were able to demonstrate normalization of sphincter hypertonia and anodermal blood flow after lateral internal sphincterotomy (LIS) in patients with anal fissures.[8]

Symptoms

The clinical hallmark of an anal fissure is pain during, and particularly after, defecation. In acute fissures, pain may be short-lived, but it can last several hours or even all day in the presence of a chronic fissure. Patients often describe the pain as a sensation of "passing razor blades or glass" from their rectum. Understandably, patients with anal fissures describe fear of having a bowel movement. In addition, a large subset of patients will describe rectal bleeding, which is generally limited to minimal bright red blood seen on the toilet tissue.

Diagnosis

Diagnosis is suggested by the characteristic description of pain with bowel movements and is generally easily confirmed by physical examination. Most fissures are readily identified by simply spreading the buttocks with opposing traction of the thumbs and a quick look at the anterior or posterior
FIGURE 12-2. Examination revealing an anal fissure.

midline (Figure 12-2). Although some clinicians use a cotton swab to depress the fissure and identify pain with contact, the authors find this approach to be unnecessary. Once the presence of a fissure is verified, further attempt to examine the anal canal with insertion of a finger or endoscopic instrumentation (anoscope, proctoscope or sigmoidoscope) is of little value. Since most patients are far too uncomfortable to justify such invasive anoscopic evaluation, further investigation is delayed until after symptoms have resolved.

Fissures are often self-diagnosed as hemorrhoids. Similarly, patients may have seen their primary care provider and diagnosed with hemorrhoids. These patients are often troubled by the fact that they have different diagnosis on further examination but can be redirected with a simple understanding of the normalcy of hemorrhoids. The practicing clinician also should be alert for the potential concomitant presence of perianal abscess, anal fistula, inflammatory bowel disease, sexually transmitted disease, and anal carcinoma when the patient complains of anal pain. In addition, atypical fissures such as those occurring off the midline and multiple, painless, and nonhealing fissures, warrant further evaluation via examination under anesthesia and possible biopsy and cultures.

Management

It is estimated that half of all patients diagnosed with an acute fissure will heal with nonoperative measures, such as sitz baths and psyllium fiber supplementation, with or without the addition of topical anesthetics or anti-inflammatory ointments. In a retrospective review by Shub et al.[9] healing occurred in 44% of fissure patients using psyllium fiber, sitz baths, and emollient suppositories. During a 5-year follow-up period, there were treatment failures or recurrences

in 27% of patients initially considered healed. A second retrospective review almost 20 years later demonstrated similar findings. Hananel and Gordon[2] reported initial healing in 44% and recurrence in 18.6% of their fissure patients with bulking agents and sitz baths.

Jensen[10] conducted two randomized controlled trials examining the effects of unprocessed bran in both initial treatment and maintenance therapy of acute fissures. In the first study, 103 patients with acute posterior anal fissures were randomized to receive either lignocaine ointment, hydrocortisone ointment, or sitz baths with unprocessed bran for 3 weeks. After weeks 1 and 2, patients treated with sitz baths and bran were found to have significant evidence of symptomatic relief as compared with the other two groups. By the 3-week end point, however, there were no differences among the three groups. At 1 year, fissure recurrence was 16% in patients receiving 15 g of unprocessed bran daily as compared to 60% of patients receiving 7.5 g of bran daily or 68% of patients receiving placebo.[11]

Sphincter Relaxants

Given the theory of increased sphincter tone in patients with anal fissure, a number of topical, oral, and injectable drugs have been tested with the aim of reducing mean maximum resting anal pressure. Preparations include (1) various nitrate formulations such as nitroglycerin ointment (NTG), glyceryl trinitrate (GTN), and isosorbide dinitrate; (2) oral and topical calcium channel blockers, including nifedipine and diltiazem (DTZ); (3) adrenergic antagonists; (4) topical muscarinic agonists, i.e., bethanechol; (5) phosphodiesterase inhibitors; and (6) botulinum toxin. Given the vast number of agents available, the reader might assume that none of the agents are "ideal." As suggested, the comparative data in this area are quite controversial as one recent review concluded "first-line use of medical therapy cures most chronic fissures cheaply and conveniently,"[12] while a second review concluded that "medical therapy for chronic anal fissure … may be applied with a chance of cure that is only marginally better than placebo… [and] far less effective than surgery."[13] These reviews will be considered in more detail with the other published literature in the following paragraphs.

Topical Nitrates

The IAS is a smooth muscle whose tone is affected by both intrinsic myogenic properties and extrinsic neural influences. Nitric oxide is the predominant nonadrenergic, noncholinergic neurotransmitter in the IAS. Release of nitric oxide results in IAS relaxation, which theoretically improves blood flow to the fissure and promotes healing. Exogenous nitrates release nitric oxide in vivo and have been used as nitric oxide donors to treat patients with anal fissures as well as other conditions.

Studies by Loder et al.[14] and Guillemot et al.[15] demonstrated decreased resting anal pressure with application of 0.2% topical GTN. This led to a series of retrospective and prospective reports, as well as randomized trials supporting the use of various nitrate preparations in the treatment of anal fissures (Table 12-1). One early clinical trial by Bacher et al.[18] randomized 35 patients with acute and chronic anal fissures to receive either topical 0.2% NTG ointment or 2% lidocaine gel for 4 weeks. After 1 month, the healing rate was 80% for patients receiving NTG, which was significantly higher than the 40% healing rate reported for patients receiving topical lidocaine. Manometric data on the 28th day of treatment also revealed a decrease in overall maximum resting anal pressure from a mean of 110 to 87 cm H_2O in the NTG group but not in patients receiving lidocaine ointment. The authors postulated that the persistence and recurrence of chronic fissures was due to lack of sphincter tone reduction.[18]

Subsequent randomized placebo-controlled trials have attempted to determine whether higher doses of NTG ointment promote healing and lessen recurrence in chronic anal fissures. Carapeti et al.[20] found no difference in chronic fissure healing between patients randomized to receive an 8-week treatment of either 0.2% topical GTN three times daily or 0.2% GTN titrated in 0.1% increments to a maximum of 0.6%. The authors found that by escalating GTN dose, healing was not accelerated. Thus, 67% of patients treated with either dose of GTN preparation healed as compared to 32% of placebo patients. Bailey et al.[27] and Scholefield et al.[28] reported similar findings when patients with chronic anal fissures were either randomized to receive placebo, 0.1%, 0.2%, or 0.4% GTN ointment twice or three times daily. In both studies, there were no significant differences in fissure healing among treatment groups as healing occurred in approximately 50% of all patients.

Additional randomized placebo-controlled trials have demonstrated comparable healing rates of 46–70% in patients with chronic anal fissures after application of 0.2% GTN ointment two to three times daily for 4–8 weeks (Table 12-1). Supportive data demonstrate statistically significant decreases in pain scores and maximal anal resting pressures in patients treated with GTN as compared to placebo. However, in a study by Altomare et al.[21], 132 patients with chronic fissures were randomized to receive 0.2% topical GTN or placebo for 4 weeks. He confirmed the effects of GTN on anodermal blood flow and sphincter pressure, but unlike similarly designed trials, they demonstrated no significant difference in healing rates between GTN and placebo (49.2% vs. 51.7%).

A series of randomized trials have also sought to compare 0.2% GTN with surgery, i.e., LIS. While initial healing rates during 4–8-week evaluation periods were similar to those in placebo-based trials (and up to 83.3% in a study by Oettle et al.),[17] healing rates were far superior for LIS (91.7–100%). In one clinical trial, Evans et al. demonstrated healing in 60.6% of patients treated with GTN as compared

TABLE 12-1. Randomized trials of nitroglycerine therapy

Year	Author	n	Treatment	Follow-up	Success (%)

to 97% of patients treated with sphincterotomy.[24] In addition, of the 33 patients initially treated with GTN, 12 eventually underwent sphincterotomy for persistent fissures. Despite early healing with GTN, 50% of those whose fissures healed with GTN treatment developed recurrences.[24] Similarly, in a randomized, controlled trial by the Canadian Colorectal Surgical Trials Group of LIS compared to topical NTG, 89.5% of patients in the LIS group compared to 29.5% in the NTG group had complete healing of fissures.[23] In addition, side effects were observed more frequently in patients treated with NTG (84%) compared to LIS (28.9%).[23] Follow-up was performed 6 years later and revealed a more durable treatment result for LIS-treated patients as compared to patients treated with topical nitroglycerin therapy.[30]

Other randomized, controlled trials drew different conclusion following GTN treatment. Libertiny et al.[26] randomized 70 patients with chronic anal fissure to receive 0.2% GTN or LIS. Only 16 of 35 patients initially treated with GTN healed without recurrence during a 24-month follow-up, in contrast to operative cure in 34 of 35 patients treated with LIS. Despite the superiority in healing for LIS patients, the authors concluded that chemical sphincterotomy with GTN should be the initial treatment in patients with chronic anal fissure and LIS should be reserved for treatment failures.[26] Zuberi et al.[22] similarly concluded that GTN ointment and NTG patch were effective treatment options in patients with anal fissures. In their prospective trial of 42 patients, healing rates were 66.7% in patients receiving 0.2% GTN, 63.2% for those receiving a 10-mg NTG patch applied at a distance from the fissure, and 91.7% in patients who underwent LIS. Their findings support the use of GTN as a first-line agent in chronic anal fissures, as the difference in healing rates was not statistically significant between groups.[22]

In addition to GTN and NTG, other nitrate preparations have also been used to treat anal fissures. A prospective, uncontrolled study by Schouten et al.[31] demonstrated reduction in anal pressure and improvement in anodermal blood flow in patients with chronic anal fissures treated with isosorbide dintirate. Topical use of isosorbide dintirate led to fissure healing in 88% after 12 weeks. Two randomized, placebo-controlled trials confirmed these findings.[32,33] In a study by Were et al.[32], healing was noted in 85% of patients with chronic anal fissure treated with isosorbide dintirate for 5 weeks as compared to 35% of patients who received

placebo. Tankova et al.[33] subsequently reported fissure healing in 80% of patients actively treated with mononitrate. In a dose-finding study, Lysy et al.[34] found that 2.5 mg of topically applied isosorbide dintirate three times daily resulted in a greater reduction in maximum anal resting pressure than 1.25 mg and excellent fissure healing rates. In a prospective randomized trial, isosorbide dinitrate had comparable levels of fissure healing as compared to surgical sphincterotomy. The authors concluded that isosorbide dinitrate ointment must be considered as the first choice of treatment in patients with chronic anal fissure.[35]

Endogenous nitric oxide donors, such as L-arginine, are also effective in producing relaxation of the anal sphincter. Preliminary in vivo studies in rats have demonstrated a decline in sphincter pressure with administration of 10 mg L-arginine rectally. This effect was reversed with the use of L-arginine antagonists.[36] In a placebo-controlled trial, 46% reduction in resting anal pressure was observed 5 min after topical application of L-arginine, and maintained for 2 h.[37] In a clinical trial of 15 patients, topical application of L-arginine promoted fissure healing without headache in 62% of patients.[38]

Despite encouraging results regarding initial healing rates with topical nitrates, concerns about long-term outcomes and adverse reactions have limited their use. Recurrence rates of 35% have been documented as well as lack of compliance with only 67% completing treatment in one study.[39] In a nonrandomized, prospective trial, Graziano et al.[40] demonstrated a 67% recurrence rate for chronic fissures during a 9-month follow-up period while 77% reported headaches. Mild headaches were also described by Bacher et al.[18] in 20% of patients receiving 0.2% topical GTN. Altomare et al.[21] reported that 34% of chronic fissure patients treated with GTN had headaches and nearly 6% of patients had orthostatic hypotension. Carapeti et al.[20] noted headaches in 72% of patients receiving GTN vs. 27% of controls receiving placebo.

Calcium Channel Blockers

The effect of nifedipine on the anal sphincter was first evaluated by Chrysos et al.[41] in a prospective trial in 1996. Anorectal manometry was performed on ten patients with hemorrhoids and/or anal fissure and ten controls, before and 30 min after receiving 20 mg of sublingual nifedipine. Anal resting pressure was reduced by almost 30% in both groups.[41] This study set the stage for further prospective clinical trials examining the efficacy of nifedipine and other calcium channel blockers in treating anal fissures. In addition to nifedipine, others have used topical DTZ to treat anal fissures.[42] In one initial trial of 2% DTZ gel in ten patients, 67% of fissures healed while no patient reported a headache or any other side effect.

Further prospective trials have substantiated the findings of these early studies. Knight et al.[43] evaluated the effects of 2% DTZ gel in 71 patients and was able to achieve healing

in 75%. Side effects were reported in five patients overall: four experienced perianal dermatitis and one patient, headache. Agaoglu et al.[44] described healing in 60% of patients treated with 20 mg oral nifedipine twice daily, while headaches were reported in only one patient. Ansaloni et al.[45] also reported encouraging results regarding efficacy of 6 mg oral lacidipine, a calcium channel blocker with long duration of action and a particular affinity for blood vessels. Although 90.4% of treated patients' fissures had healed at 2 months follow-up, 33% of patients had side effects.

Randomized, controlled trials comparing topical nifedipine gel with a combination of topical lidocaine and hydrocortisone gels have also demonstrated superiority of nifedipine in the treatment of anal fissures. Antropoli et al.[46] randomized 283 patients to either receive 0.2% nifedipine gel every 12 h or lidocaine/hydrocortisone gel. Complete healing occurred in 95% of patients receiving nifedipine as compared to 50% of controls. Perrotti et al.[47] similarly randomized 110 patients with anal fissure to receive 0.3% nifedipine gel with 1.5% lidocaine or a lidocaine/hydrocortisone mixture twice daily. In the nifedipine group, 94.5% of patients healed completely as compared to 16.4% of controls.

Calcium channel blockers can be administered in either oral form or topically to treat anal fissures. Jonas et al.[48] performed a randomized, controlled trial to ascertain whether different routes of DTZ administration had similar healing rates. The authors identified fissure healing in 38% of those individuals receiving oral DTZ and 65% of patients on topical treatment. In addition, oral DTZ caused far more side effects while no side effects were identified in those receiving topical therapy. At this time, the number of patients evaluated in trials of oral vs. topical therapy has been too small to allow for definitive conclusions.

Although long-term follow-up studies are lacking, several randomized controlled trials comparing calcium channel blockers and nitrates have been performed. Kocher et al.[49] randomized 61 patients with chronic anal fissures to receive 0.2% GTN or 2% DTZ. After 6–8 weeks of treatment, therapeutic efficacy was similar between both groups but patients in the GTN group experienced far more side effects. Bielecki and Kolodziejczak[50] also found equal healing rates between topical 0.2% GTN and 2% DTZ, as well as fewer headaches with 2% DTZ. Yet in another randomized trial, side effects of GTN and DTZ were comparable.[51] Ezri and Susmallian[52] noted improved healing with nifedipine (89%) as compared to GTN (58%) with far more side effects in the GTN (40%) group as compared to nifedipine (5%) and no differences in recurrence. Given these results, many authors have concluded that calcium channel blockers should be considered the preferred first-line treatment because of fewer side effects as compared to GTN.[49,53]

Topical calcium channel blockers have also been compared to surgical sphincterotomy. In one randomized trial, no significant difference in fissure healing was noted in patients treated with topical nifedipine (97%) as compared to LIS

(100%).[54] More side effects and relapses were identified in the nifedipine group, whereas no one in the sphincterotomy group relapsed.[54] In a similar study from Singapore, less convincing results for topical nifedipine were described. Ho found improvements in pain relief, patient satisfaction, and healing rates in patients randomized to internal sphincterotomy as compared to topical nifedipine.[55] In addition, the investigators indicated that there were substantial problems with compliance in the nifedipine group related to side effects and slow healing.[55]

It has become clear to this author that the use of pharmaceutical adjuncts is often based on preferences, but it should be remembered that many of the topical preparations are only available through compounding pharmacies. For this reason, a clinician should become familiar with the pharmaceutical resources available prior to becoming dependent on one medical treatment or another.

Adrenergic Antagonists

The effect of alpha-1 adrenergic blockade on anal sphincter pressure has been studied in two prospective trials. Pitt et al.[56,57] administered 20 mg of indoramin, an alpha-1 blocker, to seven patients with chronic anal fissure and six healthy controls. Reduction in anal pressure was observed in both groups: 35.8% in patients with fissure and 39.9% in those without. In a placebo-controlled trial, 23 patients with chronic anal fissure were randomized to receive 20 mg indoramin or placebo twice daily.[57] Although a 29.8% reduction in maximum anal resting pressure was observed 1 h after active treatment, healing occurred in only one patient (7%), despite 6 weeks of therapy. In the placebo group, 22% of patients achieved healing, although no significant change in anal pressure was observed, the trial was not completed due to lack of efficacy.

Cholinergic Agonists

Carapeti et al.[58] documented reduced anal sphincter pressure using bethanechol in a dose-finding study. The authors demonstrated a 24% reduction in maximal anal resting pressure with a dose of 0.1% of bethanechol. In a subsequent study, they reported fissure healing in 9 of 15 patients treated with 0.1% bethanechol gel three times daily.[42] Maximum resting sphincter pressure was significantly lower after treatment compared with pretreatment values with no side effects.

Phosphodiesterase Inhibitors

Early work by Jones et al.[59] has demonstrated an in vitro effect of increasing concentrations of various phosphodiesterase inhibitors on internal sphincter tone. In a study of 19 consecutive patients with anal fissures, topical administration of a phosphodiesterase-5 inhibitor (sildenafil) significantly reduced anal sphincter pressure in patients with chronic anal fissure. The beneficial effect of sildenafil may not have derived solely from the nitric oxide donor but rather the phosphodiesterase-5 inhibitor. This agent may spark future clinical trials in the treatment of anal fissure.[60]

Botulinum Toxin

Botulinum toxin (BT) is an exotoxin produced by the bacterium *Clostridium botulinum*. When injected locally, BT binds to the presynaptic nerve terminal at the neuromuscular junction, thereby preventing release of acetylcholine and resulting in temporary muscle paralysis. Its mechanism of action on the IAS has been extensively studied in animal studies. In a series of experiments, Jones et al.[61] injected BT into porcine anal sphincters, which responded with decreased mean anal resting pressure following manometric analyses. Strips of sphincter muscle were then isolated and examined in vitro. Application of electrical field stimulation and nicotinic agonists resulted in increased myogenic tone, which was blocked by guanethidine and attenuated by BT injection. These findings suggested that the predominant effect of BT on the IAS is sympathetic blockade.

BT injections can be given easily, on an outpatient basis, and are well tolerated. The commercial availability of BT has prompted several prospective trials examining its efficacy in the treatment of anal fissure (Table 12-2). One placebo-controlled trial randomized 30 patients to receive either two injections of 20 U BT or saline.[62] After 2 months, complete healing occurred in 73% of patients receiving BT and 13% of patients receiving placebo; no recurrences were observed during initial follow-up. In another clinical trial comparing BT with lidocaine in the treatment of anal fissure, Colak et al.[64] demonstrated superiority of BT, with complete fissure epithelialization in 71% of patients in the BT group vs. 21% in the lidocaine group.

The dosing and injection site for BT has also been examined in several trials. In a randomized, double-blind trial of chronic anal fissure treatment, Siproudhis et al.[66] reported that a single 20 U injection of BT was not superior to that of placebo. In a dose-finding study, Brisinda et al.[65] randomized 150 patients to initial treatment with 20 U BT followed by 30 U BT for fissure persistence, or initial treatment with 30 U BT followed by 50 U BT for persistence. One month after BT injections, greater success was noted with higher doses, with little increase in complications or side effects, which is probably related to the diffusion of the toxin to the external sphincter.[65] In addition to dosing, injection site has also been studied. Injection on each side of the anterior midline lowered resting anal pressure to a greater degree and produced an earlier healing scar than compared to BT injection on each side of the posterior midline.[73] The use of BT injections for GTN treatment failures has also been evaluated in prospective trials by Madalinski et al.[74] and Lindsey et al.[75] Both studies concluded that BT injection is an excellent second-line agent in the treatment of chronic anal fissures. Given these data, it

is the authors practice to inject 20 U of BT on either side of the anterior midline in the intersphincteric groove.

The efficacy of a single injection of BT has been directly compared to topical agents. In a prospective, randomized trial, Brisinda et al.[63] directly compared BT injection and topical NTG as first-line agents in the treatment of chronic anal fissure. BT injections (20 U) were given on each side of the IAS and 0.2% NTG ointment was applied twice daily. Fissures healed in 96% of the patients in the BT group and 60% of the patients in the NTG group with more side effects in the NTG group.[63] A follow-up to this study by the same authors revealed similar findings.[72] Others have used a single dose of 30 U BT and compared it to topical 0.2% NTG twice a day and found nitroglycerin ointment to be superior to the more expensive and invasive botulinum toxin injections for initial healing of chronic fissures.[71] De Nardi et al.[70] performed a similar analysis but used 20 U BT on either side of the anterior midline with dismal healing results for both BT and NTG, 40 and 33%, respectively.

There have been several prospective, randomized trials comparing BT to LIS in the treatment of chronic anal fissures. Mentes et al.[67] reported the results of 61 patients receiving a total of 0.3 U/kg BT in two divided doses and 50 patients who underwent sphincterotomy. By 2 months, healing rates were 74% in the BT group and 98% in the LIS group. By 12 months, however, fissures recurred in seven patients in the BT group leading to an overall healing rate of 75% which was significantly lower than the LIS group. Anal incontinence, predominantly to flatus, was reported in

16% of patients in the LIS group while no side effects were observed with BT. Similarly, Iswariah et al.[69] randomized 38 patients with anal fissures to either BT or sphincterotomy and found significantly higher 2-week pain scores, reoperation rates, and poorer healing in the BT group. In another randomized trial, Arroyo et al.[68] concluded that surgical sphincterotomy should be the first therapeutic approach for anal fissure as compared to BT.

Late recurrence rates 42 months after BT treatment of chronic anal fissures have been reported in a prospective trial by Minguez et al.[76] Patients with complete healing at 6 months after BT were reassessed at 6 month intervals with fissure recurrence demonstrated in 41.5% of patients. Stratification by various clinical parameters revealed that higher risk of recurrence was associated with anterior location, chronicity of disease (longer than 12 months), and multiple injections. They comment that lack of recurrences cited in earlier reports by Maria et al.[62] and Brisinda et al.[63] may be due to strict exclusion criteria.

Many of the studies of BT therapy for anal fissure have focused solely on short-term outcomes such as acute fissure healing. However, as stated above, recurrences are likely common. Some investigators believe that patients with fissure recurrence after one BT injection may experience some improvement in their symptoms with repeated BT injections. In the study by Maria et al.[62], repeated BT injections in four patients with recurrent fissures using 25 U of BT led to healing in all patients. In addition to high recurrence rates with BT, associated complications have been historically

minimal. Injections of BT have led to perianal hematomas in 20% of patients treated by Tilney et al.[77] and rare cases of perianal thrombosis in a study by Jost et al.[78] although thrombosis was not reported in a later study by this same author.[79] Most recently, the US Food and Drug Administration (FDA) issued a warning regarding a small number of adverse reactions to BT injections, including respiratory failure and death.[80] In early communications, the agency indicated that these serious reactions to BT injections may have been related to overdosing.[80]

Operative Treatment

The primary goal in the treatment of a nonhealing anal fissure is to decrease abnormally elevated resting anal tone. Operative procedures, such as manual anal dilatation or internal sphincterotomy, have been described as initial modes of treatment because they produce permanent reductions in maximum resting anal pressures.

Anal Dilatation

Manual dilatation of the anus for anal fissure was first reported in 1964.[81] A variety of means to enlarge the anal canal have been described including the use of four fingers and an assortment of dilation instruments. Inconsistencies with regard to technique, specifically extent and duration of sphincter stretch, have cast some doubt about true success rates of dilatation procedures. Yet, reports of anal dilatation continue to surface and recommend its use as the "first management choice in the treatment of anal fissure."[82–85] Given the controversy regarding standardization of the technique, Sohn et al.[86] standardized the anal dilatation procedure with either a Parks' retractor opened to 4.8 cm or a pneumatic balloon inflated to 40 mm and found fissure healing in up to 94%. A more recent study used pneumatic balloon dilatation in the management of chronic anal fissure and found this technique to be effective and safe without producing endosonographically detectable sphincter damage.[87]

Despite few studies describing the benefits of anal dilatation on anal fissure, long-term outcomes of anal dilatation are rare. Additional widespread criticism of the technique stems from reported complications of incontinence, secondary to diffuse sphincter damage. In a retrospective analysis of anal dilatation for anal fissure by MacDonald et al.,[84] not only was dilatation unsuccessful in 56% of patients but incontinence occurred in 27% of patients overall. Speakman et al.[88] performed endoanal ultrasound and anorectal physiology studies on 12 men with fecal incontinence after anal dilatation and found internal and external anal sphincter defects in 11 and 3 patients, respectively. Sphincter defects after anal dilatation were also recognized by Nielsen et al.[89], who reported minor incontinence in 12.5% of patients overall.

Comparisons between sphincterotomy and medical measures, combined with anal dilatation, have also been reported. In one retrospective review, questionnaires were sent to 160 patients who underwent either anal dilatation or LIS. Fewer fissure recurrences or reports of incontinence were reported in patients treated by sphincterotomy.[90] Other prospective, randomized trials did not support these findings.[91–94] In some studies, recurrence and incontinence rates were equal between groups[91,93,94]; in another, significantly worse after LIS.[92] Four months after randomization in a trial by Marby et al.[92], symptomatic improvement was reported in 93% after dilatation vs. 78% after sphincterotomy. During the same time period, recurrence rates were 10% after dilatation and 29% following sphincterotomy. Most recently, randomized trials have demonstrated superior functional results, in terms of incontinence, after LIS.[95] While recurrence rates were 3.5–10% up to 1 year after LIS, higher rates of 26–30% were observed after anal dilatation.[93,96] Although anal dilatation is still performed by some centers, clinical practices across North America no longer commonly use this technique as a primary treatment for anal fissure.

Fissurectomy

Excision of the fissure with or without sphincterotomy has been proposed as a good therapeutic approach to anal fissure. Given that the etiology of anal fissures is thought to be secondary to inadequate blood flow and spasm, one would venture to guess that this approach is unlikely to be useful. In one clinical trial by Mousavi et al.[97], fissurectomy was considered inferior to LIS, which was associated with fewer complications.

Lateral Internal Sphincterotomy

The American Society of Colon and Rectal Surgeons (ASCRS) practice parameters for the management of anal fissures recommends LIS as the surgical treatment of choice for refractory anal fissures.[98] Internal sphincterotomy was first introduced by Eisenhammer[99] in the early 1950s, but his initial approach through the bed of the fissure in the posterior midline often resulted in a scarred groove, or "keyhole deformity." The functional impairment which evolved included gas and/or stool incontinence. Subsequently, LIS emerged as an alternative and was believed to be associated with less functional impairment.[100]

LIS can be performed with an open or closed technique (Figures 12-3 and 12-4). The open technique is performed with a small incision over the intersphincteric groove and direct division of the internal sphincter with electrocautery or other instrument. The closed technique is performed by placing a small scalpel such as a beaver blade into the intersphincteric groove and carefully dividing the internal sphincter. Although the blade can be placed into the submucosal space and then rotated toward the internal sphincter, most
FIGURE 12-3. Open lateral internal sphincterotomy. **A** Radial skin incision distal to the dentate line exposing the intersphincteric groove. **B** Elevation and division of the internal sphincter. **C** Primary wound closure.
FIGURE 12-4. Closed lateral internal sphincterotomy. **A** Location of the intersphincteric groove. **B** Insertion of the knife blade in the intersphincteric plane. **C** Lateral to medial division of the internal anal sphincter (*inset*: medial to lateral division of the muscle).

find that placing the knife in the intersphincteric groove preferable. Several retrospective studies support the use of LIS as the preferred operative method for the treatment of anal fissures, whether open or closed (Table 12-3).[101,104,107,110,115,117,121] Although there was no significant difference in *acute* complications in one randomized study of open vs. closed LIS, long-term persistent complications were more frequent in the

open (55%) than the closed (20%) sphincterotomy group.[109] Similarly, the degree of continence following open vs. closed sphincterotomy was assessed by questionnaire and favored closed LIS.[116]

Persistent incontinence to gas and stool has emerged as a major concern following sphincterotomy. Incontinence rates of up to 36% have been reported, but these vary widely among studies.[109,111,112,116,119] Much of this variation can be attributed to differences in definition and assiduousness of follow-up. Reasons for incontinence after LIS have been related to the type and extent of sphincter muscle divided. Sultan et al.[122] prospectively performed endoanal ultrasonography prior to and 2 months after sphincterotomy in 15 patients. The authors found more complete sphincter deficits in women than men due to the lack of appreciation for shorter anal canals in this population and suggested that post sphincterotomy incontinence may be further lessened if external anal sphincter deficits are recognized preoperatively.

Littlejohn and Newstead[118] reported a retrospective review of 287 patients who underwent tailored sphincterotomy, division of the IAS for the length of the fissure, rather than to the dentate line. There were no reports of incontinence to liquid or solid stool in either group. In another study that sought to identify fecal incontinence related to chronic anal fissure before and after LIS and its relationship to the extent of IAS division, Elsebae[123] concluded that a mild degree of fecal incontinence may be related to the underlying pathology rather than the sphincterotomy. In addition, troublesome fecal incontinence after LIS is uncommon but much more common when sphincterotomy is performed up to the dentate line rather than up to the fissure apex. It is the authors' practice to limit the extent of sphincterotomy to include solely the length of the fissure.

In addition to the length of the sphincterotomy, other technical issues should be considered. Excision of hypertrophied anal papillae and fibrous anal polyps has been advocated by Gupta and Kalaskar.[124] In a randomized trial, patient satisfaction was rated as excellent or good after removal of these structures in 84% of patients, compared to 58% of patients whose papillae were left in vivo. In a separate prospective study, earlier wound healing rates were achieved with primary closure after open LIS as compared to healing by secondary intention.[125] Last, in patients who return with fissure recurrence after sphincterotomy, it should be understood that improper division of the IAS significantly alters fissure healing. In a study by Farouk et al.[126], ultrasound evaluations performed in patients with persistent fissures after sphincterotomy demonstrated a lack of internal sphincter division in almost 70% of patients.

Advancement Flaps

Endorectal advancement flaps have also been employed in the treatment of anal fissure. One prospective trial randomized patients with anal fissure to either LIS or advancement flap

and found no significant difference in healing rates (100% in the sphincterotomy group vs. 85% in the flap group).[113] Incontinence was not observed in either group. The authors concluded that anal advancement flap is an alternative to LIS for chronic anal fissure. The advancement flap procedure may be particularly useful in those patients with low-pressure fissures but more data is needed before it can be recommended in the patient with traditional spasm-related anal fissure.

Summary of Treatment Options

Treatment options for anal fissures are varied and unfortunately the data presented above are difficult to summarize into a cogent management algorithm. In addition to clinical experience, the clinician can utilize the findings of systematic reviews in making decisions regarding care. In the most recent systematic review of medical options and surgical sphincterotomy, Nelson[127] found that GTN was significantly better than placebo in healing anal fissures but late recurrences were common. Botulinum toxin and calcium channel blockers were equivalent to GTN in efficacy with fewer adverse events. Nelson[127] concluded that

no medical therapy came close to the efficacy of surgical sphincterotomy, although a low risk of incontinence must be considered with surgery. Nelson[128] also reviewed the results for all surgical procedures used to treat anal fissures and concluded that anal stretch and posterior midline internal sphincterotomy should probably be abandoned, while open and closed partial LIS appear to be equally efficacious. Given these data, it is our practice to step up treatment from topical agents to injectables or surgical sphincterotomy depending on the patients' potential risk for future incontinence. In women who have had children or are planning on having children, it is the authors' preference to maximize nonsurgical options prior to resorting to surgical sphincterotomy.

Atypical Fissures

The majority of anal fissures have classic signs and symptoms and respond well to LIS. However, there are groups of patients who have fissures identified at the time of anorectal examination for rectal bleeding but deny pain or complain of incontinence yet have obvious signs of anal

fissure. Incontinent patients with evidence of anal fissure are generally identified as having low-pressure fissures and they are often postpartum.[129] In a prospective study of 209 primigravid women who underwent anal manometry both pre and postpartum, 9% went on to develop fissures after birth.[130] Interestingly, in those patients who developed fissures, manometric measurements were similar both before and after birth. The authors concluded that, "surgical interference with the anal sphincter mechanism should be avoided," in patients with low-pressure fissures.[130]

It remains unclear as to optimal therapy for low-pressure fissures. A trial of conservative management should be initiated. If unsuccessful, some have advocated the advancement of healthy tissue over the fissure in the form of an island flap or a sliding endoanal advancement flap. In one study, island flaps were advanced into the anal canal leading to fissure healing in all patients and no postoperative incontinence.[131] The authors concluded that island advancement flaps may prove particularly useful for low-pressure fissures or in those patients who may be poor candidates for sphincterotomy. In addition, there are advocates of silver nitrate application to the low-pressure fissure bed, but little evidence exists to substantiate this approach.

Crohn's Disease

Patients with Crohn's disease often present with anorectal manifestations of their disease including asymptomatic or bleeding, deep, anal fissures among other disease pathology. Anal fissures complicating Crohn's most commonly follow the same pathophysiology of benign idiopathic fissures, but persistent nonhealing fissures can evolve into fistulae or perianal abscess.[132] Findings of multiple fissures, nonhealing fissures, and asymptomatic fissures should raise the index of suspicion for Crohn's disease. Large edematous and tender skin tags are also very common in Crohn's disease. In those patients in whom Crohn's disease is suspected based on anorectal examination, thorough evaluation with endoscopy and imaging is recommended.

In a review of 306 patients with Crohn's disease, anal pathology leading to symptoms was identified in 42.4% of patients.[133] The commonest presentations were perianal abscess (29.5%), anal fissure (27.6%), and low anal fistula (26.7%).[133] In another analysis of Crohn's patients treated surgically for perianal complaints, 31.8% had evidence of anal fissure.[134] In a study from the Lahey Clinic, 84% of patients with Crohn's fissures were found to be symptomatic while one-third had multiple fissures.[132] This series documented that unhealed fissures frequently progress to more ominous anal pathology, yet this finding may be related to more virulent disease in this patient population.[132]

As indicated, anorectal surgery has traditionally been contraindicated in patients with Crohn's disease. Concerns of postoperative incontinence, nonhealing wounds, and eventual proctectomy led many to avoid surgery in patients with Crohn's disease. Thus, most clinicians have advocated medical management of Crohn's fissures with a focus on reducing diarrhea, bulking the stool, and comfort measures. This regimen led to healing in 61% of patients treated medically for Crohn's fissures.[135] However, if medical management fails, an exam under anesthesia is indicated to rule out the presence of other pathology. Although, data to support the use of BT for Crohn's fissures is not available, the authors have had limited success with this approach.

Surgical outcomes following sphincterotomy for Crohn's fissures are limited to case series. Surgery for Crohn's fissures was successful in a small study published by Wolkomir et al.[136] as very few patients went on to require proctectomy. At the Lahey Clinic, patients with Crohn's fissures were more likely to report successful healing after partial internal sphincterotomy as compared to medical treatment.[132] Others have reported limited success with anal dilatation for Crohn's fissures,[82] while Allan and Keighley[137] reported the development of incontinence in one patient treated with dilatation. The authors' approach in the patient with a Crohn's fissure has been to try to control the underlying disease with medical management prior to resorting to permanent surgical therapy with LIS.

Human Immunodeficiency Virus

The patient with HIV and anorectal pain often presents with challenging pathology leading to a long differential diagnosis. However, the presence of severe pain should alert the clinician to the potential for fissures or ulcers of the anal canal. Often these findings are mistakenly interchanged, but it is important to understand the distinction between HIV-associated fissures as compared to ulcerating diseases of the anus. Classic anal fissures are common in the HIV patient as in non-HIV patients and are readily identifiable by the typical fissure appearance. Conversely, anorectal ulcers in the HIV patient are deep and boring with a broad base which may be located anywhere in the anus.[138,139] Patients with HIV and classic fissures can be treated with the same modalities that are used in non-HIV patients. In fact, early case reports of wound complications and incontinence after surgical sphincterotomy for fissures likely included a heterogeneous patient population that included patients with HIV-associated anorectal ulcers.[139] In one case series of HIV-associated anal fissures, symptomatic improvement was noted in 92% of patients treated with surgical sphincterotomy.[138] In addition, although theoretically safe, there is little data regarding the risks and benefits of BT on HIV-associated fissures. The introduction of highly active antiretroviral therapy has led some to speculate that the prevalence and distribution of HIV-associated anorectal pathology has changed considerably; however, this theory was not proven in a review at the University of Southern California HIV clinic.[140]

Conclusions

The astute clinician can often make the diagnosis of anal fissure based on a simple history and classic appearance of fissure without inflicting unnecessary pain from examination. Trauma is thought to predispose the development of anal fissures, but elevated sphincter pressure and reduced blood flow are likely to play a role in the pathogenesis. Traditionally, the standard therapeutic approach to anal fissures included oral fiber, sitz baths, and analgesics. At this time, a number of medical treatment options are available including nonoperative care, topical nitrates, topical or oral calcium channel blockers, and injections of BT. Unfortunately, medical care has had pedestrian results as the most recent Cochrane review concluded that medical therapy for anal fissures is only marginally better than placebo and for chronic fissures far less effective than surgery.[127] Despite the mixed results with medical therapy, it is our practice to trial these medical measures unless the patient is extremely uncomfortable.

Anorectal Abscess and Fistula

Carol-Ann Vasilevsky

Anorectal abscesses and fistula-in-ano represent different stages along the continuum of a common pathogenic spectrum. The abscess represents the acute inflammatory event while the fistula is representative of the chronic process.

Abscess

Anatomy

Successful eradication of anorectal suppuration and fistula-in-ano requires an in-depth understanding of anorectal anatomy. Essential is an understanding of the existence of potential anorectal spaces (Figure 13-1A).[1] The perianal space is located in the area of the anal verge. It becomes continuous with the ischioanal fat laterally while it extends into the lower portion of the anal canal medially. It is continuous with the intersphincteric space. The ischioanal space extends from the levator ani to the perineum. Anteriorly it is bound by the transverse perineal muscles; the lower border of the gluteus maximus and the sacrotuberous ligament form its posterior border. The medial border is formed by the levator ani and external sphincter muscles; the obturator internus muscle forms the lateral border. The intersphincteric space lies between the internal and external sphincters and is continuous inferiorly with the perianal space and superiorly with the rectal wall. The supralevator space is bounded superiorly by peritoneum, laterally by the pelvic wall, medially by the rectal wall and inferiorly by the levator ani muscle. The deep postanal space is located between the tip of the coccyx posteriorly and lies below the levator ani and above the anococcygeal ligament (Figure 13-1B).

At the level of the dentate line, the ducts of the anal glands empty into the anal crypts.

Some 80% of the anal glands are submucosal in extent, 8% extend to the internal sphincter, 8% to the conjoined longitudinal muscle, 2% to the intersphincteric space, and 1% penetrate the internal sphincter.[2]

Pathophysiology

Etiology

Ninety percent of all anorectal abscesses result from nonspecific cryptoglandular infection while the remainder result from the causes as listed in Table 13-1. According to the cryptoglandular theory championed by Parks,[3] abscesses result from the obstruction of the anal glands and ducts. The obstruction of a duct may result in stasis, infection and formation of an abscess. Persistence of anal gland epithelium in part of the tract between the crypt and the blocked part of the duct results in the formation of a fistula. Predisposing factors include diarrhea and trauma in the form of a hard stool. Associated factors may be anal fissures, infection of a hematoma or Crohn's disease.

Classification

Abscesses are classified according to their location in the aforementioned potential anorectal spaces: perianal, ischioanal, intersphincteric, and supralevator (Figure 13-2). Perianal abscesses are the most common type while supralevator abscesses are the rarest. Pus can also spread circumferentially through the intersphincteric, supralevator or ischioanal spaces, the latter via the deep postanal space, resulting in a horseshoe abscess.

Evaluation

Symptoms

Pain, swelling, and fever are the hallmarks associated with an abscess. The patient with a supralevator abscess may complain of gluteal pain.[4] Rectal bleeding has been reported. Severe rectal pain accompanied by urinary symptoms, such as dysuria, retention, or inability to void may be suggestive of an intersphincteric or supralevator abscess.

Physical Examination

Inspection reveals erythema, swelling, and possible fluctuation. It is crucial to recognize that no visible external manifestations are present with the intersphincteric or supralevator abscesses despite the patient's complaint of excruciating pain.[1] Although digital examination may not be possible because of extreme tenderness, palpation, if possible, will demonstrate tenderness and a mass. With a supralevator abscess, a tender mass may be palpated on rectal or vaginal examination.[4] Anoscopy and sigmoidoscopy are inappropriate in the acute setting.

Treatment

General Principles

Essentially, the treatment of an anorectal abscess involves incision and drainage. Watchful waiting under the cover of antibiotics is ineffective and may allow the suppurative process to progress resulting in the creation of a more complicated abscess and thus possible injury to the sphincter mechanism. Rarely, delay in diagnosis and management of anorectal abscesses may result in life-threatening necrotizing infection and death.[5] The American Society of Colon and Rectal Surgeons has issued practice parameters for the treatment of perianal abscess and fistula-in-ano.[6]

Operative Management

Incision and Drainage

Perianal abscesses can be effectively drained under local anesthesia.[4,7] After the most tender point has been determined,
FIGURE 13-3. Drainage of abscess: **A** injection of local anesthesia, **B** cruciate incision, **C** excision of skin, **D** drainage cavity.

the area is infiltrated with 0.5% lidocaine with 1:200,000 epinephrine. A cruciate or elliptical incision is made and the edges are trimmed to prevent coaptation which may result in poor drainage or recurrence (Figure 13-3). No packing is required.

Most ischioanal abscesses can be incised and drained in a similar fashion with the site of incision shifted as close to the anal side of the abscess, minimizing the complexity of a subsequent fistula. Large ischioanal or horseshoe abscesses often require drainage with the patient under a regional or general anesthetic with the patient in the prone jackknife or left lateral (Sim's) position. The location of infection is often in the deep postanal space. Access to this space may be achieved by a midline incision between the coccyx and anus, spreading the superficial external sphincter to enter the space. An opening is made in the posterior midline and the lower half of the internal sphincter is divided to drain the
FIGURE 13-4. Drainage of horseshoe abscess.

anal gland in which the infection originated.[4] Counter-incisions are made over each ischioanal fossa to allow drainage of the anterior extensions of the abscess (Hanley procedure) (Figure 13-4).[7]

Since the diagnosis of an intersphincteric abscess is entertained when the patient presents with pain out of proportion to the physical findings, an examination under anesthesia is mandatory to completely assess the cause of the pain. Once the diagnosis is established, either by palpation of a protrusion into the anal canal or by needle aspiration in the intersphincteric plane, treatment consists of dividing the internal sphincter along the length of the abscess cavity. The wound is then marsupialized to allow adequate drainage and quicker healing.

Prior to the treatment of a supralevator abscess, it is essential to determine its origin since it may arise from an upward extension of an intersphincteric or an ischioanal abscess, or downward extension of a pelvic abscess.[1,4] The treatment in each case is different. If the origin is an intersphincteric abscess, it should be drained through the rectum by dividing the internal sphincter and not through the ischioanal fossa, since this will result in the creation of a suprasphincteric fistula. However, if it arises from an ischioanal abscess, it should be drained through the perineal skin and not through the rectum; otherwise an extrasphincteric fistula will occur (Figure 13-5). If the abscess is of pelvic origin, it may be drained through the rectum, ischioanal fossa or abdominal wall via percutaneous drainage depending on the direction to which it is pointing.

Catheter Drainage

An alternative method of treatment for selected patients is catheter drainage. Patients suitable for this technique should not have severe sepsis or any serious systemic illness.[8] The patient is placed in the prone jackknife position or left lateral (Sim's) position. The skin is prepared with a proviodine-iodine solution and the fluctuant point of the abscess is selected. Local anesthesia consisting of 0.5% lidocaine with 1:200,000 epinephrine is injected into a 1 cm area of skin and a stab incision is made to drain the pus.
FIGURE 13-5. Drainage of a supralevator abscess.

The lidocaine should be injected into the skin around rather than immediately over the point of maximal fluctuation because the acid environment may otherwise preclude adequate anesthesia (Figure 13-6A). A 10–16 French soft latex mushroom catheter is inserted over a probe into the abscess cavity. When released, the shape of the catheter tip holds the catheter in place, obviating the need for sutures. The external portion of the catheter is shortened to leave 2–3 cm outside the skin with the tip in the depth of the abscess cavity (Figure 13-6B). This reduces the chances of the catheter falling out of or into the abscess cavity. A small bandage is placed over the catheter.

When using this technique, it is important that the stab incision be placed as close as possible to the anus, minimizing the amount of tissue that must be opened if a fistula is found following the resolution of inflammation (Figure 13-6A) and the size and length of the catheter should correspond to the size of the abscess cavity (Figure 13-7A). A catheter that is too small or too short may fall into the wound (Figure 13-7B). The length of time that the catheter should be left in place depends on the size of the original abscess cavity, the amount of granulation tissue around the catheter and the character and amount of drainage. If there is doubt, it is better to leave the catheter in place for a longer period of time.

Primary Fistulotomy

In the recent past, a contentious issue has been whether primary fistulotomy should be performed at the time of initial abscess drainage. With the advent of noninvasive techniques, such as fibrin glue and the anal fistula plug, many of the former proponents of this procedure have since abandoned this approach, electing to await the appearance of a fistula following drainage only to treat it with one of the former less invasive methods so as to avoid cutting any sphincter muscle.
FIGURE 13-6. Catheter drainage of an abscess: **A** stab incision, **B** catheter in abscess cavity.
FIGURE 13-7. Catheter in an abscess cavity: **A** correct size and length of catheter, **B** catheter too short.

The argument was based on the feeling that in the acute phase one can better trace the suppurative process because of the presence of pus. Primary fistulotomy, it was believed, eliminated the source of infection and decreased the rate of recurrence, obviating the need for subsequent surgery with the potential to decrease disability and morbidity. A meta-analysis of five randomized controlled trials comparing drainage alone to drainage plus fistulotomy when a fistula was identified showed an 83% decrease in subsequent fistula formation[9] with no increase in incontinence.

Opponents are reluctant to perform primary fistulotomy in the presence of acute inflammation since the search for an internal opening may lead to the creation of false passages resulting in neglect of the main source of infection.[10,11] Failure to identify an internal opening has been reported to occur in as high as 66% of patients.[12] In addition, 34–50% of patients who present with an abscess for the first time will not develop a fistula.[7,12] A recent retrospective cohort study showed that age less than 40 significantly increased the risk of developing a fistula or recurrent abscess after drainage of the initial perianal abscess.[13] Thus, primary fistulotomy in these patients would be unnecessary and may result in needless disturbances of continence. Of those patients whose abscesses are drained, 11% may develop a fistula while 37% may develop a recurrent abscess.[10] This is most often observed in conjunction with ischioanal abscesses.[10] The search for an internal opening converts the operative procedure from one that can be performed under local anesthesia to one that requires regional or general anesthesia. A prospective randomized trial of drainage alone versus drainage and fistulotomy for acute perianal abscesses with proven internal openings revealed that incision and drainage alone demonstrated no statistical significance in recurrence compared with concurrent fistulotomy although there was a tendency to recurrence in the former group.[14] Another prospective study advocated a conservative approach in the treatment of anorectal abscess, reserving fistulotomy as a second-stage procedure, if necessary.[15]

If the internal opening of a low transsphincteric fistula is readily apparent at the time of abscess drainage, primary fistulotomy is feasible with the following exceptions: (1) patients with Crohn's disease, (2) patients with acquired immune deficiency syndrome (AIDS), (3) elderly patients, (4) patients with high transsphincteric fistulas, and (5) women with anterior fistulas and episiotomy scars.

The decision to perform a primary fistulotomy should be individualized but should only be attempted by a surgeon with a sound knowledge of the regional anatomy. Insistence upon finding a fistula may encourage the creation of a false passage and unnecessary division of sphincter muscle.

Antibiotics

There is little if any role for antibiotics in the primary management of anorectal abscesses except as an adjunct in patients with valvular heart disease or prosthetic valves, extensive soft tissue cellulitis, prosthestic devices, diabetes, immunosuppression, or systemic sepsis.

Postoperative Care

Patients are instructed to continue with a regular diet and to take a bulk-forming agent, noncodeine-containing analgesic and sitz baths. Patients are generally seen in follow-up in 2–4 weeks or for intersphincteric or supralevator abscesses, 2 weeks postoperatively. Those patients in whom catheter drainage has been performed are seen within 7–10 days post procedure. If the cavity has closed around the catheter and drainage has ceased, the catheter is removed. If the cavity has not healed, the catheter is left in place or replaced with a smaller one. In all cases, patients are observed until complete healing has occurred.

Complications

Recurrence

Following incision and drainage, ischioanal, and intersphincteric abscesses are associated with the development of recurrent abscesses or fistulas in as many as 89% of patients.[10,15,16] Recurrence is more likely to occur in patients with a history of previous abscess drainage perhaps because the natural barriers to infection have been destroyed.[10,15,16] Reasons for recurrence of anorectal infections include missed infection in adjacent anatomic spaces, the presence of an undiagnosed fistula or abscess at initial abscess drainage, and failure to completely drain the abscess.[5]

If a patient waits too long for follow-up following catheter drainage, the skin may seal and a second incision may be required to retrieve the catheter or redrain a recurrent abscess.

Failure to detect a primary opening at the time of primary fistulotomy and abscess drainage may result in persistence of the infection.

Extra-anal Causes

Extra-anal disease should be considered once the usual causes of recurrence have been ruled out. Hidradentis suppurativa and downward extension of a pilonidal abscess should be considered.[1] A prospective review of recurrent anorectal abscesses by Chrabot et al.[17] reported hidradenitis in one third of patients with recurrent abscesses. In addition, the possibility of Crohn's disease should be suspected as well as tuberculosis, human immunodeficiency virus (HIV) infection, perianal actinomycosis, rectal duplication, lymphogranuloma venereum, trauma, foreign bodies, and a perforated rectal carcinoma.

Incontinence

Incontinence may result after incision and drainage of an abscess either from iatrogenic damage to the sphincter or inappropriate wound care. Continence may be compromised if the superficial external sphincter is inadvertently divided during drainage of a perianal or deep postanal abscess in a patient with preoperative borderline continence. Drainage of a supralevator abscess may lead to incontinence if the puborectalis is inappropriately divided.[18] Prolonged packing of a drained abscess may impair continence by preventing the development of granulation tissue and promoting the formation of excess scar tissue.[19]

Although advocated to decrease recurrence rates, primary fistulotomy may result in unnecessary division of sphincter muscle in acutely inflamed tissue. Schouten and van Vroonhoven[15] reported a 39% rate of continence disturbances in a prospective randomized trial.

Special Considerations

Necrotizing Anorectal Infection

Rarely, anorectal abscesses may result in necrotizing infection and death. Factors thought to be responsible include delay in diagnosis and management, virulence of the organism involved, bacteremia and metastatic infections, or underlying disorders, such as diabetes, blood dyscrasias, heart disease, chronic renal failure, hemorrhoids, and previous abscess or fistula.[5] Obesity and cigarette smoking are thought to be risk factors.

Symptoms and Signs

Spreading soft tissue infection of the perineum can be classified into two groups.[20] The first group includes anorectal sepsis in which the infection extends superficially around the perineum resulting in necrosis of skin, subcutaneous tissue, fascia, or muscle. Perianal crepitation, erythematous, indurated skin, blistering, or gangrene may be present (Figure 13-8). A black

3/7/2002

FIGURE 13-8. Necrotizing anorectal infection.

spot may appear early and indicates a widespread necrotizing infection.[21] The second group includes sepsis in which the preperitoneal or retroperitoneal spaces have become involved.[20] Subtle signs may be present which include abdominal wall induration, tenderness, or a vague mass. It is important to realize that systemic symptoms, such as fever, tachycardia, and vascular volume depletion may precede the appearance of overt signs of infection.[22] Computed tomography (CT) scan is an excellent diagnostic tool since it demonstrates the origin as well as the extent of infection.[23]

Treatment

Early recognition and aggressive surgical therapy as well as selection of the appropriate antibiotics result in a decrease in mortality.[24] The mean interval from the onset of symptoms to surgical intervention is seen as the most important prognostic factor with a significant impact on outcome.[24]

Treatment consists of vigorous intravenous fluid hydration, restoration of electrolyte balance, and insertion of a Foley catheter. Accompanying coagulopathy, respiratory insufficiency and renal failure must be aggressively treated. Invasive monitoring and ventilatory support may be necessary.[25] Pus or necrotic tissue from the infected region must be cultured for aerobes and anaerobes. A Gram stain can be used to distinguish between the presence of clostridial and nonclostridial organisms.[26] Empiric broad-spectrum antibiotic therapy should be instituted regardless of Gram stain and culture results. The chosen antibiotic regimen should be effective against staphylococci and streptococci, gram-negative coliforms, Pseudomonas, Bacteroides, and Clostridium. For grampositive rods seen on Gram stain, antibiotics administered should include sodium penicillin G in doses of 24–30 million units per day and an aminoglycoside. Tetanus toxoid should also be administered.[25]

Surgical treatment consists of wide radical debridement until healthy tissue is encountered. The goals of surgical debridement are to remove all nonviable tissue, halt the progression of infection and alleviate the systemic toxicity.[22] It is crucial to realize that the preoperative skin changes may be minimal compared to the operative findings which may include edema, liquefactive necrosis of subcutaneous tissues, watery pus formation, and extensive necrosis of underlying fascia.[25] Re-examination under anesthesia is usually necessary since this is the only manner by which adequate wound examination can be conducted.[25] Vacuumassisted closure of the resulting wounds may be a useful adjunct in healing of these wounds which may be rather extensive.[27] The need for colostomy is a debatable issue and has been recommended if the sphincter muscle is grossly infected, if there is colonic or rectal perforation, if the rectal wound is large, if the patient is immunocompromised or if incontinence is present.[20,22] While some authors feel that colostomy is seldom necessary,[26] fecal diversion may also

be accomplished with the use of a "medical colostomy" consisting of enteral or parenteral nutrition. Controversy also exists with regards to the need for urinary diversion by suprapubic catheterization. It has been suggested that this may be indicated in the presence of known stricture and urinary extravasation with phlegmon.[28]

Although antibiotics and adequate surgical drainage are thought to be sufficient, the use of hyperbaric oxygen (HBO) has been advocated as an adjunct to treatment, particularly in patients with diffuse spreading infections who do not have chronic obstructive pulmonary disease.[29] It is postulated that HBO has a direct antibacterial effect on anaerobic bacteria by diminishing the effect of endotoxins and optimizing leukocyte phagocytic function.[21] HBO may also promote would healing by facilitating fibroblast proliferation.[29] HBO is delivered as 100% oxygen through an oronasal mask or endotracheal tube at 3 ATM for one or two cycles each lasting 2 h. If HBO is to be used as an adjunctive therapy, appropriate surgical intervention with wide debridement cannot be compromised since ischemic tissue cannot be salvaged by HBO.[22]

Despite aggressive surgical and multidisciplinary management of anorectal sepsis, mortality rates ranging from 8 to 67% have been reported.[20,22] This high mortality rate is due in part to the aggressive nature of the infection and to the underlying comorbid diseases that are present in these patients.[22] Mortality rates are two to three times higher in diabetics, in elderly patients and in patients in whom treatment is delayed.[21]

Extent of disease at presentation and metabolic status are of utmost importance in determining prognosis.[30]

Anal Infection and Hematologic Diseases

Acute anorectal suppuration poses an interesting and often life-threatening problem in patients with acute hematologic diseases. In patients with acute leukemia, mortality rates of 45–78% have been reported.[31] There is a definite relationship between the number of circulating granulocytes and the incidence of perianal infection in patients with hematologic diseases. In one study, patients with neutrophil counts below 500 per cubic millimeter had an incidence of anorectal infections of 11%, whereas those with counts greater than 500 per cubic millimeter had an incidence of 0.4%.[32] Glenn et al.[33] reported that 63% of anorectal infectious episodes occurred when fewer than 500 neutrophils were present per cubic millimeter. The risk of developing anorectal infection in this patient population has been found to be related to the severity and duration of the neutropenia.[31] The most important prognostic indicator was the number of days of neutropenia during the infectious episode.[33]

The most common presenting symptoms include fever, which precedes pain, and urinary retention. Point tenderness and poorly demarcated induration constitute the earliest signs[31] while external swelling and fluctuation often appear late in the course of infection.[33]

Controversy surrounds the treatment of acute anorectal infections in patients with hematologic malignancies. Surgery has generally been avoided since what may seem to be simple incision and drainage may produce scant or no pus and may instead cause hemorrhage, poor wound healing or expanding soft tissue infection.[33]

Any patient with perianal pain is assumed to have a perianal complication and is started on precautionary measures which consist of no digital rectal examinations, suppositories, or enemas.[34] Sitz baths, stool softeners, bulk agents, and analgesia are advised. On aspiration of most abscesses in this group, the most common organisms are *Escherichia coli* and group D streptococcus. Consequently, infections are successfully controlled with a third-generation cephalosporin combined with anaerobic coverage or an extended spectrum of penicillin in combination with an aminoglycoside and an antianaerobic antibiotic. This combination has been associated with an 88% success rate.[33]

Barnes et al.[31] recommend an aggressive surgical approach. Through this approach, 13 of 15 patients who were severely neutropenic with neutrophil counts of fewer than 100 per cubic millimeter recovered with incision and drainage. It must be noted that these patients were found to have extensive soft tissue infection. Since appropriate antibiotic coverage has been found to control infection successfully, surgery has generally been recommended only if there is obvious fluctuation, progression of soft tissue infection, or persistent sepsis after a trial of antibiotic therapy.[33]

With severe neutropenia of fewer than 500 neutrophils per cubic millimeter, low dose radiation therapy of 300–400 rad for a period of 1–3 days has been suggested. Spontaneous drainage or subsidence of induration has been found to occur in 3–5 days.[34] A randomized controlled study, however, has failed to confirm the utility of this approach.[35]

Anorectal Sepsis in the HIV-Positive Patient

Patients who are HIV-positive and present with abscesses require drainage either by incision and drainage or the use of catheter drainage. Since these patients are immunosuppressed, adjunctive antibiotics should be used. Efforts should be directed at keeping wounds small since these patients are at risk of poor wound healing.[36] An increased incidence of perianal sepsis may be observed in HIV positive patients.[37] Serious septic complications or uncommon presentations of anorectal sepsis were found in 13% of patients who initially presented with anorectal suppuration in one study.[36] In another study, perianal sepsis was associated with in situ neoplasia.[38]

Fistula-in-ano

Familiarity of the surgeon with the anatomy of the anorectal area and with the pathogenesis and classification of fistulas is essential for their adequate management.

Pathophysiology

Etiology

A fistula is defined as an abnormal communication between any two epithelium-lined surfaces. A fistula-in-ano is an abnormal tract or cavity communicating with the rectum or anal canal by an identifiable internal opening. Most fistulas are thought to arise due to cryptoglandular infection.

Classification

The most helpful yet complicated classification of fistula-in-ano is that described by Parks[39] (Table 13-2). It has been suggested that its use is particularly applicable to the treatment of recurrent fistulas.

Intersphincteric Fistula-in-ano

This fistula is the result of a perianal abscess. The tract passes within the intersphincteric space (Figure 13-9A). This is the most common type of fistula and accounts for approximately 70% of fistulas.[39] A high blind tract passing from the fistula tract to the rectal wall may occur; in addition, the tract may also pass into the lower rectum. The infectious process may pass into the intersphincteric plane and terminate as a blind tract. There is no downward extension to the anal margin, and thus no external opening is present. Infection may also spread in the intersphincteric plane to reach the pelvic cavity to lie above the levator ani muscles. Lastly, an intersphincteric fistula may originate in the pelvis as a pelvic abscess but manifest itself in the perianal area.

FIGURE 13-9. Classification of fistula-in-ano: **A** intersphincteric, **B** transsphincteric, **C** suprasphincteric, **D** extrasphincteric.

Transsphincteric Fistula-in-ano

In its usual variety, this fistula results from an ischioanal abscess and constitutes approximately 23% of fistulas seen.[39] The tract passes from the internal opening through the internal and external sphincters to the ischioanal fossa (Figure 13-9B). A high blind tract may also occur in this situation in which the upper arm of the tract may pass toward the apex of the ischioanal fossa or may extend through the levator ani muscles and thereby into the pelvis. One form of transsphincteric fistula is the rectovaginal fistula. This is discussed further in Chap. 14.

Suprasphincteric Fistula-in-ano

This fistula results from a supralevator abscess and accounts for approximately 5% of fistulas in some series.[39] The tract passes above the puborectalis after arising as an intersphincteric abscess. The tract curves downward lateral to the external sphincter in the ischioanal space to the perianal skin (Figure 13-9C). A high blind tract may also occur in this variety and result in a horseshoe extension.

Extrasphincteric Fistula-in-ano

This constitutes the rarest type of fistula and accounts for 2% of fistulas.[39] The tract passes from the rectum above the levators and through them to the perianal skin via the ischioanal space (Figure 13-9D). This fistula may result from foreign body penetration of the rectum with drainage through the levators, from penetrating injury to the perineum, or from Crohn's disease or carcinoma or its treatment. However, the most common cause may be iatrogenic secondary to vigorous probing during fistula surgery.[4]

TABLE 13-2. Classification of fistula-in-ano

Adapted from Parks[3]

Evaluation and Treatment

Symptoms

A patient with a fistula-in-ano often recounts a history of an abscess that has been drained either surgically or spontaneously. Patients may complain of drainage, pain with defecation, bleeding due to the presence of granulation tissue at the internal opening, swelling or decrease in pain with drainage. Additional bowel symptoms may be present when the fistula is secondary to proctocolitis, Crohn's disease, actinomycosis, or anorectal carcinoma.[40] Systemic diseases such as HIV, carcinoma, and lymphoma should be entertained.[40]

Physical Examination

The external or secondary opening may be seen as an elevation of granulation tissue discharging pus. This may be elicited on digital rectal examination. In most cases, the internal or primary opening is not apparent. The number of external openings and their location may be helpful in identifying the primary opening. According to Goodsall's rule (Figure 13-10), an opening seen posterior to a line drawn transversely across the perineum originates from an internal opening in the posterior midline. An anterior external opening originates in the nearest crypt. Generally, the greater the distance from the anal margin the greater the probability of a complicated upward extension. Cirocco and Reilly[41] found that Goodsall's rule was accurate in describing the course of anal fistulas with a posterior external opening. It

FIGURE 13-10. Goodsall's rule.

was inaccurate in patients with anterior external openings since 71% of these fistulas tracked to a midline anterior primary opening. This was especially true in women in whom fistulas with anterior external openings tracked in a radial fashion in only 31%.[41]

Digital rectal examination may reveal an indurated cord-like structure beneath the skin in the direction of the internal opening with asymmetry between right and left sides. Internal openings may be felt as indurated nodules or pits leading to an indurated tract.[41] Posterior or lateral induration may be palpable indicating fistulas deep in the postanal space or horseshoe fistulas.[40,41] Bidigital rectal examination defines the relationship of the tract to the sphincter muscles and provides information as to preoperative sphincter tone, bulk, and voluntary squeeze pressure which need to be assessed preoperatively because of a possible risk of incontinence.[18,40]

Investigations

Anoscopy should be done prior to operation in an attempt to identify the primary opening. Sigmoidoscopy should be performed to locate a proximal internal opening and to exclude underlying pathology, such as proctitis or neoplasia. Colonoscopy or barium enema and a small bowel series are indicated in patients who have symptoms suggestive of inflammatory bowel disease and in patients with multiple or recurrent fistulas. Although anal manometry is not generally required, it may be useful as an adjunct to plan the operative approach in women with previous obstetric trauma, in an elderly patient, a patient with Crohn's disease or AIDS, or in a patient with a recurrent fistula.[42]

The role of preoperative imaging is to demonstrate clinically undetected sepsis, to serve as a guide at the time of the initial surgery, to determine the relationship of the fistula tract to the sphincter mechanism, and to reveal the site of sepsis in a recurrent fistula, all serving to decrease recurrence rates associated with fistula surgery. Imaging may take the form of fistulography, CT scan, endoanal ultrasound, and magnetic resonance imaging (MRI).

Fistulography

Fistulography, which involves cannulation of the external opening with a small feeding tube and injection of water soluble contrast may be useful in the evaluation of recurrent fistulas or in Crohn's disease where previous surgical forays or disease may have altered anorectal anatomy (Figure 13-11).[43] Contrast is introduced at low pressures for fear of tissue disruption. This may not allow secondary tracts to fill with contrast. It is difficult to distinguish between an abscess located high in the ischioanal fossa and one located in the supralevator space. In addition, the level of the internal opening may be difficult to see because of the absence of precise landmarks. Contrast may reflux into the rectum wrongly suggesting an
FIGURE 13-11. Fistulogram.

extrasphincteric tract with a rectal opening thus resulting in injudicious probing. Accuracy rates in identifying the internal openings and extensions in one study were found to be 16%, while a subsequent study found fistulography to be useful in 96%.[43,44] Its use resulted in altered surgical management or revealed other surgical pathology in 48%.[43] It was found, for reasons outlined previously, to have a false positive rate of 12%.[44] Fistulography is invasive and potentially may result in the dissemination of sepsis.

Computed Tomography Scan

CT scanning performed with intravenous and rectal contrast is a noninvasive method used to assess the perirectal spaces. Its use may be to distinguish an abscess requiring drainage from perirectal cellultitis. It does not permit visualization of tracts in relation to the levators but may be helpful in assessing the degree of rectal inflammation in patients with inflammatory bowel disease.

Endoanal Ultrasound

The role of endoanal ultrasound is to establish the relation of the primary tract to the anal sphincters, to determine if the fistula is simple or complex with extensions and to determine the location of the primary opening. It may aid in the identification of complex fistulas and may serve as an adjunct in the evaluation of complex suppuration to assess the adequacy of drainage (Figure 13-12A).[45] A prospective study which compared this modality to digital examination found that while endosonography was able to detect a large portion of intersphincteric and transsphincteric tracts, it was unable to detect primary superficial, extrasphincteric,

and suprasphincteric tracts or secondary supralevator or infralevator tracts.[46] A study conducted 10 years later using a 10 mHz probe along with injection of hydrogen peroxide into the tract, was able to identify the internal opening in 93%.[47] While this investigative modality is rapid and well tolerated, it is operator dependent and scars or defects caused by previous sepsis, surgery or trauma confuses ultrasonographic interpretation and makes delineation of fistula tracts difficult.[46] The concomitant use of enhancing agents such as hydrogen peroxide (Figure 13-12B) or Levovist™[48] at the time of ultrasound examination has been found to improve its accuracy and it has been suggested that it be used prior to operative treatment since it assists the surgeon by delineating the anatomy of the fistulous tract and provides information that may be of value in planning therapeutic surgery, thereby reducing the risks of incontinence and recurrence.[49,50]

Magnetic Resonance Imaging

MRI in the form of endoanal coil, body coil, and phase array (Figure 13-13) coil may be of value in the assessment of patients with complex fistulas and in those with anatomic distortion resulting from previous surgery. Since MRI can provide multiplanar visualization of the sphincter muscles, differentiation of supralevator from infralevator lesions is easier.[51] MRI has been found to accurately delineate the presence and course of a primary fistulous tract, but also demonstrates the site and presence of any secondary extensions.[52] It also provides the most accurate imaging technique of localizing the site of the internal opening since its location can be inferred from the proximity of the tract in the intersphincteric space.[52] A prospective study which compared the accuracy of MRI in the preoperative assessment of anal fistulas to operative findings, found concordance rates of 88% for the presence and course of the primary tract, 91% for the presence and site of secondary extensions or abscesses, 97% for the presence of horseshoeing, and 80% for the position of the internal openings.[45] In the same study, failure of healing in 9% was found to be related to pathology missed at the time of surgery which had been documented on preoperative MRI.[52] Difficulties in interpretation, however, may occur since neural and vascular structures may be mistaken for fistulas and chemical shift artifacts may simulate a fistula filled with fluid.[52] The use of the endoanal coil has been found to be superior to external MRI for the identification of complex sphincter anatomy especially in the demonstration of the morphology of the internal and external sphincters;[53,54] however, definition may fall off outside the sphincter and may fail to show the tracts that lie beyond its range. It is also painful. A prospective study comparing hydrogen peroxide endoanal ultrasound to endoanal MRI found good agreement for the classification of the primary fistula tract and the location of the internal opening. These results also demonstrated good agreement with the surgical findings enabling both to be reliable for the preoperative evaluation of fistulas.[55]
FIGURE 13-12. **A** Anal endosonogram, **B** with hydrogen peroxide. Courtesy Dr. Julio Faria.
FIGURE 13-13. Phase array MRI.

A prospective trial comparing the use of the endoanal coil to the body coil found that surgical concordance for the endoanal coil was 68% versus 96% for the body coil, presumably due to field of view limitations.[56] This can be overcome with the use of the phase array coil which has a larger field of view and may be useful in Crohn's disease and recurrent fistulas.[57]

In a prospective study to determine the impact of MRI with primary fistulas, Buchanan et al.[58] found that MRI changed the surgical approach in 10%. In another study with respect to recurrent fistulas, recurrence rates were found to be higher for those surgeons who never used MRI.[59] They concluded that MRI-guided surgery can decrease recurrence rates by 75% in surgery for recurrent fistulas.

Treatment

General Principles

The principles of fistula surgery are to eliminate the fistula, prevent recurrence, and preserve sphincter function. Success is usually determined by identification of the primary opening and dividing the least amount of muscle possible. Several methods have been proposed to identify the primary opening in the operating room.[1,4]

1. Passage of a probe or probes from the external opening to the internal opening or vice versa.
2. Injection of a dye such as dilute solution of methylene blue, milk, or hydrogen peroxide and noting their appearance at the dentate line. Although methylene blue may stain surrounding tissues, diluting it with saline or hydrogen peroxide obviates this problem.
3. Following the granulation tissue present in the fistula tract.
4. Noting puckering of an anal crypt when traction is placed on the tract. This may be useful with simple fistulas but is less successful in the more complicated varieties.

Operative Management

Lay-open Technique

For the treatment of simple intersphincteric and low transsphincteric fistulas, the patient is placed in the prone jackknife position following the induction of a regional anesthetic. Local anesthesia consisting of 0.5% lidocaine or 0.25% bupivacaine hydrochloride with 1:200,000 epinephrine is injected along the fistula tract for hemostasis following the insertion of an anal speculum. Use of bupivacaine provides analgesia of longer duration than most regional anesthetics. A probe is inserted from the external opening along the tract to the internal opening at the dentate line. The tissue overlying the probe is incised and the granulation tissue curetted and sent for pathologic evaluation. A gentle probe is used to identify any high blind tracts or extensions, which are unroofed, if found. If desired, the wound may be marsupialized on either edge by sewing the edges of the incision to the tract with a running locked absorbable suture. There is no need to insert packing if an adequate unroofing has been accomplished (Figure 13-14A–C).

Seton

The problem of preserving anal continence and treating the fistula is more complicated when managing high transsphincteric fistulas. If the tract is seen to cross the sphincter muscle at a high level, the use of the lay-open technique in combination with insertion of a seton is safer. A seton may be any foreign substance which can be inserted into the fistula tract to encircle the sphincter muscles. Materials commonly
FIGURE 13-14. Technique of laying open: **A** insertion of probe and incision of tissue overlying probe, **B** curettage of granulation tissue, **C** marsupialization of wound edges.
FIGURE 13-15. Seton.

employed include silk or other nonabsorbable suture material, penrose drains, rubber bands, vessel loops, and Silastic catheters.[18] The lower portion of the internal sphincter is divided along with the skin to reach the external opening and a nonabsorbable suture or elastic suture is inserted into the fistulous tract. The ends of the suture or elastic are tied with multiple knots to create a handle for manipulation (Figure 13-15). This form of seton, known as a cutting seton, is tightened at regular intervals to slowly cut through the sphincter. This allows the tract to become more superficial, converting a high fistula into a low one. The proximal fistulotomy subsequently heals by stimulating fibrosis behind it reestablishing continuity of the anorectal ring to prevent separation or retraction of the sphincter muscle at a second stage repair 8 weeks later when the remaining external sphincter is divided. The seton also allows delineation of the amount of remaining muscle thus enabling improved postoperative assessment by outlining the tract. A seton may also be used as a drain which is left loosely in place to facilitate prolonged drainage, thereby referred to as a draining seton. In the past, specific indications for seton use included:[60] (1) To identify and promote fibrosis around a complex anal fistula that encircles most or all of the sphincter mechanism; (2) To mark the site of a transsphincteric fistula in cases of massive anorectal sepsis where the normal anatomic landmarks have been distorted; (3) Anterior, high transsphincteric fistulas in women. Since the puborectalis is absent in this area and the external sphincter is quite tenuous, primary fistulotomy may result in incontinence; (4) The presence of a high transsphincteric fistula in a patient with AIDS in whom healing is known to be poor; (5) To avoid premature skin closure and formation of recurrent abscesses and promote long-term drainage in patients with Crohn's disease. In these patients, a Silastic catheter can be left in place for a prolonged period of time to promote epithelialization of the fistula tract or tracts;

(6) When there is suspicion that primary fistulotomy results in incontinence such as in those patients with multiple simultaneous fistulas, patients who have undergone multiple prior sphincter operations, such as fistulotomy or internal sphincterotomy and in elderly patients with weakened sphincter muscles. A recent extensive literature search suggested that the use of cutting setons be abandoned because of high incontinence rates of 12% since ultimately they damage the sphincters.[61] This position was supported by the Association of Coloproctologists of Great Britain and Ireland (ACGBI) who recommended that a cutting seton be used only for low transsphincteric fistula or as the secondary treatment for a low transsphincteric fistula.[62]

Another option available to treat transsphincteric fistulas without division of muscle involves the use of a dermal island flap.[63] Division of muscle was able to be avoided in 90%, however, a 23% failure rate was reported. This was found to be more likely in males, patients who had previous treatment of their fistulas, patients with large fistulas requiring combined flaps and patients who underwent simultaneous fibrin glue injection.

Treatment of suprasphincteric fistulas requires an appreciation that the tract involves the entire external sphincter complex as well as the puborectalis muscle. Laying-open the entire tract would render the patient incontinent. Thus, several methods have been proposed to manage this fistula without the ensuing devastating consequences. The use of a seton has been advocated in combination with division of the internal sphincter and the superficial portion of the external sphincter to the external opening. The seton is placed around the remaining external sphincter as was previously described.[64]

A modification of this approach has been proposed by Kennedy and Zegarra[65] in which an internal sphincterotomy is performed, followed by opening of the tracts outside the external sphincter without division of any portion of the external sphincter which is encircled by a seton to promote fibrosis and assure adequate drainage. Complete healing using the latter approach has been reported in 66% with posterior fistulas and in 88% with anterior fistulas.[65] Parks[64] obtained healing in 63%. Another method that has been proposed to treat this type of fistula is the anorectal advancement flap which is described.

The horseshoe variety of the suprasphincteric fistula also presents the problem of complete sphincter involvement combined with the presence of multiple external openings a great distance from the cryptoglandular source. Treatment consists of identification of the internal opening and proper drainage of the postanal space as was previously described. The horseshoe extensions are enlarged for counter-drainage and the granulation tissue is curetted.

The treatment of an extrasphincteric fistula depends on its etiology. If the fistula arises secondary to an anal fistula, a secondary opening above the puborectalis is thought to be iatrogenic due to extensive probing of a transsphincteric fistula. The lower portion of the internal sphincter is divided

and the rectal opening is closed with a nonabsorbable suture. A temporary colostomy may be necessary but a medical colostomy consisting of preoperative mechanical and antibiotic bowel preparation followed by enteral feeding may suffice. If the fistula is the result of entrance of a foreign body, it must be removed, drainage must be established, the internal opening closed and a temporary colostomy constructed to decrease rectal pressure. This type of fistula may also be a manifestation of Crohn's disease. Treatment depends on the nature of the anorectal mucosa and drainage may be assisted by the placement of a seton. Finally, the fistula may be the result of downward tracking of a pelvic abscess which must be drained so that the fistula can heal.

Figure 13-16A–D shows the anorectal advancement flap.

When the traditional laying-open technique may be inappropriate, for example, in anterior fistulas in women, in patients with inflammatory bowel disease, in patients with high transsphincteric and suprasphincteric fistulas as well as in those with previous multiple sphincter operations, multiple and complex fistulas, the use of an anorectal advancement flap has been advocated.[66] Advantages of this technique include a reduction in the duration of healing, reduced associated discomfort, lack of deformity to the anal canal as well as little potential additional damage to the sphincter muscles since no muscle is divided.[18]

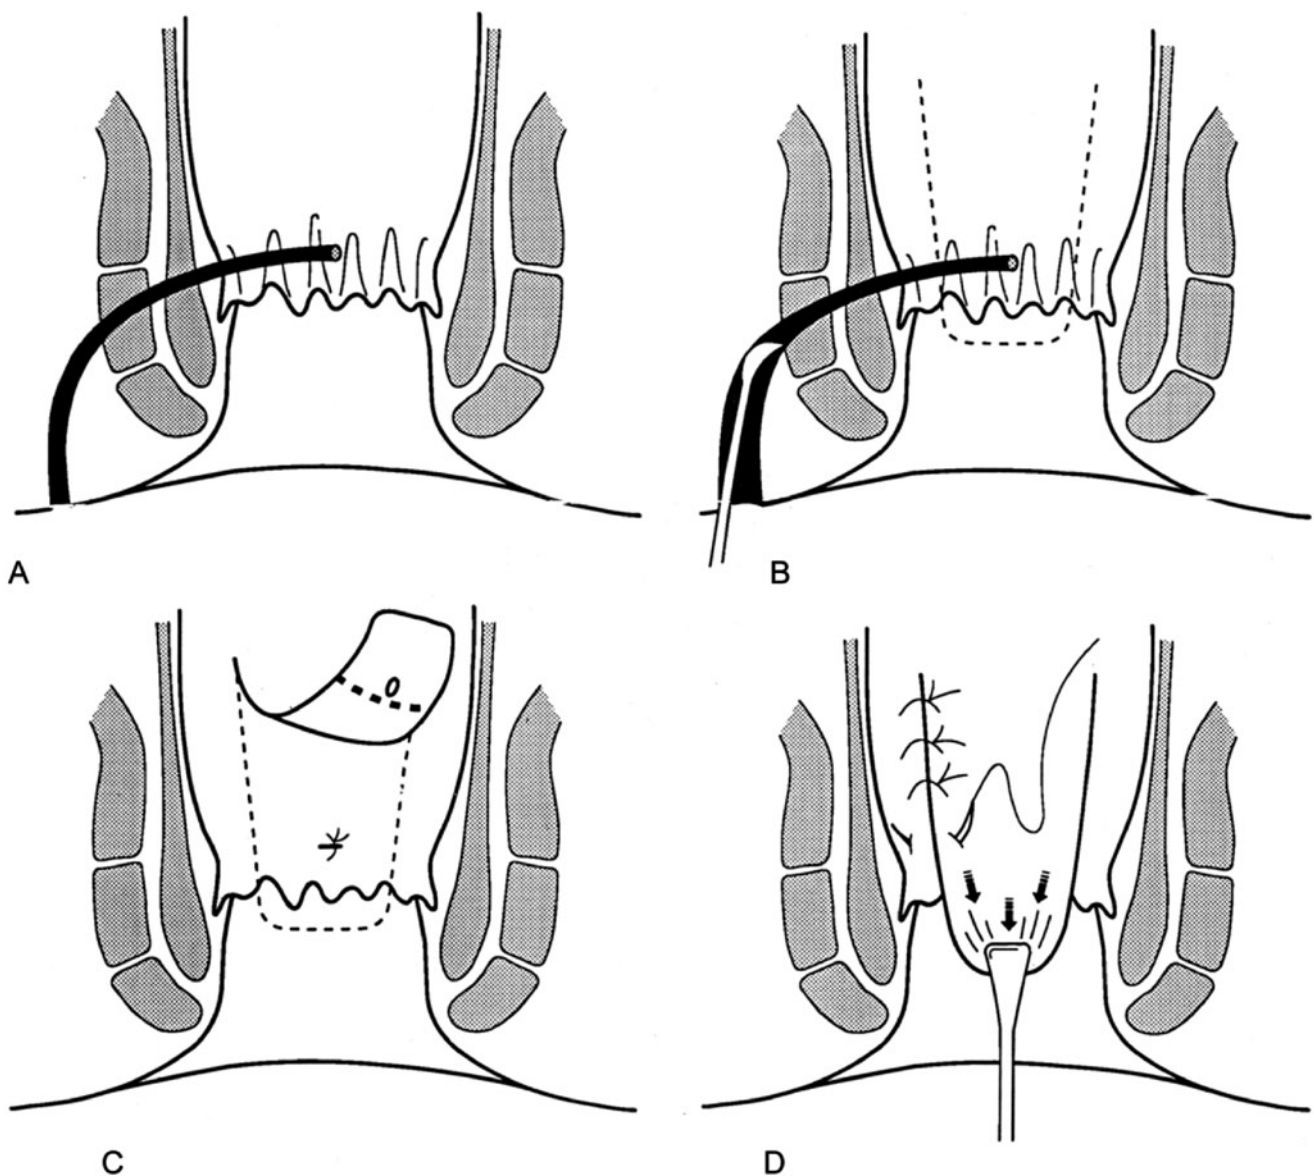
Following full mechanical and antibiotic bowel preparation, the patient is placed in the prone jackknife of left lateral position. Under a regional or general anesthetic, following


FIGURE 13-16. Anorectal advancement flap: **A** transsphincteric fistula-in-ano, **B** enlargement of external opening and curettage of granulation tissue, **C** mobilization of flap and closure of internal opening, **D** suturing of flap in place covering internal opening.

insertion of a Foley catheter, the fistula tract is identified with a probe and either cored out or curetted. The internal opening is identified and excised. The external opening is enlarged to allow for drainage. A full thickness flap of rectal mucosa, submucosa and part of the internal sphincter is raised. The residual internal opening is closed with absorbable suture. The flap is then advanced 1 cm below the internal opening. The tip of the flap containing the fistulous opening is excised and the flap is sewn into place with absorbable sutures ensuring that the mucosal and muscular suture lines do not overlap. The base of the flap should be twice the width of the apex to maintain good blood supply. Successful results have reported in over 90% of patients.[67] Factors associated with poor outcomes include Crohn's disease and steroids.[68] Cigarette smoking was found to be another significant variable in another study.[69]

Fistulectomy

Although excision of the fistula or fistulectomy was thought to be a satisfactory method of treatment of fistula-in-ano, its use is no longer recommended. Larger wounds are created significantly prolonging wound healing time.[70] A greater separation of muscle ends occurs[1] and there is greater risk of injuring or excising underlying muscle,[66] thereby increasing the risk of incontinence. Schouten and van Vroonhoven[14] have found that fistulectomy, whether primary or secondary, was associated with a clinically significant disturbance in anal function. In recent years, alternative therapies have been developed to avoid division of the sphincters but aimed to obliterate the fistula tract. These include fibrin glue and the anal fistula plug (AFP).

Fibrin Glue

The use of fibrin glue (Tisseel, Baxter Healthcare Corp, Deerfield, IL) as a primary treatment alone or in combination with an advancement flap was appealing since it is a simple, noninvasive approach that avoids the risk of incontinence associated with fistulotomy. In the case of failure, it may be repeated several times without jeopardizing continence. As with fistulotomy, the fistula tract along with its internal and external openings is identified and curetted (with currettes or flexible brushes). Fibrin glue is injected into the fistula tract through a Y connector so that the entire tract is filled and the glue can be seen emerging from the internal opening. The injecting catheter is slowly withdrawn so that the entire tract is filled. Petrolatum jelly gauze may be placed over the external opening.

Enthusiasm generated because of short-term success rates of 70–74%[71,72] has been tempered due to delayed fistula recurrence despite initial apparent healing.[73] With longer follow up, 60% of fistulas were found to have healed in a recent study although patients underwent a two-stage approach consisting of seton placement followed by glue injection at a second stage.[74] Patients who failed underwent

repeat injection which allowed 69% to heal. The 29% who failed to heal underwent either fistulotomy or advancement flap. Late recurrences (6%) occurred more than 6 months postoperatively and were treated with reinjection. Buchanan et al.[75] found fibrin glue injection to be useful in 14% with complex anal fistulas without extensions.

Although the exact mechanisms responsible for failure have not been entirely appreciated, it has been suggested that curettage may not adequately remove all granulation or epithelialized tissue thus failing to provide the correct environment for the glue to work.[75] Other adverse factors shown to influence healing include the presence of a short tract which may make it easier for the fibrin glue plug to become dislodged as well as the presence of a cavity on endoanal ultrasound.[76] The latter was associated with a complication of perianal abscess since the tract may not have been entirely filled with glue.[77–81] Fibrin glue is associated with a low incontinence rate as well as a disappointing low cure rate. Results using fibrin glue are summarized in Table 13-3.[73–75,78–81]

Anal Fistula Plug

Recently, the use of a bioprosthetic plug made from lyophilized porcine intestinal submucosal has been described for the treatment of complex anal fistulas.[79] The Surgisis AFP™ (Cook Surgical Inc, Bloomington, IN), when implanted, is colonized by host tissue cells and blood vessels and thus provides a scaffold to allow infiltration of the patient's connective tissue. A consensus conference[82] defined the indications for the use of the plug in fistulous disease to include: (1) Transsphincteric fistula; (2) Intersphincteric fistula if conventional fistulotomy posed a risk of incontinence, such as in patients with inflammatory bowel disease; and (3) Extrasphincteric fistula. Contraindications for the use of the plug included: (1) Fistula with persistent abscess cavity; (2) Fistula with infection; (3) Allergy to porcine products; and (4) Inability to identify both the external and internal openings. The latter constitutes an absolute contraindication for the use of the plug. Following full mechanical bowel preparation or the use of a small volume enema along with a single preoperative dose of antibiotics, the patient is placed in the prone jackknife position. The internal and external openings must be clearly delineated. This can be accomplished by irrigation with saline or peroxide. Gentle passage of a probe is essential to confirm the position of the tract and facilitate insertion of

the plug. Debridement or curettage of the tract should not be performed. A seton should always be used temporarily only if there is acute inflammation or drainage. The plug should be immersed in sterile saline for 2 min and thus rehydrated. A fistula probe is placed through the tract and a 2-0 suture is placed through the tapered end of the plug and the ends of this suture are attached to the fistula probe at the primary opening. The suture is pulled from the primary opening, through the fistula tract to exit at the secondary opening. For patients with a "horseshoe" fistula, an incision is made over the fistula tract distal to the anal verge to create a secondary opening that the ends of the suture are brought through. With gentle traction on the suture, the porcine plug is pulled into the primary opening of the fistula until "wrinkling" of the superficial layer of the plug is first seen. The plug is not forced tightly. Excess plug is removed by transecting the plug at the level of the primary opening. The plug is secured in the primary opening using a 2-0 absorbable suture placed in a "figure 8" fashion with the suture crossing through the center of the plug and incorporating a generous portion of the sphincter mechanism on both sides. Any plug protruding through the secondary opening is also excised. The distal end of the plug is not sutured to the fistula tract and the distal opening is left open for drainage. Patients are advised to avoid vigorous physical activity for 2 weeks after plug placement to minimize the chance of plug dislodgement. No dietary restrictions are necessary nor are topical antibiotics indicated.

The first prospective study comparing the AFP to fibrin glue in 25 patients with high transsphincteric or deeper fistulas found greater success rates with the plug (87% vs. 40%) at 3 months.[79] The authors concluded that closure of the primary opening of a fistula tract using a suturable biologic AFP is an effective method of treating anorectal fistulas. Although the technique has appeal for its simplicity and avoidance of sphincter injury, more recent reports, however, have tempered enthusiasm with success rates ranging from 13.9 to 87% (Table 13-4).[79,83–92] Dislodgement has been reported in 9 (41%) while sepsis requiring abscess drainage has been reported in 4 (29%) patients.[83–92]

Ligation of the Intersphincteric Fistula Tract Procedure

Recently, a new sphincter-sparing technique has been introduced [ligation of the intersphincteric fistula tract (LIFT)].[93] The LIFT technique is based on the secure closure of the internal opening and removal of the infected cryptoglandular tissue in the intersphincteric space. The only patients not suitable are those with early fistulous abscess in which the intersphincteric tract is not well formed.

Technique

Patients undergo mechanical bowel preparation and are placed in the prone jackknife position. A Fansler anoscope is inserted into the anal canal and

1. Internal opening is identified.
2. 1.5–2.0 cm curvilinear incision is made at the intersphincteric groove overlying the fistula tract.
3. Cautery is used to dissect into the intersphincteric plane staying close to the external sphincter avoiding cutting through the internal sphincter and breaching anal mucosa.
4. Internal and external sphincters are retracted. The intersphincteric tract is dissected and ligated next to the internal opening with a 3-0 absorbable suture.
5. Tract next to the suture is ligated.
6. Tract excision is confirmed by injection or probing of the external opening.
7. Granulation tissue is curetted.
8. The external opening is sutured through the intersphincteric wound.
9. Incision is closed with 3-0 absorbable suture.

Postoperatively wounds are cleansed with tap water twice a day and following bowel movements. Patients are given 2 weeks of Ciprofloxacillin and Metronidazole.

A pitfall with this technique may be the intersphincteric approach for high tracts especially with horseshoe tracts. Also exposure of the intersphincteric space may damage the internal sphincter.

Although there are only a few reports in the literature, success rates of 58–94% have been reported.[93,94] In addition, time to failure has ranged from 4 to 64 weeks with a median of 19 weeks.[93,94]

New Biologic Injectables

Recently, new options in viable alternative treatments have been promoted experimentally. These include the injection of human acellular dermal matrix, a biologic plug consisting of dermis without cellular components.[95] The graft serves as a scaffold that allows native cellular ingrowth and remodeling. A healing rate at 6 months was 86%, however, failures were observed with longer follow-up of 3–6 months.

Permacol Injection™ (Covidien, Mansfield, MA) is a suspension of cross-linked porcine dermal collagen matrix in saline. It is readily colonized by host tissue cells and blood

vessels, minimizing infection. Although initially evaluated in a porcine model, there is one case report documenting its success in fistula healing.[96] It is a liquid injected into the fistula tract and all around the fistula. This may prove to be an effective first-line nonoperative procedure which remains to be evaluated in large trials.

Postoperative Care

Following the lay-open technique, patients are placed on regular diets, bulk agents and noncodeine-containing analgesia. Patients are instructed to take frequent sitz baths to ensure perianal hygiene. Patients are evaluated at 2-week intervals to ensure that healing has occurred from the depths of the tract. Granulation tissue can be cauterized using silver nitrate sticks and cotton-tipped swabs are often used to probe the depths of the incision to ensure that adequate healing is occurring. Following the advancement flap technique, the Foley catheter is removed on the following day. Patients are discharged as soon as they can tolerate a diet.

Complications

Incontinence

Incontinence following fistulotomy depends both on the amount of muscle divided at operation as well as on preexisting sphincter damage and scarring of the anal canal.

Minor disorders of continence following fistulotomy have been reported to range from 18 to 52% while soiling and insufficiency have been reported in as many as 35–45% (Table 13-5).[97,98,100–104] The occurrence of continence disorders has been found to be related to the complexity of the fistula and to the level and location of the internal opening.[97]

Patients with complicated fistulas, high openings, posterior openings, and fistula extensions have been found to be at higher risk.[97] In the treatment of complicated fistulas and those with high openings, more muscle is divided thus

decreasing anal pressures while posterior fistula wounds have been associated with higher rates of incontinence because of their more circuitous routes.[97] Drainage of extensions may accidentally damage small nerves and create more scar tissue around the anorectum.[97] If the edges of the fisulotomy wound do not approximate precisely, the anus may be unable to properly close, resulting in intermittent leakage of gas and stool.[61] In addition to these factors, impaired continence was associated with increasing age[97] and female gender.[97,98] The latter is probably the result of partial anal sphincter disruption and/or traction injury to the pudendal nerves sustained during vaginal delivery.[98]

Although excellent results employing a seton have been reported,[105] its use does not protect against the development of impaired continence.[99] Minor continence disorders were reported in 73%,[99] while Williams et al.[106] reported minor disturbances in 54%. Parks and Stitz[64] found that minor incontinence occurred in 39% with the two-stage approach versus 17% when only the first stage was performed and the seton was removed rather than dividing the muscle. Major fecal incontinence was reported in 6.7%[60] after a review of several series (Table 13-6).[60,99,100,105–109] The degree of incontinence is thought to be influenced by the patient's preoperative state of control as well as to how the anal wound heals.[61] Analysis of data compiled in a recent literature search found that a 12% rate of incontinence with the rate increasing as the location of the internal opening moved more proximally.[62] Excellent results with respect to continence have been reported with the use of the advancement flap[69] although recent reports have observed disturbances in continence in 9–35%,[110,111] attributed to over-stretching of the sphincters by self-retaining retractors. Disruption of the internal sphincter also occurs if some internal sphincter fibers are developed with the flap.[112]

As would be expected, continence is unaffected with the use of fibrin glue and the fistula plug. In a study that looked at changes in anorectal morphologic and functional parameters after fistula surgery, it was found that fistulotomy and advancement flaps were most associated with changes in internal anal sphincter defects with decreased resting and squeeze pressure on manometry noted after fistulotomy while rectal advancement flaps were associated with decrease in resting pressure.[113] It therefore behooves the surgeon to recognize preexisting sphincter defects by endoanal ultrasound prior to embarking on fistula surgery.[113]

Recurrence

Recurrence rates following fistulotomy range from 0 to 18%.[97] Causes include failure to identify a primary opening or recognize lateral or upward extensions of a fistula.[98,104] Inability to locate the primary opening may imply a circuitous tract, spontaneous closure of the primary opening or a microscopic opening.[104] The presence of secondary tracts[98] which can be easily missed accounted for early recurrence in 20%.[104] Premature closure of the fistulotomy wound can be obviated by producing an external wound twice the size of the anal wound resulting in proper healing of the internal wound prior to the external wound.[98] Diligent postoperative care can also reduce recurrence rates by avoiding bridging and pocketing of the wound.[114] Epithelialization of the fistula tract from internal or external openings rather than chronic infection of an anal gland has also been suggested as the cause of a persistent anal fistula.[115]

Recurrence rates following staged repairs utilizing a seton range from 0 to 29%.[59]

Although recurrence rates following anorectal advancement flaps were initially reported to be low, with long-term follow-up, recurrence rates of 40% have been reported.[111] Recurrence can be minimized provided that care has been taken to avoid necrosis or retraction of the flap. The use of full-thickness rectal wall has been advocated to prevent ischemic necrosis of the flap.[116]

Early postoperative complications that have been reported following fistula surgery include urinary retention, hemorrhage, fecal impaction, and thrombosed external hemorrhoids which were found to occur in less than 6% of cases.[19] Late complications, such as pain, bleeding, pruritus, and poor wound healing have been reported in 9% of patients.[66] Anal stenosis may occur and is usually the result of loose stools allowing healing of the anal canal by scar contracture.[40] Mucosal prolapse due to extensive division of sphincter muscle may also occur and can be treated by band ligation, sclerosis, or excision.[66] With attention to both operative detail and postoperative follow-up, these complications can be reduced to a minimum.

Special Considerations

Crohn's Disease

Anal fistulas are the most difficult and challenging complication of Crohn's disease to manage. They constitute the most common perianal manifestations, occurring in 6–34% of patients.[117] The location of Crohn's disease in the bowel has an impact on the frequency of fistulas. Patients with colonic Crohn's have a higher incidence with the rate approaching 100% in those with rectal Crohn's.[118]

As discussed previously, patients with Crohn's disease should undergo sigmoidoscopy, colonoscopy, and small bowel follow through to determine the extent of disease. Delineation of the fistulous tract is especially important in Crohn's disease since many fistulas may be complex in nature. In this context, endoanal ultrasound has been found to be as useful as MRI. MRI has been found to detect abscesses that were clinically unsuspected on clinical exam and has been helpful in determining the relationship of the fistulous tract to the sphincter muscles.[119]

Therapeutic goals in managing anorectal fistulas in Crohn's disease remain the alleviation of symptoms and preservation of continence. Surgical treatment of fistulas is associated with poor and delayed wound healing and with the risk of sphincter injury. Alexander-Williams[120] stated that, "Incontinence is likely to be the result of aggressive surgeons, not of aggressive disease." A conservative approach has therefore been advocated, especially since 38% of such fistulas have been reported to heal spontaneously without any surgical intervention. Medications used in the treatment of fistulas include antibiotics such as metronidazole and ciprofloxacin and immunomodulators such as corticosteroids, 6 mercaptopurine (MP), azathioprine, and infliximab. Although several studies have reported spontaneous closure of fistulas in 34–50% of patients treated with metronidazole, improvement is usually seen after 6–8 weeks of treatment with relapses common once the medication is discontinued.[118] A recent placebo-controlled trial comparing a 10-week course of metronidazole, ciprofloxacillin, and placebo in patients with perianal Crohn's disease found a 40% response in the ciprofloxacillin group compared to 14.3% in the metronidazole group and 12.5% in the placebo group. These differences, however, were not significant.[121] In another study, 6MP and azathioprine were found to be efficacious in only one third of patients with fistulizing perianal disease.[122] These effects seemed unrelated to their effects on intestinal disease. The authors concluded that their results did not support the use of these medications solely for the improvement of perianal disease. The use of infliximab has been associated with a 62% reduction in draining fistulas.[123] The combination of infliximab and 6MP may prolong the effect of initial infliximab treatment on fistula closure.[124] Selective seton placement combined with infusion of infliximab and maintenance therapy with azathioprine or methotrexate resulted in complete healing in 67% with Crohn's fistulas in a recently reported retrospective study.[125] Maintenance therapy with infliximab has been reported to result in the absence of draining fistulas in 36% of patients compared to 19% in placebo patients at 54-week follow-up.[126]

Although fistulas may occur in as many as 73% of patients after previous abscess drainage, it is imperative that primary fistulotomy not be performed because of the high risk of creating false passages and injuring the sphincter mechanism.[117] Asymptomatic fistulas require no treatment. Low fistulas with simple tracts can be managed with the standard lay-open method in the absence of active proctitis. Successful outcome as gauged by healing has been reported

to occur in 42–100%, mostly in the 70–80% range of procedures.[127]

Fistulotomy has been associated with prolonged healing.[128] Factors associated with delayed healing are rectal involvement;[12,100] anorectal complications, especially strictures;[129] and the presence or absence of an internal opening.[129] Successful healing has occurred in patients with a classic internal opening at the dentate line and in those without rectal involvement[129] although Halme and Sainio[128] found that delayed healing occurred in 80% of patients despite the presence of a normal rectum and Van Dongen and Lubbers[130] found no difference in healing even in the presence of rectal involvement. Nonetheless, initial therapy should be directed at resolving inflammation in the rectum. This can be accomplished with the use of topical steroid or 5-acetylsalicylic enemas or suppositories. In addition, oral medication may be necessary.

Incontinence has been reported in patients with proctitis who have not undergone anal surgery.[130] A patient with severe rectal involvement and even a simple low fistula is not a candidate for fistulotomy. Division of any sphincter muscle in this situation may result in frank incontinence because the noncompliant rectum acts as a conduit rather than as a reservoir. Continence problems have been reported in 25% of patients after simple incision and drainage of abscesses during which the sphincter mechanism has not been touched.[130] Allan and Keighley[131] reported a 50% frequency of major fecal incontinence and minor incontinence has been described in 33% of patients who have undergone only simple drainage or local surgery.[128] It is thought that diarrhea from either associated intestinal involvement or multiple previous small bowel resections is important in control disorders in these patients.[117,128,130] Appropriate medical therapy should be employed to control the diarrhea.

Complex fistulas with high rectal openings might best be managed conservatively because impaired continence may certainly result if the sphincter muscle is divided. Eradication of the fistula in this situation may not be possible because of the complexity of the tracts. Seton placement has been advocated to promote drainage, limit recurrent suppuration, and preserve sphincter function.[132] Rectal advancement flaps have been used in the absence of severe rectal disease.[133] These have been found to succeed in patients without concomitant small bowel Crohn's.[134]

The importance of quiescent intestinal disease for successful outcome of local fistula surgery has been suggested, but not generally accepted and practical. Proximal fecal diversion has also been suggested as an option to ameliorate severe perianal disease since diversion of the fecal stream may reduce perianal inflammation.[135] However, improvement is temporary because fistulas reactivate following restoration of intestinal continuity.[14]

Complicated fistulas are more likely to recur due to the reluctance of the surgeon to divide sphincter muscle. The use of a long-term in-dwelling seton as a drain is therefore recommended.[132] Fistula recurrence may be as high a 39% following the removal of the seton and may necessitate the use of concomitant medical therapy.[117] The use of a rectal advancement flap has been successful; however, breakdown is possible because of sepsis.[133] In patients with mild proctitis, a 20% success rate has been reported.[133] The presence of a protective stoma in this situation does not guarantee success, with failure reported in 55% of patients.[133] A covering stoma may be beneficial in the patient who has undergone multiple unsuccessful repairs.[115]

Disappointing results with standard treatment of anal fistulas has led to the use of noninvasive procedures, such as the fibrin glue and the AFP™ in the armamentarium of treating fistulous Crohn's disease.[136,137] A closure rate of 60% has been reported in one study with the use of fibrin glue. This may also be combined with an endorectal advancement flap in the absence of rectal involvement. Excellent short-term success rates of 77–83% have also been associated with the use of the AFP without alteration in continence.[83,138] Many fistulas may require repeat fistulotomy to achieve complete healing or repeat injections of fibrin glue or repeated use of the plug.[128]

A novel approach reported on recently is the use of mesenchymal adipose stem cells used to stimulate fistula closure.[139] In a randomized controlled trial comparing adipose-derived stem cells and fibrin glue to fibrin glue alone, the fistula closed in 71% in the stem cell group compared to 16% in the fibrin glue group.[138] For severe intractable disease, an intersphincteric proctectomy may ultimately become necessary. The intersphincteric technique reduces the size of the resulting wound and reduces the incidence of unhealed sinuses.

Fistula-in-ano in the HIV Positive Patient

Anal fistulas are prevalent in the anoreceptive HIV positive individual.[140] Disturbed locoregional defenses may allow infection to occur.[141] Although anal fistulas in HIV positive patients arise from the dentate line similar to those in HIV negative patients, they are more likely to have incomplete anal fistulas leading to blind sinus tracts.[142] Concern for wound healing has tempered enthusiasm for operative intervention. However, selective operative management results in a high rate of complete or partial wound healing with symptomatic relief without excessive morbidity or mortality.[142] Severity of illness must be assessed prior to operative intervention since patients with more advanced disease are less likely to heal their wounds. Data are conflicting as to whether preoperative CD4+ lymphocyte counts can be related to poor wound healing,[142] however, Consten[31] found that low CD4+ lymphocyte counts in patients with perianal sepsis were a risk factor for disturbed wound healing. Use of Highly Active Antiviral Therapy (HAART) may reduce the incidence of opportunistic infections and anorectal disease and aid healing.[142]

Asymptomatic fistulas require no treatment. Perioperative antibiotic therapy over a 5-day course has been recommended because of the high risk of infectious complications.[142] Care should be exercised to avoid creation of large wounds and to preserve as much sphincter muscle as possible since these patients may be prone to diarrhea which may overwhelm a partially divided sphincter.[142] In patients who are good operative risks, fistulotomy is appropriate in patients with intersphincteric or low transsphincteric fistulas. For high or complex fistulas as well as for those patients who are poor operative risks, liberal use of draining setons is recommended.[40,142] It is important to realize that cellulitis may be seen with a fistula without concomitant underlying exudates.[142] Metastatic abscesses to other organs, including brain, liver, and mediastinum have been reported with asymptomatic perianal fistulas.[31] Healing has been reported in 55–80% of patients.[36,142]

Mucinous Adenocarcinoma Arising from a Fistula-in-ano

Mucinous adenocarcinoma carcinoma arising from an anal fistula is an extremely rare entity with a handful of cases having been reported in the literature.[143,144] It is associated with a longstanding fistula-in-ano and the chronic inflammatory changes associated with it. Diagnostic criteria include: (1) The fistula should antedate the carcinoma by 10 years; (2) The only tumor present should be secondary to direct extension from the carcinoma into the fistula; (3) The internal opening should be in the anal canal and not into the tumor itself.[145]

Early diagnosis is difficult since the lesion may be obscured within the ischioanal fossa or perineum. Patients do not have bleeding and digital exam may only reveal induration at the site of the fistula. MRI is the most helpful diagnostic tool with several characteristics having been identified. These include pools of extracellular mucin lined by columns of malignant cells, cords, and vessels which produce a mesh-like structure[146] and the presence of a fistula between the mass and the anus.[147] Management has traditionally consisted of abdominoperineal resection; however, more recently improved survival rates have been reported from combined pre- and postoperative chemoradiation or from chemoradiation alone, reserving abdominoperineal resection as a salvage procedure.[147]

Rectourethral Fistulas

Pathophysiology

Rectourethral fistulas are rare but devastating complications that may occur following radical open or laparoscopic prostatectomy, radiation treatment for prostate cancer, trauma, and recurrent perineal abscess of cryptoglandular origin or due to Crohn's disease or following treatment with radiofrequency hyperthermia for benign prostatic hypertrophy. The prostatic urethra is the most common site for fistulization to occur since this portion of the urethra is adjacent to the rectal wall.

Evaluation and Treatment

Symptoms

The most common symptoms include leakage of urine through the rectum during voiding, pneumaturia, and fecaluria. These symptoms tend to occur during the early postoperative period following prostatectomy. In addition, recurrent urinary tract infections resistant to antibiotic treatment following one of the aforementioned causes should suggest this diagnosis.

Investigations

PSA determination should be done to rule out recurrence of carcinoma. Digital rectal examination should always be performed to determine if there is any anorectal pathology that could be the cause. Sigmoidoscopy shows the fistula opening which is located on the anterior rectal wall and in addition rule out rectal pathology as a source. Cystoscopy and retrograde urethral cystography should be performed to determine the presence of a urethral stricture. Assessment of urinary continence should be done prior to any attempt at surgical repair.

Operative Treatment

Operative repair of rectourethral fistulas is challenging due to technical difficulties that are often encountered due to difficult exposure. Multiple repairs have been developed but there is no consensus as to which is best. Traditionally, it has been suggested that the first attempt at repair is the best and that subsequent repairs become more difficult.[148]

Rectal injury during laparoscopic radical prostatectomy may be repaired laparoscopically.[149] Most importantly, they must be recognized at the time of injury. Small fistulas can be managed conservatively with an indwelling foley catheter.[150] Treatment consisting of fecal diversion with either colostomy or ileostomy and urinary diversion with suprapubic catheterization under cover of antibiotics has been described in the management of rectourethral fistulas secondary to radiation when the urethral defect has been found to be too large to repair. This has been associated with bouts of recurrent sepsis and persistent symptoms.[150]

Transabdominal Approach

The transabdominal approach combines the use of abdominoanal pullthrough in combination with omental interposition.

Difficulties with this procedure include limited exposure deep in the male pelvis making closure of the urethral defect very difficult. A fenestrated splinting catheter apposed to the omentum has been used when leaving the prostatic defect open. Complications associated with this approach include impotence and urethral stricture.[151]

Perineal Approach

Perineal approaches using the gracilis muscle, dartos, or Martius flap have all been described. The most popular and easiest involves the use of a rotation flap of the gracilis muscle due to its ease of mobilization and its sufficient length. Several principles important for repair include excision of the fistula, development of layers on the urinary and rectal sides of the fistula and closure of nonoverlapping suture lines with interposition of the levators, when possible. Placement of the gracilis muscle between the rectum and the urethra provides well-vascularized tissue as an interface between these two surfaces allowing healing to occur. Several studies have documented from 97 to 100% success rates with the employment of the gracilis interposition.[152–154] Complications with this procedure include urinary incontinence and stricture as well as complications associated with the muscle harvest.

Anterior Transanorectal Approach

In this approach, a midline perineal incision is deepened by incising all structures superficial to the prostatic capsule which include the superficial perineal fascia, the central tendon of the perineum and the internal and external sphincters.[154] This approach allows better access in the repair of complicated membranoprostatic fistulas with the preservation of continence and erectile function.

Peranal Approach

This approach has the theoretical advantages of minimal scarring and fewer wound infections although it suffers from limited exposure. Initially described by Parks and Motson,[155] it involves the use of a full thickness advancement of anterior rectal wall protected by diverting colostomy. Success rates of 83% have recently been reported when combined with fecal diversion, urinary diversion, both, or none at all.[155] Success rates have been found to be higher when the flap was done for fistulas secondary to iatrogenic causes or trauma as opposed to Crohn's disease.[155] Advancement flap repair can be achieved with minimal morbidity and good postoperative quality of life without compromise to future interventions if needed.

Kraske Laterosacral Approach

This approach provides excellent exposure without division of the sphincter mechanism. The need to excise two to three sacral segments as well as the nerves, muscles, and ligaments around them pose a disadvantage.[156]

York Mason (Transsphincteric) Approach

This approach affords a rapid, bloodless exposure through fresh territory and allows for complete separation of the urinary and fecal streams. It avoids the neurovascular bundles and pelvic floor structures essential in maintaining continence and sexual function. It may be performed in combination with a diverting colostomy or a so-called medical colostomy consisting of mechanical preparation and postoperative elemental diet.

It has been associated with longer operative times and more postoperative pain than the other procedures mentioned but has a reported 100% success rate.[157]

Transanal Endoscopic Microsurgery

This highly specialized technique allows for a meticulous two-layer closure of the rectal wall and may be combined with transurethral fulguration of the opposite urethral opening of the fistula.[158] There has been no reported morbidity associated with this procedure although experience is very limited.

Cystectomy and Ileal Conduit

Cystectomy and ileal conduit may be considered for those patients with a low probability of success in resolving the fistula or in maintenance of urinary continence.[148]

Benign Anorectal and Rectovaginal Fistulas

David A. Etzioni and Ann C. Lowry

Introduction

Although infrequently life-threatening, rectovaginal fistulas are an aggravation to both patients and surgeons. Passing flatus or stool through the vagina is understandably distressing to patients; the lack of a uniformly successful repair is frustrating to surgeons.

Etiology

Rectovaginal fistulas arise from a broad range of causes, and may be congenital or acquired. Congenital rectovaginal fistulas are outside the scope of this chapter.

Obstetrical injury is the most frequent cause of acquired rectovaginal fistulas. In general, immediate repair is the treatment of choice after a third or fourth-degree laceration. After an obstetrical injury the fistula may manifest immediately but more commonly appears 7–10 days after delivery. Inadequate repair, breakdown of the repair or infection may result in fistula formation. In developed nations, rectovaginal fistulas occur after 0.06–0.1% of vaginal deliveries.[1–3] In developing countries, the incidence of rectovaginal and vesicovaginal fistula after childbirth is almost three times higher, with more than half of these fistulas being larger than 4 cm in diameter.[4,5] In these countries prolonged labor, causing necrosis of the rectovaginal septum, leads to the formation of a fistula. The resultant social stigma generates significant suffering for these women who have limited access to treatment.[6]

Infectious and inflammatory disease processes may also cause rectovaginal fistulas. The most common infectious cause is cryptoglandular infection with an abscess that spontaneously drains into the vagina. Women with inflammatory bowel disease (IBD) – more commonly Crohn's disease than ulcerative colitis – develop spontaneous rectovaginal fistulas with some frequency. In a population-based study of patients with Crohn's disease in Olmsted County, 8 of 169 patients developed a rectovaginal fistula.[7] In a similar study of patients in St. Mark's Hospital, 90 of the 886 women with Crohn's disease and an intact rectum developed a rectovaginal fistula during a 30-year follow-up.[8]

Operative and nonoperative trauma may also result in a rectovaginal fistula. Complications of rectal or vaginal surgery usually result in fistulas opening low in the rectum. High fistulas are most frequently complications of stapled anastomoses. In one series of 140 patients undergoing low anterior resection for rectal carcinoma four (2.9%) developed a rectovaginal fistula.[9] Rectovaginal fistula is also reported after stapled transanal resection for obstructed defecation syndrome, stapled hemorrhoidopexy, and in 3–12% of patients undergoing an ileoanal pouch procedure.[10–16] Fistulas have also been documented after dilatation of a radiated vaginal cuff, fecal impaction, viral/bacterial infection in human immunodeficiency virus (HIV) patients, sexual assault, and spontaneously in patients undergoing treatment with antiangiogenic chemotherapeutics.[17–24] Finally, anorectal and gynecologic malignancies may result in fistulas due to local extension of the tumor or secondary to treatment with radiotherapy.

Evaluation

Initial evaluation of a woman with a known or suspected rectovaginal fistula should focus first on confirming the presence of a fistula, and subsequently on evaluating the anatomy of the fistula and the integrity of the surrounding tissues. The specific types of investigations required vary mainly according to the underlying etiology of the fistula.

History

Several important aspects of a woman's history may have a significant impact on a patient's workup and selection of surgical treatment. Any history of anorectal or gynecologic malignancy should prompt a thorough investigation for recurrence, both in the rectovaginal septum and pelvis. Prior treatment

with radiation should be specifically elicited. Issues related to continence should also be documented. If the mechanism of injury is childbirth, the patient with a fistula is at significant risk of a sphincter defect. In a review by the University of Minnesota, 48% of women with rectovaginal fistulas complained of incontinence preoperatively.[25] Bowel function as well as signs/symptoms of IBD should also be targeted as possible areas for workup and preoperative optimization. Evaluation of the intestinal tract by colonoscopy and contrast studies is indicated in patients with known or suspected IBD.

Physical Examination

Information obtained from physical examination is critical to the evaluation and surgical decision-making for women with rectovaginal fistula. During the initial examination, the possibility of local sepsis should be considered. Findings of fluctuance, cellulitis, or any other harbingers of active infection should prompt an exam under anesthesia and drainage with or without placement of seton(s). Any mass lesion discovered on exam should be biopsied to evaluate for malignancy. In patients with a prior history of anorectal or gynecologic malignancy, the threshold for a biopsy should be especially low. In patients with a history of radiation treatment for malignancy an examination under anesthesia with biopsies is often necessary.

The site of rectovaginal fistula can usually be readily identified on digital examination as a palpable dimple in the anterior midline. Multiple perianal fistulas suggest Crohn's disease as the etiology. The rectal opening is frequently visible on anoscopy, but in some women the diagnosis may be elusive. A methylene blue test may confirm the presence of a communication and aid in locating the site. During this test, the patient is placed in prone position and a vaginal tampon is inserted; a 20–30-ml enema colored with methylene blue is then administered. Staining on the tampon is diagnostic of a rectovaginal fistula, assuming no spillage of dye. Alternatively, saline can be instilled in the vagina with the patient in the lithotomy position. The rectum is then insufflated with air and the vagina observed for bubbles.

A patient's sphincter function should also be assessed during the physical examination. Patients with clinically significant sphincter interruption may benefit from a surgical approach which encompasses a sphincter repair.

Radiography

Radiographic tests may help identify an elusive fistula. Vaginography can detect fistulas that are obscure to the maneuvers described above, and gives objective determination of fistula location. It is performed by instilling contrast into the vagina through a Foley catheter with the balloon inflated to occlude the vaginal opening. The technique has a sensitivity of 79–100% for the detection of the fistula tract. Vaginography is most helpful for colovaginal and enterovaginal fistulas; it is less useful for low rectovaginal fistulas.[26,27]

Computed tomography (CT) scans may identify the fistula tract and characterize the surrounding tissue. Contrast material in the vagina after oral or rectal administration is diagnostic of a fistula. Suggestive evidence includes air or fluid in the vagina if there is no history of recent instrumentation. Magnetic resonance imaging (MRI) and endorectal ultrasound are also useful in identifying fistulas; the injection of hydrogen peroxide into fistulas has been shown to increase the yield of ultrasonography.[28] At present there is no clear "best" radiologic test to detect elusive fistulas. Since results are likely highly operator-dependent, local expertise should be considered when selecting a test.

Endoanal ultrasound and MRI also have an important role in assessing the structural integrity of the anal sphincter. One study found that 100% of women presenting with an obstetric rectovaginal fistula had evidence of an anterior sphincter defect.[29] Symptoms of the fistula frequently mask anal incontinence; failure to study the sphincter may lead to a poor choice of repair and persistent incontinence postoperatively.[25,30] Endoanal ultrasound and MRI are reported to be essentially equivalent in detection of a sphincter defect.[31]

MRI, CT, and endosonography also have a role in evaluating for the presence of local sepsis. MRI appears to be more accurate than ultrasound for this purpose, but its superiority to CT has not been demonstrated.[32] Ultrasonography may be a useful tool for intraoperative radiologic guidance for drainage of complex abscesses.[33]

Classification

A variety of classification systems exist for rectovaginal fistulas. Each has importance in terms of generating aspects of the patient's workup and treatment.

Fistula Height

Daniels classified fistulas by their location along the rectovaginal septum as low, middle, or high.[34] With low fistulas, the rectal opening is at the dentate line and the vaginal opening just inside the vaginal fourchette. The vaginal opening is at or near the cervix in high fistulas. Middle fistulas are located between high and low fistulas. In general, high fistulas are more likely to require laparotomy; perineal approaches are appropriate for most low and middle fistulas. Fistulas may also be classified by the location of the rectal opening. Ones opening at the dentate line or above are considered rectovaginal fistulas; fistulas opening below the dentate line as "anovaginal fistulas." The use of this classification is quite inconsistent and has not translated to clear differences in etiology or surgical approach.

Simple vs. Complex Fistulas

Another system classifies fistulas as simple vs. complex.[35] Simple fistulas are small (<2.5 cm), low and secondary to

trauma or infection. Complex fistulas are large, high, caused by IBD, radiation or malignancy, or persistent after failed repair(s). This system has some utility in directing surgical decision-making because it reflects the status of the local tissue. Simple fistulas are more amenable to local repairs, whereas complex fistulas are more likely to require resection or interposition. Fecal diversion is a consideration for complex fistulas but rarely, if ever, necessary for simple fistulas.

Surgical Management

In this section, we will catalog the main options for surgical treatment. The following section will discuss the main considerations that should drive decision-making regarding the choice of procedure.

General Considerations

Patients undergo mechanical and antibiotic preparation preoperatively. Most procedures require general anesthesia, although some repairs may be performed under regional anesthesia. A urinary catheter is inserted. Prone jackknife position with taping of the buttocks provides the best exposure for transanal and perineal approaches, while lithotomy position is better for transvaginal repairs. A well-functioning headlight is critical. Depending on the procedure at hand, operative exposure may be greatly facilitated by access to a Lone Star retractor, Pratt bivalve or Fansler anoscope, Wylie renal vein retractors, and narrow Deaver or malleable retractors.

Fistulotomy

Simple fistulotomy is an option for only a very select group of rectovaginal fistulas. Patients who may benefit more than be harmed by this approach have very low fistulas with no (or vanishingly little) sphincter involvement. Fistulotomy should be avoided in other rectovaginal fistulas due to the risk of incontinence.

Fibrin Sealant

A significant body of experience has been accumulated regarding the efficacy of fibrin glue instillation for various types of fistula-in-ano. The technique is straightforward, requiring the gentle curettage of the fistula, followed by injection of an admixture of cryoprecipitate and thrombin. Success rates for fistula-in-ano vary widely, ranging from 31 to 61%.[36,37] An interesting approach – adding fibrin glue to mucosal advancement flap repair was analyzed by Ellis and Clark[38] with similar outcomes.

The accumulated experience in using fibrin glue for rectovaginal fistulas is more limited. Abel et al.[39] reported healing in three of five patients, and Venkatesh and Ramanujam[40] reported success in six of eight patients. These series are too small to yield stable estimates regarding the true effectiveness of fibrin glue for rectovaginal fistulas. Unpublished experience with fibrin sealant has not yet matched the enthusiasm and success rates of these initial reports. The approach has appeal mainly in that the risk (in terms of injury to surrounding tissues) is minimal, and the success rate appears to be greater than zero.

Mucosal Advancement Flaps

Mucosal advancement flaps aim to eradicate rectovaginal fistulas by occluding one side or the other of the tract with healthy epithelial tissue. The approach can be undertaken either transanally or vaginally. The transanal approach is intuitively preferable in that the repair is on the high pressure side of the fistula. With the patient in the prone jackknife position and adequate exposure, a U-shaped flap of mucosa, submucosa, and circular muscle is raised for a distance sufficient to allow a tension-free repair (usually 4–5 cm). Dissection should generate a flap with a base two to three times wider than the apex. The fistula tract is debrided (not excised), and the muscles are approximated over the fistula opening with long-acting absorbable suture in 1–2 layers. Distally, the end of the flap including the fistula site is excised and the flap sutured in place; the vaginal side is left open for drainage (Figure 14-1). Patients typically resume a normal diet with fiber supplements to prevent constipation. Diarrhea must also be controlled as it will affect healing as much as constipation. Postdischarge instructions should include avoiding intercourse and the use of tampons for 6 weeks.

A vaginal approach is performed in similar fashion, with an incision in the posterior vaginal wall near the introitus. A flap of vaginal wall is raised laterally to the ischial tuberosities to provide adequate mobility. The vaginal and rectal defects are closed with absorbable sutures, and the levator ani muscles are approximated in the midline; this portion of the repair is felt to be critical to its success. Absorbable suture are then used to suture the vaginal flap in place.

The success rates of endorectal and vaginal advancement flaps for rectovaginal fistulas have been reported widely in the literature (Table 14-1). Variations in outcomes are likely attributable more to the small size of these series than any underlying patient or technical factor. Differences in length of follow-up are also important, as fistulas may recur more than 4 years postrepair.[58] Importantly, success rates are measured in terms of fistula closure, and measures of continence are rarely included. Studies examining advancement flaps in the treatment of patients with fistula-in-ano document disturbances to continence in 21–40% of patients.[52,53,56] The lack of standardized measures of continence in these reports makes objective comparison challenging, however. Several technical modifications have been attempted with the goal of improving success rates with advancement flaps. One group of investigators added labial fat transposition to endorectal advancement flap but had outcomes no different from an advancement flap alone.[54] At least two early

reports documented the successful use of transanal endoscopic microsurgery (TEM) to facilitate mucosal flap repair for rectovaginal fistula.[59,60] Interestingly, smoking has been linked to failure of endorectal advancement flaps, possibly the result of impairments in mucosal blood flow.[61,62] It is not known whether smoking cessation prior to surgery can increase rates of success.

Retrograde anocutaneous flaps are an option for very low rectovaginal fistulas. A flap of anoderm and perineal skin is raised and advanced into the anal canal. After the fistula is debrided, the flap is sutured into place.[63] A similar approach has also been utilized on the vaginal side in conjunction with an endoanal advancement flap.[64] Only a small number of cases have been reported with either technique.

Fistulectomy with Layered Closure

Another option that can be approached through the rectum, vagina, or perineum is excision of the fistula tract. An elliptical incision is made around the fistula and mucosal flaps are raised for 2–3 cm. The fistula is excised in its entirety. Vaginal mucosa, rectovaginal septum, rectal muscle, and rectal mucosa are closed in succession. Plication of the levator muscles is added by some surgeons. If done through the perineum, a transverse incision is made and extended down to the fistula tract. The fistula is then cored out of the rectal and vaginal walls and a layered closure performed. Using layered closure, successful repair is reported in 88–100% of patients in several small series.[65–68]

Rectal Sleeve Advancement

Rectal sleeve advancement involves the circumferential mobilization of the distal rectum and advancement to cover the anorectal side of a fistula. This technique is reserved for situations where there is a rectovaginal fistula and co-existing diffuse disease in the proximal anal canal and/or distal rectum. Simmang et al.[69] emphasized that this approach is useful for someone with a rectovaginal fistula and an anal stricture, as both problems will be corrected with the procedure.

Technically, the procedure is performed using a circumferential incision at the dentate line which is deepened through the submucosa into the internal sphincter. This plane is continued cephalad, becoming full thickness above the anorectal ring. Mobilization continues until healthy, nonscarred tissue is reached and that tissue can be pulled down to the dentate line without tension. The remaining diseased anorectal mucosa is pulled through the anal canal, and excised; healthy rectum is then sutured to anoderm below the dentate line. In a series of five patients with rectovaginal fistulas and Crohn's disease reported by the Cleveland Clinic, all three of the patients with fecal diversion healed.[70] One patient required two rectal sleeve advancements before healing occurred. Of the two patients without fecal diversion, one healed.

Two variations of the sleeve advancement deserve mention. Schouten and Oom[71] reported using a Kraske approach to sleeve advancement for six women with rectovaginal fistulas after prior failed treatment; they reported success with five. A second variation of the sleeve advancement technique is the modified Noble–Mengert–Fish technique.[72] With this method the full thickness of the anterior rectal wall is mobilized. A curvilinear incision is made at the mucocutaneous junction over the anterior 180° of the anal canal. The dissection continues until the rectovaginal septum is entered. The superior limit is the vault of the vagina; the lateral margin is the full width of the rectovaginal space. There needs to be adequate dissection to ensure that the flap will reach the area of the external sphincter without tension. The flap is then anchored to the external anal sphincter and the perineal skin forming a new mucocutaneous junction. Older reports of this technique documented successful repair of rectovaginal

fistulas in 86–100% of patients. Minor incontinence troubled 25% of patients.[73–75] The only recent report combined this repair with sphincter reconstruction or perineal body repair in the majority of patients.[72] The overall anatomic success was 94%; the results for the anterior rectal wall advancement alone were not reported separately.

Sphincteroplasty and Perineo-Proctotomy

Sphincteroplasty and perineo-proctotomy are related techniques in that they both involve converting the rectovaginal fistula to a fourth-degree laceration, with a subsequent layered anatomical repair of mucosa and intervening tissues. A sphincteroplasty procedure is commonly utilized when a defect in the external sphincter is present with the rectovaginal fistula. In that situation, an overlapping sphincteroplasty serves dual purpose, both obliterating the fistula and repairing the sphincter defect. The technical details are described and illustrated in Chap. 46 on incontinence. Successful closure of rectovaginal fistulas with this operation is reported in 65–100% of patients (Table 14-2).[25,29,30,43,44,46,74,77]

The perineo-proctotomy technique differs from the sphincteroplasty primarily in that it is performed in a patient with an intact sphincter complex. This approach begins with the identification of the fistula and division of the bridge of skin, subcutaneous tissue, sphincter muscle, rectal and vaginal walls overlying the fistula. The tract is excised and both the rectal and vaginal walls are dissected away from the muscle. Internal and external sphincter musculature must be adequately mobilized in order to avoid tension when they are reapproximated. After repair of both the rectal and vaginal defects, the sphincter muscles are sutured together. The perineal body is reconstructed and the skin closed (Figure 14-2).

Women with rectovaginal fistula and an accompanying sphincter defect are ideal candidates for sphincteroplasty; the reapproximation of the sphincter may theoretically improve continence, although this has not been proven. The extension of this approach to patients with an intact sphincter (perineo-proctotomy) should not be undertaken lightly. Perineo-proctotomy has a high success rate – success rates for fistula closure range from 87 to 100% in small series.[40,47,68,79] The impact of the procedure on postoperative continence has not been well-studied, but Mazier et al.[47] report that none of 38 women undergoing this repair were incontinent

postoperatively. Despite these results, the potential for significant short- and long-term impairment of continence as a result of injury to an intact sphincter mechanism cannot be ignored. We recommend a dedicated trial of one or more attempts at repairs which do not significantly injure the sphincter mechanism before attempting perineo-proctotomy.

Inversion of Fistula

Inversion of the fistula is a simple technique usually performed through the vagina. The vaginal mucosa is mobilized circumferentially around the fistula, and the tract is excised. A purse-string suture is then used to invert the fistula into the rectum and the vaginal wall is closed over the inversion.[80] One recent series reports a 100% success rate in 39 women with this technique.[78] A similar procedure – ligation of the intersphincteric fistula tract (LIFT) – has generated significant enthusiasm for the treatment of fistula-in-ano.[81,82] With this approach, an intersphincteric dissection is performed to encircle the fistula. The fistula track is divided and suture ligated on both sides; the perineal side is curetted and allowed to drain. While there is only limited experience in using the LIFT procedure for rectovaginal fistulas, the success rates with fistula-in-ano (60–94%) are encouraging.[82,83] There is no intuitive reason why this technique could not be applied to rectovaginal fistulas occurring within the sphincter mechanism. A good candidate for this

procedure is a patient with an intact sphincter and a fistula that traverses the sphincter complex. We believe it is unlikely that any repair which depends entirely on anorectal and/or vaginal mucosa has a good chance of success; it is the ability of the intersphincteric plane to heal to itself that is critical to the success of this repair.

Tissue Interposition: General Considerations

The insertion of healthy, well-vascularized tissue between the anorectal and vaginal sides of a rectovaginal fistula is an effective treatment for rectovaginal fistulas. Muscular tissue from a wide range of sources has been used in this capacity, including rectus, bulbocavernous, gracilis, gluteus and sartorius muscles (Table 14-3).[5,84–97] Regardless of which muscle is used, the perineal dissection is similar. The posterior vaginal wall is separated from the anal sphincter and anterior rectal wall until soft, pliable tissue is reached. This dissection is often difficult because of dense scarring. Care must be taken to avoid entering the rectum; injection of saline (with or without epinephrine) may widen this plane and decrease the risk of mucosal injury. Digital manipulation of the rectovaginal septum throughout the dissection is helpful to maintain the appropriate plane. At the site of the fistula, the rectal and vaginal walls are closed with absorbable sutures. It is generally not necessary to trim the vaginal or rectal wall, and doing so often only makes a significantly larger defect. The mobilized

muscle is then inserted between the rectum and the vagina and tacked to the posterior vaginal wall, and the incision is closed loosely over a closed suction drain.

Tissue Interposition: Labial Fat Pad or Bulbocavernous Muscle

The labial fat pad (also known as Martius flap) is an excellent source of tissue for transposition into a rectovaginal fistula. This technique is performed with the patient in modified lithotomy position. After a standard perineal dissection is performed, a longitudinal incision is made over the labia majora and skin flaps are raised laterally and medially. There is often a plane similar to Scarpa's fascia for this portion of the dissection. The dissection is continued to the periosteum of the pubis posteriorly and superiorly to the pubic symphysis. Once the entire fat pad with the bulbocavernous muscle is mobilized, the anterior end is divided, preserving the posterior pedicle with the perineal branch of the pudendal artery. A subcutaneous, subvaginal tunnel is created from the base of the pedicle to the perineal incision. The flap is pulled through this tunnel and sutured to the posterior vaginal wall cephalad to the site of the fistula. The labial and perineal incisions are then closed in two layers over drains (Figure 14-3). When vaginal stenosis is a concern, inclusion of an island of skin from the inner thigh with the pedicle is an alternative.[5] Aartsen and Sindram[98] reported 100% initial success in 14 patients with rectovaginal fistulas secondary to radiation

damage. Their report has a cautionary note; however, finding that after a 10-year follow-up 8 of the 14 patients required diversion for progressive radiation damage.[98] Others report success in 78–84%.[97,99,100]

Tissue Interposition: Bioprosthetics

The use of bioprosthetic materials to treat rectovaginal fistulas was initially reported in small series in 2004.[101,102] These materials can be interposed trans-perineally between an interrupted rectovaginal fistula or as a "plug" that is inserted into the tract itself. Ellis[103] reported a series of 34 patients treated for rectovaginal fistulas with a bioprosthetic comprised of porcine intestinal submucosa. Of 27 patients who underwent a trans-perineal approach, the success rate was 81%; the seven patients who were treated with a plug had a success rate of 86%.[103] Another series reported by Schwandner et al.[104] reported a 71% primary success rate with a trans-perineal approach in 21 patients. While these reports should be cause for optimism, experience with the plug for fistula-in-ano has been sobering. Initial reports of bioprosthetic quoted success rates of 80–83%.[105,106] Other recent series have been more pessimistic, with healing in 34–43% fistulas.[107,108] In general, the attraction of bioprosthetics in the treatment of rectovaginal fistulas is that the approach is technically straightforward, and there is no injury to the sphincter mechanism. The plug procedure has the additional advantage of avoiding dissection within the perineum, and therefore not impeding future repairs. Likelihood of success is still uncertain, but patients and physicians should expect that these approaches are at least as likely to fail as succeed.

One recent innovation worthy of note is a bioprosthetic plug designed specifically for use in rectovaginal fistulas.[109] The effectiveness of this plug was recently examined in one series of 12 patients.[110] Success was achieved in three of five rectovaginal fistulas and four of seven pouch-vaginal fistulas. A total of 20 plug placements were required, yielding a procedural success rate of 35% and an overall success rate of 58%.

Tissue Interposition: Muscle

Healthy, well-vascularized muscle is an ideal material for interposition and obliteration of a rectovaginal fistula. Several options are available for this approach, but the technique most commonly performed utilizes a gracilis muscle pedicled flap. The outcomes achieved with gracilis interposition are excellent, with successful repairs in 75–83% in recent series.[87,89,91] Healing has been noted to occur less often in patients with Crohn's disease.[89] Rectus, sartorius, and gluteal muscle flaps have also been reported as case reports or small series.[86,94,111,112] Fecal diversion is routinely performed for these procedures.

The major problem with this approach is the morbidity associated with the mobilization of the pedicled muscle flap and the extent of perineal dissection required to accommodate the bulky interposed tissue. Details of mobilization of the rectus, gracilis, and sartorius muscles are beyond the scope of this chapter.

Tissue Interposition: Bowel

Healthy bowel can also be used as an interposition for patients with high rectovaginal fistulas, a procedure described by Bricker and Johnston.[113] Through an abdominal incision the fistula is divided. The sigmoid colon is mobilized and divided; the proximal end is used for a temporary colostomy, and the distal end is sutured in an end to side manner to the debrided edges of the defect in the rectal wall. When healing is confirmed with a contrast study, the proximal sigmoid colon is sutured to the loop of colon utilized in the repair (Figure 14-4). Bricker et al.[114] reported excellent or satisfactory results in 19 of 26 patients.

Resection

An extended low anterior resection may be done with excision of the rectum containing the fistula and creation of an anastomosis below. The vaginal defect is closed and if possible separated from the new anastomosis with omentum. Parks and associates described a sleeve coloanal technique when the fistula is very low.[115] The rectum is mobilized to a level below the fistula and divided. From a perineal approach, a distal rectal mucosectomy is performed and
FIGURE 14-4. Onlay patch (Bricker procedure).

the proximal healthy colon is pulled through the muscular sleeve covering the fistula. A hand-sewn coloanal anastomosis is then completed, and proximal diversion is customary. Technical success is reported in 78–100% of patients.[115–117] In a review of functional results after stoma closure, 64% of patients were completely continent at 6 months and 75% at 1 year.[117]

Choice of Treatment

Not all rectovaginal fistulas require surgical treatment. Initial medical management is appropriate for women with small fistulas and minimal symptoms. Obstetric fistulas, in particular have a high rate of spontaneous closure in the 6–9 month postpartum period. Optimizing the patient's bowel function, particularly controlling diarrhea, can only improve the success of any treatment program. Unfortunately, for the majority of women with rectovaginal fistulas the symptoms are intolerable, and many require one (or more) efforts at surgical repair.

Fibrin glue instillation or fistula plug are reasonable initial attempts particularly in low, small fistulas. Their success rates are unproven, but these procedures are well tolerated, carry minimal risk, and do not impede future efforts at repair. Other surgical options should be selected on the basis of factors related to the patient and their disease process.

Rectovaginal Fistulas Secondary to Obstetrical Injury

Rectovaginal fistulas may close spontaneously in the early postpartum period (3–6 months); all others require surgery to close.[78] To facilitate surgical repair and healing, the surrounding tissue must be free of local sepsis before proceeding with surgery; this may involve surgical debridement and draining setons. Once the surrounding tissue is amenable to repair, timing of operation may be chosen by the patient together with her surgeon. Patients with significant symptoms need not wait until their childbearing is complete, although depending upon the choice of repair subsequent children should be delivered by cesarean section.

As mentioned above, an important part of the evaluation of women with rectovaginal fistulas caused by obstetrical injury is assessment of anal sphincter anatomy and function. In multiple studies, the incidence of associated sphincter defect is close to 100% in this subset of patients.[25,29,30] In women with sphincter defects, sphincteroplasty addresses both the fistula and the sphincter defect. The advantage of this technique is the excellent exposure it provides; the disadvantage is the potential risk of incontinence if intact sphincter muscle is divided. For women with intact sphincters and a rectovaginal fistula after childbirth, an advancement flap or layered fistulectomy are recommended as the initial approach. Failure should prompt an attempt with

tissue interposition –Martius flap or bioprosthetics are good options. Perineo-proctotomy and sleeve advancement are best reserved for use only after multiple other approaches have failed. Preoperative diversion should be strongly considered as an adjunct in these difficult cases. Despite the many studies performed to date, the literature does not categorically support a single technique as superior; the choice of the repair should be based upon the surgeon's experience.

Rectovaginal Fistulas Secondary to Cryptoglandular Disease

Rectovaginal fistulas secondary to cryptoglandular disease are rare. Evaluation must include evaluation/treatment of associated local sepsis, and endoanal ultrasound to exclude an occult sphincter defect. In the absence of a significant sphincter defect, endorectal/endoanal advancement flap, fibrin glue, and fistula plugs are reasonable alternatives.

Rectovaginal Fistulas Secondary to Crohn's Disease

The treatment of patients with rectovaginal fistulas secondary to Crohn's disease differs from other patients with rectovaginal fistulas in several ways. Given the nature of Crohn's disease, control of symptoms becomes the primary goal as opposed to elimination of the fistula in this subset of patients.

Once any associated sepsis is controlled, medical management with antibiotics and immunosuppressive medication is the initial approach to treatment for virtually all patients with Crohn's disease and rectovaginal fistulas. Recently, infliximab (antitumor necrosis α) has demonstrated efficacy in healing Crohn's rectovaginal fistulas. In 1999, Present et al.[118] reported the results of a randomized trial comparing infliximab to placebo for Crohn's perianal fistulas with closure in 55% for infliximab vs. 13% for placebo. The multicenter trial entitled, A Crohn's disease clinical trial evaluating infliximab in a new long-term treatment regimen in patients with fistulizing Crohn's disease (ACCENT II), investigated the importance of infliximab maintenance on fistula closure; in a subset analysis of patients with rectovaginal fistulas, Sands et al.[119] reported a 44.8% closure rate at 14 weeks in 25 patients. These data are still early, and the true long-term effectiveness of infliximab is unknown, especially given the fact that the radiological healing rate is lower than the clinical healing rate.[120] Results are better when drainage of local sepsis and placement of a seton are done prior to initiating infliximab.[121] If the goal is complete healing, the seton must be removed before the completion of the course of infliximab.

In cases where medical management is able to control Crohn's proctitis, then surgical intervention for fistula repair can be considered. In these patients, the same considerations apply as in the treatment of rectovaginal fistulas in patients without Crohn's. One possible difference is that procedures which involve a significant injury to the sphincter complex (e.g., perineo-proctotomy/sphincteroplasty) should be avoided. The necessity of diversion is controversial, but it is commonly performed in this subset of patients particularly ones requiring immunosuppressive medication to control their intestinal disease. Eradication of the fistula with an endorectal advancement flap is reported in 30–70% of patients.[53,122] Kodner et al.[45] reported an initial healing rate of 71% which increased to 92% with additional procedures. The Cleveland Clinic surgeons tailor the advancement flap according to the height and length of the fistula and the presence of rectal ulceration or inflammation.[70] They report an initial healing rate of 54% and an overall success rate of 68% including repeat repairs. All of these results predate the introduction of infliximab.

For patients with rectovaginal fistulas and medically refractory Crohn's proctitis, surgical options are limited. The inflamed, friable anorectal tissue responds poorly to any intervention. Long-term use of draining setons should be considered in these patients as a bridge to future abatement of disease or progression to definitive treatment (often proctectomy). Patients with anal stricture and active colonic disease appear to be most likely to progress to proctectomy.[123] Of significant concern is the potential for developing a malignancy in the fistula. In one study, Heyen et al.[124] traced the course of 28 women with Crohn's disease and a rectovaginal fistula. Malignancy resulting in death developed in the fistula of two patients.

Rectovaginal Fistulas Secondary to Malignancy

The treatment of rectovaginal fistulas associated with underlying malignancy is dictated primarily by the therapy required for the patient's cancer. For rectal cancer, neoadjuvant chemoradiation therapy followed by surgery (including vaginectomy, with or without reconstruction) is the standard of care for nonmetastatic disease. Fecal diversion prior to initiation of treatment may be necessary for patient comfort. When resection is performed, interposition of tissue (e.g., omentum, rectus muscle) between the colorectal anastomosis and closure of the vagina may prevent a postoperative fistula if a pelvic abscess or anastomotic leak occurs.

For squamous cell carcinoma of the anus, a preexisting fistula or one that develops during chemoradiation often requires diversion for symptom control. If there is complete resolution of the tumor after chemoradiation, repair of the fistula with interposition of the bulbocavernous or gracilis muscle is indicated after a waiting period to allow for resolution of any acute radiation changes. It is unlikely that a local repair would be successful in an irradiated field. If tumor persists after chemoradiation an abdominoperineal resection is necessary. Low rates of perineal wound healing in this situation have led many surgeons to use muscle flaps for wound closure either routinely or selectively.

Rectovaginal Fistulas Secondary to Radiation Therapy

Patients with rectovaginal fistulas resulting from radiation therapy pose a challenging clinical problem. In the diagnostic evaluation of these patients, a thorough examination of the fistula site, preferably under anesthesia should be undertaken, including biopsies of the fistula to exclude recurrent cancer. Fecal diversion should be strongly considered to allow inflammation in the surrounding tissue to resolve.

Decisions regarding surgical intervention center on the patient's overall medical condition, the degree of symptoms caused by the fistula, associated abnormalities, and the risk of a proposed corrective procedure. Not uncommonly, the combination of those factors makes a colostomy alone the most reasonable choice. Permanent diversion is particularly appropriate if the patient is experiencing significant fecal incontinence. However, a variety of surgical options do exist, but these are generally different from those offered to patients who have not been treated with radiation. A guiding principle is that without interposing healthy (nonirradiated) tissue into the fistula tract, the likelihood of success is so small as to render the approach futile.

In cases where the fistula is low and the rectum is relatively normal, tissue interposition (e.g., gracilis muscle, Martius flap) through the perineum is a reasonable choice. If the fistula is high, tissue interposition (e.g., rectus muscle, Bricker procedure) through the abdomen is preferable. Stricture or severe radiation proctitis may require proctectomy, with the introduction of nonirradiated colon as a neorectum. The morbidity of this approach is high, 24% in one series.[125] A Bricker procedure avoids the morbidity of proctectomy and pelvic dissection but leaves a diseased rectum in place. The final option for some patients is an end colostomy, which may provide a quality of life superior to a poorly functioning anorectum. Patient selection and operative choice must be based on clinical experience as comparative studies do not exist.

Iatrogenic Rectovaginal Fistula

The choice of treatment for an iatrogenic rectovaginal fistula is dictated by the factors discussed previously. Fistulas developing after rectal resection almost always arise at the anastomosis and are reported after both hand-sewn and stapled anastomoses.[126,127] An important step toward preventing this

complication is to palpate the posterior wall of the vagina while simultaneously rotating the closed EEA stapler during creation of the anastomosis. If dimpling is felt or the vaginal mucosa is felt to be in close apposition to the stapler, the device should be repositioned. Once a fistula occurs, the first goal of therapy is to control local sepsis, which may require temporary diversion and/or drainage procedures. Repair is determined by the level of the fistula. Low fistulas may be amenable to rectal or vaginal advancement flaps; a trans-perineal approach with interposed bioprosthetic material or muscle is also reasonable. High fistulas usually require repeat resection with anastomosis or interposition of omentum or muscle. Large fistulas or those failing initial attempts at repair will usually require tissue interposition.

Persistent Rectovaginal Fistula

There are little data regarding fistulas which persist after an attempted repair. Repeat repairs after one failed attempt appear to have a reasonable success rate, but failure rate after additional procedures increases dramatically so subsequent options should be chosen carefully.[76,77] Work by MacRae et al.[46] highlights the importance of tailoring the surgical approach. They retrospectively reviewed 28 patients who had failed at least one previous attempt at repair. Of 18 patients with simple fistulas, successful repair was accomplished in 13; these successes included 5 advancement flaps, 5 sphincteroplasties, and 3 coloanal anastomoses. In ten patients with complex fistulas, only four patients healed; these involved one sphincteroplasty, one coloanal anastomosis, and two gracilis muscle interpositions. In a report from the Cleveland Clinic, Halverson et al.[77] retrospectively reviewed 33 patients with recurrent rectovaginal fistulas. Advancement flap, sphincteroplasty, rectal sleeve advancement, insertion of fibrin glue, and ileal pouch revision were utilized. Fistula closure was accomplished in 27 of these 33 patients (82%) after a median of two operations. While the overall results are encouraging, the highly heterogenous patient cohort makes it difficult to extract meaningful recommendations for specific patient populations.

Recent studies on bioprosthetic material offer an encouraging alternative to the surgical options described by Halverson et al.[77] and MacRae et al.[46] Ellis[103] reported success in 10 of 14 women (71%) with recurrent rectovaginal fistula using a trans-perineal placement of porcine intestinal submucosal biologic mesh. Similar success has been reported by Schwandner et al.[104] who achieved closure in 15 of 21 women (71%) with recurrent fistulas. Of note, 38% of patients in the Schwandner study had their procedures performed with fecal diversion; no data regarding diversion were reported by Ellis.

From the data available, it appears that a reasonable approach to recurrent rectovaginal fistulas would begin with a period of conservative treatment during which any areas of sepsis are drained and the integrity of the sphincters are evaluated. For low fistulas, the treatment choice depends upon the status of the sphincter and the number of prior repairs. If the sphincter is intact and only one or perhaps two previous repairs have been attempted, an advancement flap or rectal sleeve advancement would be appropriate. Insertion of fibrin glue is a safe alternative but there are little data regarding the expected success rate. If there is a defect in the sphincter muscle, sphincteroplasty or perineo-proctotomy is an appropriate choice. In cases where the sphincter is intact and two or more repairs have failed then an interposition technique should be considered. The choice of technique depends on the expertise of the surgeon; insertion of bulbocavernous muscle is the least morbid transposition method, but there are no good comparative data regarding outcomes of the various interposition methods. Fecal diversion is not absolutely necessary but likely increases the success of repair, especially in patients with Crohn's disease. Recurrent fistulas involving the middle of the vagina almost always require tissue interposition. The choice depends upon the level of the fistula and the body habitus of the patient. Bulbocavernous muscle may not reach if the patient is obese or the fistula is in the upper middle third of the vagina. Gracilis muscle would be a good alternative in those situations. High fistulas require resection or tissue interposition through an abdominal approach.

Conclusion

The literature on rectovaginal fistulas documents a wealth of clinical experience. However, there is a definite lack of uniform terminology, standardized evaluation and comparative studies. Given the multitude of etiologies and the varying nature of the anatomy and condition of surrounding tissue, improving the quality of research will be challenging. However, continued work is necessary to determine appropriate patient selection and optimal surgical repair.

Pilonidal Disease

Background and Incidence

Pilonidal disease refers to a subcutaneous infection occurring in the upper half of the gluteal cleft. It may present as an acute pilonidal abscess with pain, erythema, and induration or as a pilonidal sinus, which is an indolent wound that is resistant to spontaneous healing, and can cause significant discomfort and drainage. Pilonidal disease is commonly found in young adults, and typically present in the second decade of life.[1] Men are more frequently affected than women at a ratio of three or four to one, and is more commonly seen in individuals with more body hair.[1] It is not known to be more common in any one racial group; however, certain occupations such as the military, hairdressers, and sheepshearers have been associated with the development of pilonidal disease.[2–4] Other predisposing factors to pilonidal disease have been suggested and include obesity, being a vehicle driver, a sedentary occupation, and having a history of a furuncle at another site on the body.[5,6] Others have implicated anatomic factors such as natal cleft as risk factors for pilonidal disease.[7] In a study of 50 patients with pilonidal disease, the depth of natal cleft was compared to 51 volunteers.[7] The report shows a significantly deeper natal cleft in the pilonidal disease group (27.1 vs. 21.1 mm; $p<0.01$). Although a genetic predisposition has not been determined, family history does seem to play a role in this disease process. A recent report indicates that a family history of pilonidal disease predisposes patients to earlier onset of the disease and higher long-term (25 years) recurrence rate of over 50%.[8]

The incidence of pilonidal disease is not accurately known, but has been reported to affect up to 0.7% of adolescents and young adults[1] and up to 8.8% of recruits in the Turkish army.[5] Others have calculated the incidence of the disease at 26 per 100,000 persons regardless of age.[6]

Pilonidal disease first appeared in the medical literature in 1833 when William Mayo published his first descriptions of this problem.[9,10] In 1880, Hodges[11] introduced the term "pilonidal," which means "hair nest." The term pilonidal "cyst" is a misnomer, because no epithelialized wall exists in the cavities this disease creates. Pilonidal "sinus" or "disease" are the more accurate terms. Pilonidal disease itself, and the surgical and medical treatment related to it, can be a significant source of morbidity and disability. This disease disables patients primarily because of pain and its inconvenient location in the gluteal cleft.

Traditionally, treatment for pilonidal disease was wide local excision; however, in World War II entire hospital wards were filled with soldiers convalescing from these large excisional operations.[12] In fact, nearly 80,000 soldiers were hospitalized for an average of 55 days for wound healing.[13] It became such a problem that the Surgeon General forbade wide local excision as primary therapy. Thus, World War II symbolizes a paradigm shift that occurred in favor of conservative management for pilonidal disease. Much has evolved in the treatment of pilonidal disease and ranges from nonoperative treatments such as shaving and hygiene to operative procedures ranging from excision to flap reconstruction. Each has its role in treating this disease spectrum, and management of pilonidal disease should be tailored to the individual clinical presentation; however, no treatment has proved completely satisfactory. Treatment goals should be maintained and include the complete resolution of the pilonidal disease through methods that have low recurrence and low morbidity.

Pathogenesis

The etiology of pilonidal disease has been controversial, with initial beliefs tied to embryologic origins. Pilonidal disease was considered to be an inborn defect of the skin in the interguteal region secondary to a remnant of the medullary canal and infolding of the surface epithelium; however, empiric data currently supports this disease as being an acquired condition. First, the disease is not present at birth, but in young adults; second, it is more frequent in hirsute men; and third,

certain occupations predispose people to develop pilonidal disease.[14] Pilonidal disease has been observed in the hands of barbers and sheep shearers, implying that shed hairs may initiate the condition.[3,4]

The acquired theory of pilonidal disease is most popular, but the mechanism varies widely. This disease most likely results from problems that attack the epidermis in the gluteal cleft, rather than from a problem in the deep tissues.[13] Bascom believes that the skin in the natal cleft is normal; however, conditions may exist that predispose a patient to pilonidal disease.[13,15] Bascom[16] believes that hair follicles in the natal cleft become distended with keratin and then infected, forming an abscess that eventually ruptures into the subcutaneous tissue. Vacuum forces and negative suction in the natal cleft draws hair and debris into the midline pits of the hair follicle then into the abscess cavity (pilonidal abscess).[9] Karydakis[17] proposed that hair with chisel-like roots inserts itself into the natal cleft leading to foreign body tissue reaction and infection. Both theories seems plausible as pilonidal lesions have the pathologic characteristics of a foreign body reaction, presumably from burrowed or subcutaneously displaced hair and epithelial debris[1]; however, no published study exist which directly prove or refute the current theories about how pilonidal disease occurs.

Certain anatomic features of pilonidal disease are well established and not associated with any particular theory.[14] They include a midline pit in the natal cleft that is referred to as the primary opening. The pit often extends into a subcutaneous fibrous tract called the pilonidal sinus, which connects to a secondary opening. The secondary opening is located off the midline and is characterized by drainage of purulent or serosanguinous fluid, the presence of granulation tissue, and hypertrophy of the epithelium surrounding the opening. Hair is seen extruding from the primary opening. The pilonidal sinus tract may be single or multiple, short or long, and up to 93% run in the cephalad direction. If the pilonidal sinus runs caudad, the secondary opening may resemble the opening of a fistula-in-ano.

Clinical Presentation and Diagnosis

Pilonidal disease can present acutely as a pilonidal abscess or as a chronically draining sinus tract with intermittent symptoms of pain and drainage followed by long quiescent periods. Diagnosis is indicated by the site and appearance of the disease, and identification of midline pits in the natal cleft skin. Findings can be classified into *acute pilonidal abscess*, *chronic pilonidal sinus*, and *recurrent* or *complex pilonidal sinus*.

Acute pilonidal abscess can be characterized by a tender fluctuant subcutaneous mass with surrounding cellulitis located off midline of the natal cleft. Onset is rapid and pain is severe. *Chronic pilonidal sinus* has a primary pit in the midline natal cleft located 4–5 cm cephalad to the anus. The pit will sometimes have hair extruding from the opening.

There may be a secondary opening located cephalad and off midline at a variable distance from the primary opening. Patients with long-standing disease may have *complicated pilonidal sinus* with multiple sinus tracts and partially drained abscess cavities. Uncommonly, this process can be quite destructive with large sinus cavities extending out into the lateral gluteal regions. Occasionally, patients may present with *recurrent pilonidal disease* having had many different surgical procedures performed in the past for their disease. These patients may have a persistent wound from a midline excision or a failed flap procedure.

The differential diagnosis for these patients includes hidradenitis suppurativa and fistula-in-ano, and, less commonly, actinomycosis and syphilitic or tuberculous granulomas. Patients with chronic draining wounds or multiple failed operations for pilonidal disease may have osteomyelitis with draining sinus tracts. In these patients, a bone scan or magnetic resonance imaging (MRI) should be considered.

Treatment

The treatment of pilonidal disease is determined by the initial presentation of the disease. All *acute pilonidal abscesses* must be incised and drained. Most simple *chronic pilonidal sinuses* can be layed open, while *recurrent* and *complex pilonidal sinuses* may require excision with reconstruction. Optimal treatment protocols for each group include the following goals: ease of performance; short or no hospitalization; low recurrence rate; minimal pain and wound care; fast return to normal activity; and cost effectiveness. It is important to remember that no single procedure or treatment meets all these criteria.

Acute Pilonidal Abscess

Drainage of a pilonidal abscess can be performed in the office or emergency room under local anesthesia. The incision is made parallel to the midline and at least 1 cm laterally, to facilitate healing of the wound (Figure 15-1). A small ellipse of skin from the wound is removed to prevent the skin edges from sealing and reforming the abscess. Packing of these wounds is painful and potentially interferes with drainage and healing, and is therefore discouraged. Simply cover the wound with a dressing and have the patient do Sitz baths or use a hand-held shower to clean the wound and remove hair and debris two to three times a day. Antibiotics are only necessary in the patient with diabetes, prosthetic implants, immunocompromised diseases, or significant cellulitis. The patient should return to the office every week or two until the wound heals. Any hair that has grown back within 2 in. of the entire gluteal cleft is shaved during each visit (Figure 15-2). Once the wound has healed, the recurrence rate is 50% and may be in the form of an abscess or chronic pilonidal sinus.[14]

Chronic Pilonidal Sinus

Chronic uncomplicated pilonidal sinus has minimal to no acute inflammation. Primary and secondary openings are
FIGURE 15-1. Incision placement for acute pilonidal abscess.
FIGURE 15-2. Shaving technique.

frequently visualized and the sinus tract connecting the two may be palpable. In these patients, treatment can be either nonoperative or operative. The choice of treatment is determined by extent of disease and patient preference.

Nonsurgical Approach

Hair Removal

For the initial treatment of chronic pilonidal sinus, shaving alone has been advocated as the sole alternative to surgery. In 1994, Armstrong and Barcia[15] tested the hypothesis that wide, meticulous shaving was equal or superior to surgical therapy of any kind for patients with chronic pilonidal sinus. The authors performed a pilot nonrandomized cohort study with retrospectively obtained follow-up. One group of patients was treated with weekly strip shaving (5 cm circumferentially around the

entire gluteal cleft) until healing occurred and the other group was treated with surgery (any method). They then followed the patients for 3 years, comparing the number of occupied bed days and number of operations required. The authors found a highly statistically significant difference in favor of the group that received only shaving with lower number of occupied bed-days, with only 23 operations required in 101 consecutive cases of conservative management with weekly shaving. Although this study shows significant benefit for shaving alone, it is important to note that the authors did not control for the type of surgery performed in the nonconservative group, or for the severity of disease. Healing and recurrence rates were not reported, which is a major factor to consider when choosing a treatment modality. Furthermore, the data may be flawed in that it is plausible that although conservatively treated patients were not occupying hospital beds, they still could have been suffering from persistence of their disease, or they may have just sought treatment elsewhere. Despite these limitations, this study provides evidence that conservative nonsurgical treatment through shaving can improve pilonidal sinus healing.

Recently, several authors have described laser hair removal as an alternative to shaving.[18–20] In a recent retrospective review on laser depilation of the natal cleft to aid in healing pilonidal sinus, the authors report 14 patients treated over 5 years.[20] Only four patients (29%) had on-going disease requiring further depilation using the Alexandrite laser. All patients subsequently healed without complication. The authors concluded that although laser depilation in the natal cleft is not a cure for pilonidal disease, it does represent an alternative means of hair removal that is long lasting and allows sinuses to heal rapidly.

Collectively, these data suggest that control of hair in the natal cleft by shaving or laser hair removal may be an effective initial therapy in patients with chronic pilonidal sinus without an acute or chronic abscess; however, it is important to note that it is unknown how long one should continue shaving in order to prevent recurrence. Currently, we recommend shaving until complete healing has occurred.

Surgical Approaches

Surgery for pilonidal disease includes incisional procedures and excisional procedures with or without primary closure. As the acquired theory for pilonidal disease has gained wide acceptance, wide excision techniques have fallen out of favor. Minimal surgical techniques for pilonidal disease are now considered as the treatments of choice, and benefit the patient by decreasing hospital stay and minimizing morbidity. For thoroughness, we will describe all surgical options for chronic pilonidal sinus.

Midline Excision

Most chronic pilonidal sinus are located midline, therefore, the most common operation performed is midline excision,

with or without primary closure. En block excision is made of the entire pilonidal sinus. It is not necessary to always excise down to presacral fascia. The wound can be packed with moist gauze and dressings are changed daily. Excision without closure is associated with prolonged wound healing times, and it seems logical that excision with primary closure would decrease wound healing time and may afford improved outcomes.

Surprisingly, the literature contains only four randomized, prospective studies comparing open excision to excision and primary closure. In 1985, Kronborg et al.[21] randomized 88 patients to one of three treatment groups: excision, leaving the wound open; excision and wound closure; and excision and closure with postoperative clindamycin coverage. This study is important because it was the first to look at the utility of using antibiotics after pilonidal excision. The authors then looked at recurrence and healing rates. They followed each patient for 3 years. Healing rates between each of the primary closure groups were not statistically significant, and there was no benefit shown from the addition of clindamycin (14 vs. 11 days, $p > 0.10$). Healing took a substantially longer amount of time in the open group compared to the primary closure groups (64 vs. 15 days, $p > 0.001$). Recurrence rates were not significant in any of the groups ($p > 0.40$); however, there was a tendency toward more recurrences in the primary closure group (7 vs. 0 at 3 months and 7 vs. 4 at 3 years).

Fuzun et al.[22] randomized 91 patients to either excision without closure or excision with primary closure. The authors then followed the patients for a minimum of 4 months. They primarily looked at infection and recurrence rates. In the two patients who experienced infection in the closed group, this was treated with simple suture removal and healing by secondary intent without the need for further hospitalization. They used no antibiotics. Patients whose wounds were left open had a lower infection rate (1.8% vs. 3.6%, $p < 0.01$) and no instances of recurrence, while the recurrence rate for those undergoing wound closure was 4.4% ($p < 0.01$). They did not specify the duration of healing for either group. Patients who had delayed healing were those few who developed a wound infection. Despite the statistically significant differences in favor of open excision, the authors concluded that either method is acceptable.

Sondenaa et al.[23] randomized 153 patients to midline excision and primary closure with or without cefoxitin prophylaxis; 78 patients received preoperative antibiotics and 75 patients did not receive antibiotics. The complication rate (44% vs. 43%) and wound healing at 1 month (69% vs. 64%) was no different between the groups. Based on this data the authors did not recommend cefoxitin antibiotic prophylaxis. In a follow-up study published a year later the same group reported their results of a randomized trial of open excision or excision with primary closure for chronic pilonidal sinus.[24] A total of 120 patients were enrolled with half in the excision and primary closure arm and the remainder in the open excision only arm. The patients were followed for a median of 4.2 years. The authors detected no significant difference between the groups, and therefore, concluded that either method was acceptable.

Collectively, these data suggest that excision with primary closure decreases wound healing time; however, this accelerated wound healing time may come with the price of increased wound complications and recurrence of pilonidal disease. Furthermore, the routine use of prophylactic antibiotics is not necessary.

Unroofing and Secondary Healing

Midline excision without primary closure leaves a large wound that is associated with prolonged healing times. If wound closure is not indicated (i.e. with an associated abscess), a smaller wound with much shorter healing times can be achieved with unroofing or laying open the pilonidal sinus. In fact, unroofing and curettage has been advocated for the treatment of acute pilonidal abscess and chronic pilonidal sinus. In a recent study, 297 consecutive patients presenting with chronic pilonidal sinus, acute abscess, or recurrent disease were treated with unroofing and curettage for removal of hair and granulation tissue.[25] The wound was left open to heal by secondary intention. The investigators found that patients returned to work on average of 3.2 days after the procedure. Mean time for wound healing was 5.4 weeks; however, classification of disease to chronic, recurrent, and abscess revealed a longer wound healing time for abscess group (4.9 vs. 5.0 vs. 7.2 weeks; $p < 0.001$, respectively). Six patients (2%) developed recurrence, which were believed to be consequences of poor compliance and follow-up. Postoperative wound care included weekly follow-up with wound debridement and separation of premature skin bridges. Furthermore, the wound area was kept free of hair during wound healing, and the authors stress the importance of hair control to prevent recurrence through the dictum, "No hair, no pilonidal sinus." Others have reported similar good results.[26,27] It is important to keep in mind that open wounds require dressing changes and wound care, but unroofing is associated with half the healing time of wide and deep excision, and marsupialization of the skin edges to the fibrous tract can decrease the wound surface by 50–60%.[21]

Bascom's Chronic Abscess Curettage and Midline Pit Excision (Bascom I)

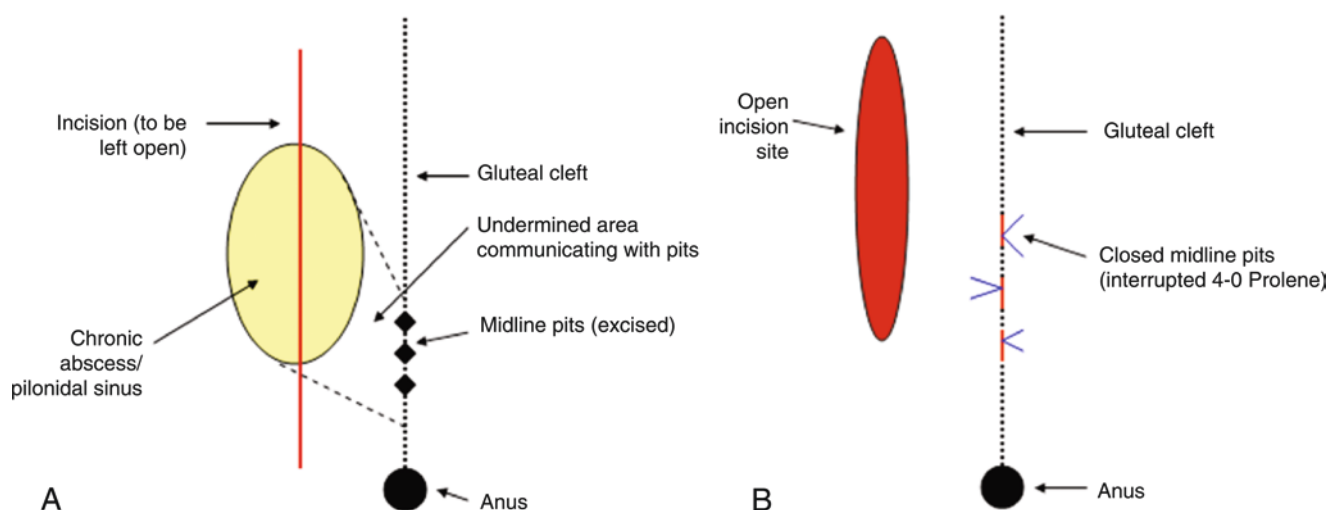
Bascom bases this procedure on the premise that efforts to treat pilonidal disease should be directed at changing the gluteal cleft conditions rather than excising a large amount of normal tissue associated with the diseased area. In patients who present initially with a chronic abscess, this procedure has given excellent results. He does this by making a generous, vertically oriented incision through the site of the abscess cavity more than 1 cm off the midline (Figure 15-3A) and then removing hair and debris through curettage. The fibrous sinus tract or abscess wall is left in place. The connecting


FIGURE 15-3. **A** Bascom procedure. Lateral incision and debridement of cavity. **B** Bascom procedure. Removal of a midline pit with small incisions after lateral debridement, and closure of midline wounds without closure of the lateral incision.

tracts to the midline pits are identified and the overlying skin undermined so that they drain to the site of the incision. The midline pits are then excised utilizing a small diamond-shaped incision to circumferentially remove each of them.[13,16] According to Bascom, the excised pit should be about the size of a grain of rice. The undermined flap of skin, between the incision and drainage site and the excised midline pits, is then tacked down, and the pit excision sites are closed with either subcuticular or vertical mattress, nonabsorbable suture (4-0 or 3-0) (Figure 15-3B). Once this has been accomplished, meticulous shaving of the gluteal cleft should continue at least once a week until the wound has healed. Shaving can be done in the physician's office, or at home by a family member or friend who has been properly instructed.

Senapati et al.[28] published a prospective series of 218 patients treated with Bascom's operation described above. The mean follow-up was 12.1 months (range 1–60), and consisted of phone calls, office visits, and mailed questionnaires. All but one patient healed his or her pit excision sites. The lateral wound in one patient failed to heal and required further excision. All the other wounds healed at an average of 4 weeks (range 1–15 weeks). Eight percent of patients reformed their abscesses when the lateral skin wound healed before the underlying cavity completely healed. This required reopening the lateral wound. Ninety percent of patients healed completely with only 21 patients (10%) ultimately requiring further surgery for recurrent pilonidal disease. Furthermore, patients who failed to heal or recurred were not any worse than when they initially presented. Therefore, the authors recommend the use of this technique. To date, no trials compare Bascom's procedure with another approach to chronic pilonidal sinus and abscess.

Karydakis Procedure (Advancing Flap)

The Karydakis procedure was first performed by Dr. Karydakis in Athens, Greece in 1965. The procedure involves an elliptical incision that is made parallel to the midline at a distance at least 1 cm from the midline. The skin and gluteal fat that contains the pilonidal sinus are then excised down to the sacral fascia (Figure 15-4). Mobilization of the subcutaneous flap is performed on the side closest to the midline to allow advancement to the opposite side. This flap is then sutured down to the sacral fascia, and skin closure should be entirely lateral to the cleft. This procedure achieves two goals: (1) eccentrically excise "vulnerable" tissue in the midline, or laterally displace it, and, (2) laterally displace the surgical wound out of the midline gluteal cleft.

In 1992, Karydakis[17] reported the results of this approach in 7,471 patients over a period of 34 years from 1966 to 1990, and is one of the largest series in the surgical literature. Follow-up was obtained in 95% of cases, and ranged from 2 to 20 years. He reported a recurrence rate of 1% in the first 6,545 cases, finding that new disease occurred from new midline pits. The overall complication rate was 8.5%, mainly from infections and seromas or fluid collections. Antibiotics were not routinely used; however, a drain was always placed at the upper end of the wound for 2–3 days.

Recently, the Karydakis procedure was compared to a midline primary closure in a study conducted by the military hospital in Ardahan, Turkey.[29] This retrospective review reported results on 200 military service members treated for pilonidal disease over a 30-month period. The Karydakis procedure was performed on 78 patients and midline primary closure in 122 patients. The authors reported that the Karydakis procedure group had a significantly lower recurrence rate
FIGURE 15-4. Karydakis advancing flap operation.

TABLE 15-1. Complex pilonidal procedure results

Procedure	% Healing (mean)	% Complications (mean)	% Recurrence (mean)
Rhomboid flap [31,32]	100	13.5	4.9
Karydakis [17]	–	8.5	1
Bascom cleft lift [13]	100	–	0
V-Y plasty [35]	100	8	0
Z-plasty [36,37]	100	–	0
Myocutaneous flap [38]	100	100	0
Skin graft [39]	96.6	–	1.7

(4.6% vs. 18.4%; $p < 0.03$), lower complication rate (8.9% vs. 30.3%; $p < 0.02$), and higher degree of patient satisfaction (70.8% vs. 32.6%; $p < 0.001$).

These studies indicate that this procedure is highly successful with low complication and recurrence rates; however, comparative series report inpatient hospital stay of over 5 days.[29] This may be due to institution and physician preference as one recent study reported on the successful treatment of chronic pilonidal sinus using the Karydakis flap in a day-surgery setting. These data suggest the Karydakis flap is an effective procedure in the treatment of chronic pilonidal sinus, and should be considered in recurrent or complex cases.

Recurrent or Complex Pilonidal Sinus

Controversy exists over how to manage patients with recurrent and complex pilonidal sinus. Many of these patients have failed standard surgical treatments and conservative measures such as midline excision and hair control and elimination techniques. In these complex patients, excision of the pilonidal sinus is combined with a flap closure and modification of the midline natal cleft. These procedures include rhomboid flaps, Z-plasty, the Karydakis procedure (see above), Bascom's cleft lift procedure, V-Y plasty, gluteus maximus myocutaneous flaps, and skin grafting (Table 15-1). Some level-one evidence exists regarding flap-based or asymmetric closures off the midline for pilonidal disease, but most data comes from patient series and retrospective reports. The major disadvantages with flaps are longer operative times, greater blood loss, potential flap loss, and infection. However, these flap-based procedures offer a quicker

time to healing than midline excision, with no increase in infection rate.

Asymmetric wound closure technique is believed to be one advantage in flap procedures used for reconstruction after excision of complex pilonidal disease. This avoids midline closure and obliterates the natal cleft that are both implicated in wound complications following surgery. In a retrospective review of the literature, Petersen et al.[30] reported their findings comparing asymmetric closure techniques to midline excision for pilonidal disease. Asymmetric closure was associated with a significantly decreased incidence of recurrence, and the midline pits recurred less often than the midline excision groups.

Rhomboid Flap

The rhomboid, or Limberg flap, is a cutaneous rotational flap used to fill soft tissue defects. It is ideally suited for pilonidal disease as it brings adjacent healthy tissue to fill the defect after wide excision of sinus tracts and removes the natal cleft from midline (Figure 15-5A–D). In 2009, Darwish and Hassanin[31] reported their experience with superior-based Limberg flap. Over a 3-year period, they treated 25 male patients with pilonidal sinus using this flap technique. Operative time averaged 40 (range 30–45) min, and hospital stay averaged 2 (range 1–6) days. Primary healing was observed in 22 patients, with two patients developing sterile seromas and one patient superficial wound infection. Complete healing of all patients occurred without recurrence during the follow-up period. A larger prospective series used the rhomboid flap on 102 patients regardless of the severity of their disease.[32] Complete healing of the wounds was reportedly 100%; however, time to complete healing was unspecified. They reported a 6% complication rate consisting of three seromas, two partial wound dehiscence, and one wound infection. The recurrence rate was 4.9%, and these patients were successfully treated with a repeat rhomboid flap. Average time to return to normal activity was 7 days. Collectively, these data suggest that the use of the rhomboid flap for reconstruction after excision of chronic pilonidal sinus is reliable, can be quickly performed in the operating room, and is associated with low complication and recurrence rates.

Given these findings, one may ask, "How does the rhomboid flap compare to surgical excision with primary closure?"
FIGURE 15-5. Rhomboid flap technique for recurrent pilonidal disease. **A** Initial excision of the sinus cavity. Counter incisions are created as shown. **B** Flaps are raised and maneuvered as shown to close defect. **C** Final surgical result. **D** Result at 1 month postoperatively.

Abu Galala et al.[33] randomized 46 patients with chronic pilonidal sinuses either to the rhomboid flap or to midline excision with primary closure. Reported follow-up included postoperative wound healing and recurrence of disease. Wound healing in the rhomboid flap patients was 100% and was significantly higher than the midline excision with primary closure group (77%; $p < 0.02$). Furthermore, recurrence rate after 18 months follow-up was higher in the midline excision with primary closure group (9% vs. 0%). These data indicate that rhomboid flap closure after complex pilonidal sinus excision may improve wound healing and decrease recurrence rates.

Flap closure results in the creation of large spaces under the flap tissue. Drains have been used to prevent seroma formation and deep wound space infections in an attempt to improve outcomes. However, recent evidence indicates that drains may not improve outcomes. A recent randomized, prospective trial compared the use of drains after rhomboid flap surgery for chronic pilonidal disease.[34] The authors randomized a total of 40 patients, where drains were used in one-half. The study found no difference in wound healing or recurrence ($p > 0.05$), but the drain group did experience a significantly longer hospital stay ($p < 0.001$).

Despite the overall good results with use of the rhomboid flap for recalcitrant pilonidal disease, this technique necessitates excision of a large amount of normal tissue and subsequently creates a large scar at the flap site (Figure 15-5). Furthermore, chronic abscesses may be located far lateral and cephalad to the midline pits making the use of this technique more morbid due to the size of the flap required to cover the excised area. However, if the disease is localized close to the midline, the abscess cavity, sinus tracts and midline pits are easily excised. Additionally, this technique should be considered for flap coverage of chronic wounds in the gluteal cleft that have failed to heal over a prolonged period of time.

Bascom Cleft Lift (Bascom II)

This procedure may be the most technically challenging of all the techniques dealing with multiple recurrent and severe pilonidal disease. It also may prove to be the most revolutionary

technique to come along since the Karydakis procedure. The key difference between the cleft lift procedure and other flap-based procedures is that normal subcutaneous tissue is not excised in the cleft lift procedure. As described above, the Karydakis procedure does excise normal fat in order to create the flap. The only tissue excised during the cleft lift is a portion of skin. The goal of the cleft lift procedure is to undermine and completely obliterate the gluteal cleft in the diseased area.[13] This procedure detaches the skin of the gluteal cleft from the underlying subcutaneous tissue as a flap. A portion of this flap containing the diseased skin (containing pits) is then excised from the side of the buttocks to which the flap will be sutured (Figure 15-6A). When the flap is pulled across the midline, the gluteal subcutaneous tissue is approximated underneath the flap, thus obliterating the gluteal cleft. Any open chronic wounds or sinus cavities are simply curetted out, but not excised. The raised skin flaps cover these prior wound sites in addition to coapting the normal gluteal fat. The final suture line lies parallel to, but well away from, the midline, and is free from tension (Figure 15-6B). Bascom and Bascom[13] studied 28 consecutive patients with recurrent, festering wounds who received this treatment; 22 patients healed their wounds immediately and had their sutures removed at 1 week. Six patients took longer to heal due to small wound separations. Three patients required operative revision to achieve healing. Finally, one obese patient took 13 months to heal. The median follow-up was 20 months (range 1 month to 15 years) and all patients remained healed. This procedure has enjoyed spectacular results in Dr. Bascom's hands, but these results await duplication.
FIGURE 15-6. **A** Cleft lift technique as described by Bascom for nonhealing midline wounds. **B** Final result after flaps are raised and underlying gluteal fat is approximated.

V-Y Flap

Advancement flaps are designed to slide along the flap's long axis, and moves healthy tissue for reconstruction into the excised area. The size of flap, and therefore, the volume of tissue used, is primarily determined by the arterial input (and venous drainage) not length-to-breadth ratios. The V-Y flap maintains blood supply from the fascia, and division of the blood supply and venous drainage should be avoided.

The use of these advancement flaps have been applied to the surgical treatment of pilonidal disease. Schoeller et al.[35] retrospectively investigated their use of the V-Y advancement flap in 24 patients with complex pilonidal sinus. The mean follow-up was 4.5 years. The investigators reported two cases of wound dehiscence, but achieved healing in all cases. There were no recurrences. Overall, they found the method to be satisfactory, but demanding, and recommended a simpler approach. However, it may have applicability in some situations where other flaps have failed, such as the rhomboid flap.

Z-Plasty

Combining excision with Z-plasty for reconstruction is a well-suited treatment option for complex pilonidal sinus. The diseased tissue is excised and the natal cleft is obliterated with a Z-plasty for reconstruction. The limbs of tissue are fashioned 30–45° angles from the wound axis. Full thickness subcutaneous skin flaps are raised and transposed before suturing the skin edges. Early application of this technique showed promise with one study reporting no recurrences in 110 patients with pilonidal sinus disease treated with excision and Z-plasty.[36]

Hodgson and Greenstein[37] reported his results of a randomized, prospective study on complex pilonidal sinus treated with Z-plasty vs. midline excision. The Z-plasty group required no further surgery, but 40% of the open excision group did go on to have repeat operations. In addition to advocating Z-plasty for complex pilonidal sinus excision, this study provides evidence that open excision, while eliminating risk of wound breakdown, does not decrease risk of short-term wound complications.

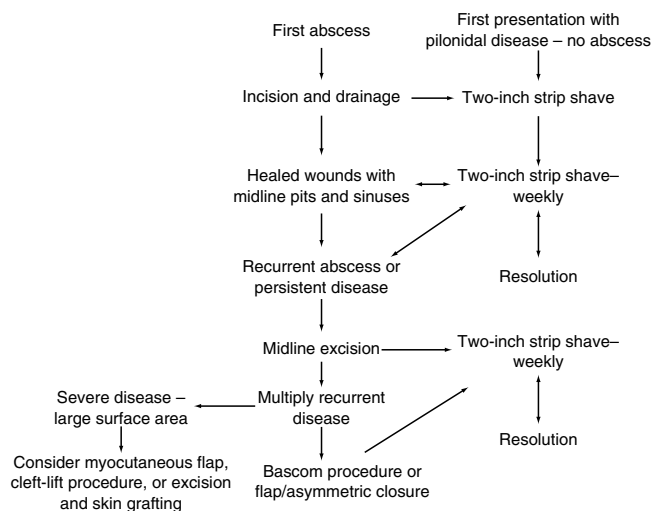
Myocutaneous Flaps

Myocutaneous flaps are rarely used due to the large nature of the defect and reconstruction created. The procedure may be significantly debilitating as most myocutaneous rotational flaps are harvested from the gluteal area; however, they can be successful for the treatment of pilonidal disease. Rosen and Davidson[38] reported their series of five patients with severe pilonidal disease treated with gluteus myocutaneous flaps. They were all young males and had received an average of six previous procedures. All patients healed with an average follow-up of 40 months and 13 hospital days. Most surgeons reserve this technique for the most severe cases, usually after failure of multiple simpler techniques.

Skin Grafting

Skin grafting is an infrequent procedure used for the treatment of pilonidal disease. Guyuron et al.[39] published their retrospective study of 58 patients with pilonidal disease treated with excision and split-thickness skin grafting. Over 70% of these patients initially presented with recurrent disease. The authors reported a 1.7% recurrence rate and a 3.4% graft failure rate. The authors recommended use of this method for recurrent or extensive pilonidal disease; however, there have been no further publications on skin grafting for the treatment of pilonidal disease. This can be explained conceptually, as it does not achieve the modern goals of surgical treatment for pilonidal disease. Skin grafting leaves the natal cleft left unchanged, requires prolonged hospital stay for wound care of donor site and graft site, and the graft site, generally the sacrum and/or gluteal area is in zones of high friction. Furthermore, graft success is likely to require significant immobility that prolongs return to normal activity. Taking these factors into account, we cannot recommend skin grafting for the treatment of pilonidal disease.

Summary

Treatment of pilonidal disease is dependent on the disease presentation. Pilonidal abscess, chronic sinus, complex sinus tracts, and chronic recurrent pilonidal abscess and sinus encompass the spectrum of pilonidal disease. Each has specific considerations in the treatment and management of this disease process; however, the cornerstone of all surgical and nonsurgical therapeutic interventions for pilonidal disease should always include wide, meticulous shaving and hygiene. The algorithm in Figure 15-7 outlines a common approach to pilonidal disease based on the evidence presented in this chapter. In patients presenting initially with simple midline pits, or sinus tracts without acute abscess,


shaving can be offered as the initial treatment. Meticulous and ritualistic shaving is critical as one single hair protruding from a midline pit will keep it open and result in recurrent or persistent disease. During both the primary and postoperative healing phase, shaving should be continued on a weekly basis until healing is complete.

Patients with acute pilonidal abscess require incision and drainage, ideally making the incision lateral to the midline whenever possible. At the same time, one should do a 2-in. strip shave circumferentially around the affected area. Dressing changes, Sitz baths, and shaving are continued until the wound has healed. The majority of acute pilonidal abscess treated in this manner do not recur.

Many patients will present initially with chronic pilonidal sinus. Location of the sinus relative to the midline helps guide the choice of management. In the case where all the disease, sinuses, and pits are located near and in the midline, then a conservative midline excision or unroofing with curettage is a reasonable first line treatment; however, if multiple draining sinuses exist, and they are located far from the midline, then simple midline excision becomes impractical due to the larger wound created. In this case, we recommend the Bascom I procedure or excision with rhomboid flap reconstruction. These procedures are also useful for patients who have failed midline excisions. Patients presenting with multiple recurrent pilonidal disease, or chronic persistent abscess despite conservative management, are more challenging to treat. Continued shaving in this situation is unlikely to succeed, since the abscess cavity and the epithelialized tracts connecting it to the midline pits will contain a great deal of burrowed hair. In this case, we recommend the Bascom I procedure with chronic abscess curettage and midline pit excision. Alternatively, a cutaneous flap procedure with asymmetric closure is also effective.

In the event, a prior operation results in a chronic nonhealing wound, a rotational flap is ideal. These flaps should move the wound closure and natal cleft off the midline. In these circumstances, we suggest the rhomboid flap for this purpose. For extensive recurrence in the midline with abscesses and multiple nonhealing wounds, the Bascom II cleft lift procedure or Z-plasty may be effective. Myocutaneous flaps are reserved for patients with severe complex pilonidal disease or persistent wounds encompassing large surface areas. In these situations, consultation with a plastic surgeon may be advised.

Hidradenitis Suppurativa

Background

Hidradenitis suppurativa is an uncommon cutaneous condition, which primarily affects young individuals and exhibits chronicity with frequent flare-ups followed by quiescent periods. The severity of this disease is variable. It may present

FIGURE 15-7. Pilonidal disease algorithm.

initially as an abscess, but is typically chronic or multiply recurrent in the affected area, and ultimately can lead to severe scarring, contracture, possible malignancy, and disability for the patient. Hidradenitis suppurativa commonly occurs in the perineum, axilla, and groin, but can also be seen in the inguinal and mammary regions as well.[40] These areas contain high concentration of apocrine glands, which may play a role in the disease.

Incidence and Etiology

The exact incidence of hidradenitis suppurativa is not known; however, 1 in every 300 individuals may be affected in some way.[41] African Americans appear to be affected more often than Caucasians, and perianal disease is approximately twice as common in males.[14,40,41] Almost all patients present after puberty in the second and third decades of life, thereby implicating hormones and the development of secondary sexual characteristics as potential causative factors.[41] Harrison et al.[43] demonstrated androgen excess and a decrease in progesterone in patients with hidradenitis. Obesity has been suggested as a predisposing factor through increased shear forces in the affected areas; however, it is more likely an aggravating factor rather than a causative factor.[14,41] Additional predisposing factors include tobacco use, acne, stress, poor skin hygiene, excessive heat, hyperhidrosis, and chemical depilatories. In a series from the Ochsner clinic, 70% of affected patients were smokers, but no causal relationship could be definitively shown.[41] Proposed mechanism of tobacco influence suggests that smoking may alter granulocytes, modify sweat gland activity, and give off toxic metabolites in sweat. Perianal hidradenitis affects males twice as often as females, but hidradenitis in all locations may be more common in females and African–American persons.[41,42] Fortunately, for sufferers of perianal hidradenitis, it appears to recur less often after surgical treatment (<0.5%) than does inguinal–perineal disease (37–74%).[40,42]

Bacteriology

Wound cultures from hidradenitis patients have grown *Staphylococcus epidermidis*, *Escherichia coli*, *Klebsiella*, *Proteus*, *α-Streptococcus*, anaerobic bacteria, and diphtheroids; however, one study reported that wound cultures of early lesions were negative.[44] *S. epidermidis* and *Staphylococcus aureus* are the most frequently isolated organisms from hidradenitis suppurativa lesions.[14,45] *Chlamydia trachomatis*, often associated with lymphogranuloma venereum, and *Bilophila wadsworthia* infection have also been implicated in hidradenitis, but the clinical significance is not known.[41,42]

Pathophysiology

It is believed that hidradenitis suppurativa originates from the occlusion of hair follicles.[46,47] Dilation and rupture of hair follicles into the dermis leads to dermal infiltration by inflammatory cells, giant cells, and formation of sinus tracts, and fibrosis.[48] Involvement is typically in skin that contains apocrine sweat glands, but the inflammation and destruction of these glands seems to be incidental rather than a causative factor.[24] Attanoos et al.[45] examined 118 pathologic hidradenitis specimens and found some degree of keratin plugging in all cases along with an active deep folliculitis. They concluded that plugging of the hair follicle itself led to apocrine inflammation, making the actual apocrine gland destruction of hidradenitis suppurativa a secondary process.[45] These glands secrete a milky, odorless fluid that only becomes malodorous after it interacts with bacteria on the skin. The apocrine glands secrete into the hair follicle as opposed to directly onto the skin like eccrine sweat glands. The function of apocrine secretion is unknown. Nevertheless, obstruction leads to secondary bacterial infection and rupture of the gland into the dermis and subcutaneous tissue, thus causing cellulitis, abscess, and draining sinuses. This process then leads to the characteristic "pit like" scars from chronic fibrosis of the destroyed glandular unit. Over time, this disease can become not only disfiguring, but also debilitating. Microscopically, the pathognomonic serpentine epithelialized sinus tracks with giant cells and granulomas are typically seen.[40,41,49,50]

Clinical Presentation and Diagnosis

Patients with hidradenitis suppurativa typically presents with pain, erythema, and swelling in the affected area. There is frequently a malodorous discharge from the affected skin. Physical examination may reveal a spectrum of indurated subcutaneous nodules, subcutaneous abscess, and/or draining skin sinuses. Sinuses may be simple or complex coalescing to form a network of subcutaneous cavities and tracts with extensive fibrosis.

The diagnosis is based on clinical findings, and diagnostic biopsy is seldom required; however, if the differential diagnosis includes perianal Crohn's disease or cancer, biopsies should be obtained to establish a definitive diagnosis. Differentiating hidradenitis suppurativa from other inflammatory conditions of the perianal region can be difficult, and some of them may coexist. Cutaneous infections such as furuncles, carbuncles, lymphogranuloma venereum, erysipelas, epidermoid or dermoid cysts, and tuberculosis may present in a similar fashion. It is important to distinguish hidradenitis from other fistulizing or sinus-forming processes of the perineum such as Crohn's disease or cryptoglandular perianal abscess. Crohn's disease typically affects the anus and rectum with fistulas arising from the dentate line or higher in the rectum. Fistula-in-ano or perianal abscesses that are cryptoglandular origin will arise from the dentate line and involve the sphincter complex. In contrast, hidradenitis does not affect the rectum or involve the dentate line, because apocrine glands only exist in the lower two-thirds of the anal canal and do not penetrate into the sphincter complex. Thus, patients will not have sinus or fistula tracks to or from the rectum.[40,41] If fistulas are present, then the surgeon should perform anoscopy to rule

out the possibility of fistula-in-ano from a cryptoglandular source or consider Crohn's disease as the etiology. Fistulas from hidradenitis should only connect areas of involved skin, and not penetrate the anal sphincters or involve the dentate line. Several case reports have been published describing the association of Crohn's disease and hidradenitis, but no definitive link between the two conditions has ever been proven.[51–55] Nonspecific granulomas (required for a pathologic diagnosis of Crohn's disease) are seen in pathologic specimens in both diseases and may be confused with one another.

In patients with longstanding history of hidradenitis and chronic nonhealing wounds, it is important to rule out malignancy (Figure 15-8). There have been several reports of squamous cell carcinoma arising in chronic hidradenitis wounds.[56–60] A retrospective review of a Swedish database of hospital discharge diagnoses from 1965 to 1997 revealed a 50% increased risk of developing *any* cancer in patients with hidradenitis suppurativa over the general population, but significant increases were specifically found in nonmelanoma skin cancers, buccal cancer, and primary liver cancer.[61] Most patients with cancers had untreated disease for longer than 20 years. In fact, a recent review reports that the mean duration of hidradenitis suppurativa before diagnosis of malignancy is 25 years.[60] One should at least keep a high index of suspicion for this entity in patients with long standing disease and extensive scarring in the affected areas.

Treatment

The clinical presentation of hidradenitis suppurativa encompasses a wide spectrum of severity. Furthermore, the persistent and recurring nature of the disease requires an individualized treatment plan. This may include nonsurgical and surgical techniques for acute and chronic disease. It is imperative to educate the patient about the chronic relapsing nature of the disease, and to reassure the patient that the disease is not contagious or due to poor hygiene.[62]
FIGURE 15-8. A large squamous cell cancer (SCC) arising in an area of chronic hidradenitis suppurativa.

Nonsurgical Treatment

Antibiotic therapy is the cornerstone for nonsurgical treatment of hidradenitis. Patients with cellulitis and no definable abscess may be successfully treated with antibiotics for 1–2 weeks. Both topical (clindamycin) and systemic (tetracycline) antibiotics have been advocated, and antimicrobial spectrum must cover skin flora, particularly *Staphylococcus* species. No evidence exists supporting the use of prophylactic antibiotics beyond the initial treatment course, and it is unclear if the natural history or disease process is altered by such therapy.[60]

Other medications have been used for the treatment of hidradenitis suppurativa, and include retinoids, antiandrogen therapy, immunomodulators and anti-inflammatory (etanercept, infliximab, adalimumab) drugs.[60] Most were evaluated through retrospective chart reviews and meaningful conclusions are difficult to draw; however, the potential side effects of these medications are significant and should be considered prior to initiation. Radiotherapy has been used in the past with modest success.[60] These positive results are likely a direct result of hair follicle destruction, but wound healing problems are significant. Others have reported the use of photodynamic therapy, cryosurgery, carbon dioxide laser therapy, and radiofrequency treatments with variable success.

Surgical Treatment

The surgical management of hidradenitis suppurativa can be divided into two categories: (1) surgery to control local infection; and (2) surgery for curative intent. Incision and drainage of abscess and sinus tracts are simple methods that control local infection; however, diseased skin remains and recurrence is highly likely. This is illustrated by a recent report that compared recurrence rates of hidradenitis suppurativa after incision and drainage/limited excision vs. wide excision of disease.[63] After a 3-month follow-up, the study found 100% recurrence after limited excision and 27% recurrence after wide excision of disease. These data suggest that the surgeon must excise the entire involved area, otherwise, the patient will be at risk for recurrence. For this reason, once local inflammation has been controlled with incision and drainage, the patient is offered further surgery for curative intent or initiated on nonsurgical treatment modalities for disease control.

Surgery for curative intent requires complete excision of diseased skin. Excision with primary closure may be performed in selected small wounds if it can be closed without tension. This treatment modality results in decreased morbidity, decreased length of hospitalization and decreased postoperative disability.[64,65] Others have advocated wide excision and healing by secondary intention. All of the grossly involved apocrine bearing skin in the perianal area should be excised full-thickness into the uninvolved gluteal fat. Excision to involve a wide margin has proven to be beneficial. In addition, this method is simple, does not require fecal diversion, and depending on size excised, may be performed as

an outpatient procedure. Patients with large areas of involvement may require staged excision. The extent of excision should remain outside the anal verge as long as there is no obvious involvement or history of involvement in the anal canal. If excision near the anal canal is necessary, it should be limited, or staged, in order to prevent anal stricture. Prolonged wound healing of 1 month or longer is a significant disadvantage of this method. These patients require daily wound care and consideration should be given to physical therapy to prevent contracture formation.

Recently, reports on the use of negative pressure dressings have appeared as a way to promote healing and shorten the time to wound closure.[66] The purported benefits of these dressings include increased wound oxygen tension, decreased bacterial counts, better control of fluid produced by the wound, increased granulation tissue formation, and decreased shear forces. Negative pressure dressings have been used successfully on open wounds and on skin grafts[66,67]; however, consideration must be given to cost and technical difficulties inherent to dressings placed in the perianal area. These dressings require an air-tight seal at all times, which can be difficult to achieve near the anal verge and perineum.

Patients with chronic disease, extensive scarring, and sinus tracts rarely respond to conservative measures (Figure 15-9A). The gold standard of care remains wide excision of all hidradenitis involved skin bearing apocrine glands (Figure 15-9B and C). Reconstruction then can follow a number of paths – cutaneous flap closure, myocutaneous flap closure, immediate or delayed split-thickness skin grafting (Figure 15-9D), or excision, and simple healing by secondary intent. Cutaneous or myocutaneous flaps are typically taken from the posterior thigh, gluteus muscle, or lumbosacral region. They are analogous to those used for pilonidal disease. Patients who might benefit from diversion
FIGURE 15-9. A male patient with significant perianal and inguinal hidradenitis suppurativa of a chronic nature. **A** Preoperative photo of extent of disease. **B** Planned surgical resection preserving skin at the anal verge. **C** Wide excision of perianal and inguinal hidradenitis suppurativa. **D** Split thickness skin graft (STSG) used for immediate reconstruction.

are those who cannot take care of their wounds long term and those who suffer from both hidradenitis and Crohn's disease, although this is rarely needed.[41,68]

Summary

Hidradenitis suppurativa is a skin disease that typically affects young adults and is characterized by intermittent flares and periods of quiescence. The algorithm in Figure 15-10 outlines one suggested approach to treating patients with perianal hidradenitis suppurativa. Patients who present with acute disease and abscess should have incision and drainage, ideally in an office setting.[69] Antibiotics may be used for excessive cellulitis and to decrease acute inflammation. This process can be repeated, if necessary, and is usually performed for recurrent disease. It is important to rule out other causes of fistulous disease such as Crohn's disease or perirectal abscess from a cryptogladular source. For patients with chronic or recurring disease, definitive excision should be considered. This may include excision with primary closure for small areas of disease, healing by secondary intent for larger areas of disease, or reconstruction with split-thickness skin graft or flap closure for wide excision. Flap procedures are typically reserved for patients with extensive scarring and tissue damage that involves large areas of perianal skin around the anus extending out to the buttocks. By the time a patient reaches the point where they desire surgery, they have usually suffered for many years with recurrent abscesses in the affected area.

Introduction

Perianal skin is subject to virtually all of the diseases that affect skin and mucosa. The differential diagnosis of disease in perianal skin is broad (Table 16-1) and includes a variety of diagnoses. These diseases almost never present solely within the perianal area; however, there are common diseases such as psoriasis that may present in the perianal area without obvious ties to other areas of the body unless a careful search is made. Certain diseases have specific causes and well-recognized treatment protocols (e.g., psoriasis, candida, and Bowen's disease), other diseases have less well-defined causes and all too often where therapy is established it is poorly defined. Recognition of important treatable causes requires a disciplined, organized approach to diagnosis with careful and complete history, physical exam, and the frequent use of biopsy. This chapter's objective is to lay out a strategy to facilitate accurate diagnosis and successful treatment of perianal and anal skin conditions. Implicit in this strategy is (1) the ability to properly examine the anus with appropriate instruments and bright light and (2) to understand diseases peculiar to the anal area. Hence, the importance of the colorectal surgeon, who possesses the unique skills, experience and training needed to accomplish this task. The importance of complete, accurate evaluation is demonstrated by a St. Louis University series in which 209 patients with the presenting symptom of pruritus ani revealed 75% of those patients had coexisting anal or colorectal pathology. While the majority of patients had hemorrhoids or fissure diagnoses also included 11% with rectal cancer, 6% anal canal cancer, and 2% with colon cancer.[2]

Definitions

Accurate description of the morphology of skin lesions can aid in the diagnosis and follow-up of patients with pruritic complaints. Macules are flat spots. Papules are elevated circumscribed solid lesions. Vesicles are separations of the epidermis from the dermis filled with serum. Bullae are larger vesicles or blisters greater than or equal to 10 mm. Pustules contain pus. Ulcers are surface lesions with loss of continuity of the skin and may result from rupture of vesicular lesions, infection, or trauma. Intertrigo is inflammation seen between two opposing skin surfaces, often the result of mixed bacterial, fungal infection associated with moisture, obesity, and poor hygiene.

Pruritus ani is a term of Latin derivation, which means itchy anus. Pruritus ani is a symptom, a Medline MeSH searchable diagnosis, and is also used to designate a specific condition of multiple etiologies recognized since antiquity.[1,3] The term pruritus when used alone simply means itchy: there is no distinction between pruritus and itch (an unpleasant sensation that provokes the desire to scratch). To avoid confusion in this chapter, the syndrome will always be referred to as pruritus ani. Pruritus ani is classified as either primary or secondary. The primary form is the classic syndrome of idiopathic pruritus ani, whereas the secondary form implies an identifiable cause or a specific diagnosis.

Physiologic Considerations

There are different types of itch which may respond to different forms or modalities of therapy: (1) pruritoceptive (C-fiber mediated), (2) neuropathic (e.g., Post-zoster), and (3) central or neurogenic. Itch is a surface phenomenon mediated by unmyelinated C-fibers in the epidermis and subepidermis, these fibers may have a lower threshold for stimulation when reporting itch than when reporting pain. Itch receptors may be located more superficially than those dedicated to pain. Because receptors are superficial, innocuous, nondamaging stimuli such as wearing long fibered fabric (i.e., wool) or other minor mechanical stimuli may induce itching. In addition to histamine, kallikrein, bradykinin, papain, and trypsin experimentally produce itching, but these substances do not respond to blockade with classic histamine antagonists such as diphenhydramine; hence, topical antihistamines are not

TABLE 16-1. Differential diagnosis of anal dermatoses

Inflammatory diseases	Nonsexual infectious disease
Pruritus ani	Pilonidal disease
Psoriasis	Hidradenitis suppurativa
Lichen planus	Beta hemolytic streptococcus
Lichen sclerosus et atrophicus	Fistula-in-ano
Atrophoderma	Crohn's disease
Contact (allergic) dermatitis	Tuberculosis
Contact (irritant) dermatitis	Actinomycosis
Seborrheic dermatitis	Herpes zoster
Atopic dermatitis	Vaccinia
Radiation dermatitis	Fournier's gangrene
Behçet's syndrome	Tinea cruris
Lupus erythematosus	Candidiasis
Dermatomyositis	"deep" mycoses
Scleroderma	Amebiasis cutis
Erythema multiforme	Trichomoniasis
Darier's disease	Schistosomiasis cutis
Familial chronic pemphigus	Bilhartziasis
(Hailey-Hailey)	Oxyurasis (pinworm)
Pemphigus vulgaris	Creeping eruption (larva migrans)
Cicatricial pemphigoid	Larva currens
Bullous pemphigoid	Cimicosis (bed bugs)
Dermatitis herpetiformis	Pediculosis (lice)
	Scabies
Sexually transmitted disease	Premalignant and malignant disease
Gonorrhea	Acanthosis nigricans
Syphilis	Leukoplakia
Chancroid	Mycosis fungoides
Granuloma inguinale	Leukemia cutis
Lymphogranuloma venereum	Basal cell carcinoma
Molluscum contagiosum	Squamous cell carcinoma
Herpes simplex	Melanoma
Condyloma acuminata	Bowen's disease (AIN)
	Extramammary Paget's disease

(Modified from Corman ML, Colon and rectal surgery. 2nd ed. Philadelphia, PA: Lippincott, 1989. p. 287.[1])

always effective against itching.[4] Recent studies suggest that gastrin releasing peptide receptors may, at least in part, mediate itch. This finding could explain some of the impact of H2 blockers (nonclassic antihistamines) on itch. The phenomenon of hyperesthesia with chronic pain may have a parallel with itching; just as minimal stimulation of the skin may induce itching, scratching with subsequent injury may produce an expanding area of itchy skin. Scratching produces inadequate feedback to inhibit itching, more scratching occurs with cutaneous injury, which provides an additional stimulus to scratch in a self-defeating loop. Substituting heat, cold, painful, or stinging stimulus for the itch by applying alcohol or pepper extract (capsaicin) may provoke an inhibitory feedback not supplied by scratching alone and lead to inhibition of the urge to scratch. Cowhage induced itching does not produce an inflammatory reaction and is mediated by different neurons than histamine-induced itching and may be the type of itching blocked by use of capsaicin.[5,6] Antidepressant medications (such as paroxetine) and anticonvulsants (gabapentin) have antipruritic effects at the central nervous system

level though mechanisms of action may not be clear.[7] Itching associated with healing probably results from the combination of histamine release, release of other kinins and prostaglandins involved in the inflammatory phase of healing, and regeneration of nerves which may be thinly myelinated in immature scars. Antihistamines, topical anti-inflammatory agents (steroids), topical anesthetics, moisturization, petrolatum, and aloe preparations (prostaglandin inhibitors) all have beneficial effects on the itching of healing wounds.[4]

Etiology of Pruritus

Because pruritus is a symptom that may have protean causes, it is useful to consider diagnoses which have been associated with pruritus ani. Table 16-2 is a list of diagnoses and conditions modified from Stamos and Hicks.[8] Specific causes are considered below.

Localized Itch Syndromes

Notalgia paresthetica is a defined syndrome with itching or pain of the upper mid-back to either side of the scapular region. This has been attributed to spinal nerve damage or entrapment, although an inherited form has been described. Skin biopsies have shown increases in sensory innervation in the area of notalgia paresthetica; other changes are seen in the biopsy which could be attributed to repeated rubbing and scratching. Treatment by application of pepper cream (capsaicin 0.025%) has been effective. Such treatment may exacerbate the symptoms during the first week of application, but thereafter both the symptoms and the side effects of the treatment subside. Topical application of eutectic mixture of local anesthetic (EMLA) (2.5% lignocaine + 2.5% prilocaine), a topical anesthetic cream, has also been effective.[4] Dermatographism has been reported as a cause of anogenital pruritus.[9,10] It is not unreasonable to propose that one etiology of the idiopathic forms of pruritus ani may be related to dermatographism or notalgia paresthetica, and that the skin changes are the sole result of skin trauma. The effectiveness of the anal tattooing procedures, discussed later, may lend some insight into the etiologies of idiopathic pruritus ani.

Fecal Contamination

Systematic, rigorous studies of anal pruritus are rare, but good evidence supports fecal contamination as one cause of symptoms. Caplan[11] performed a study in 27 Caucasian men on whom fresh autologous feces was applied as a patch test both perianally and on the inner arm, and perianal skin was also cultured for fungi. In ten control subjects fecal samples were collected and while the skin was spatulated, feces were not applied. The patch tested subjects ($n = 27$) had several pH-adjusted samples applied to the skin in addition to the

TABLE 16-2. Proposed etiologies of idiopathic pruritus ani

Anatomic factors	Obesity, deep clefts, hirsutism, tight clothing
Anorectal disease	Fissure, fistula, tags, prolapsing papilla, hemorrhoids, mucosal prolapse, sphincter insufficiency, deforming scars
Antibiotics	
Contact dermatitis	Chemicals in topical preparations, toilet paper, wet wipes, alcohol, witch hazel, "caine" anesthetics, fecal soiling
Dermatoses	Psoriasis, seborrheic dermatitis, atopic dermatitis, lichen planus, lichen simplex, lichen sclerosis, dermographism
Diet	Coffee (caffeinated and decaffeinated), chocolate, spicy foods, citrus fruits, tomatoes, beer, dairy products, vitamin A and D deficiencies, fat substitutes, consumption of large volumes of liquids
Diarrhea	Infectious diarrhea, irritable bowel syndrome, Crohn's Disease, ulcerative colitis
Drugs	Quinidine, colchicine, IV steroids
Gynecologic conditions	Pruritus vulvae, vaginal discharge of infection
Idiopathic	
Infection	Viruses: herpes simplex, cytomegalovirus, papillomavirus; Bacteria: *Staphylococcus aureus*, beta hemolytic strep, mixed infections; Fungi: dermatophytes, Candida species; Parasites: pin worms, scabies, pediculosis; Spirochetes: syphilis
Neoplasms	Bowen's disease (AIN), extramammary Paget's disease, squamous cell carcinoma variants, secreting villous tumors
Personal hygiene	Poor cleansing habits, over meticulous cleansing producing mechanical trauma, use of soaps
Psychogenic/neurogenic	Anxiety, neurosis, psychosis, neurodermatitis, neuropathy, "itch syndromes"
Radiation	Radiation dermatitis, sphincter compromise or leakage due to radiation proctitis
Systemic disease	Jaundice, diabetes mellitus, chronic renal failure, iron deficiency, thyroid disorders, lymphoma, polycythemia vera

(Modified from Stamos MJ, Hicks TC, Pruritus ani: diagnosis and treatment. In: Perspectives in Colon and Rectal Surgery, 1998;11(1):1–20. Thieme Medical Publishers.[8])

unadulterated samples; 12 of the 27 had a history of pruritus ani prior to being enrolled in this study. pH of the perianal skin varied from 5.0 to 7.0 and was not different between the two groups. Five of twelve pruritus subjects (42%) grew yeast (non *Candida albicans*) but no dermatophytes, while 4 of 15 nonpruritus subjects (27%) grew *C. albicans* (3) or *Geotrichum*. Twelve of 27 (44%) with feces applied to the skin developed symptoms from the feces. Four of 12 (33%) of the pruritus group developed symptoms, 8 of 15 (53%) of the nonpruritus group developed symptoms, while none of the control group developed symptoms. Symptoms occurred within 1–6 h in all but one subject and were relieved by washing the skin. Only one of the 27 subjects reacted to feces on the arms patch test, suggesting that the skin in different locations reacts differently. The prompt appearance of symptoms and relief with cleansing was felt to indicate an irritant effect rather than an allergic effect.

Smith et al.,[12] in a rigorous study of 75 patients with pruritus, found that half of their patients had poorly formed stools and 41% of their patients complained of soiling from daily to several times a week. Seepage of liquid and mucous was felt to be an important factor in the etiology of the symptoms. Coffee consumption lowered anal resting pressure in 8 of 11 patients.

Allan et al.[13] showed that leakage during a saline infusion test occurred sooner in patients with pruritus ani than in nonpruritic controls (median leak point 600 ml vs. 1,300 ml in controls). This is consistent with findings by Farouk et al.[14] and Eyers and Thompson[15] who both found that the anal inhibitory reflex was more pronounced in patients with pruritus ani. Rectal distension makes these patients more prone to leak and

soil, because the fall in anal pressure from baseline is greater in patients with pruritus ani.

Viral Infection

Condylomata accuminata is a common cause of itching, but the diagnosis is generally easy to recognize and should not be confused with idiopathic pruritus ani. Condylomata, human papilloma virus infection and anal intraepithelial neoplasia (AIN) will be discussed extensively elsewhere. Herpes syndromes are usually accompanied by pain or burning rather than itching and the clinical course is accompanied by a characteristic eruption consisting of red macules, which progress to vesicles that rupture, ulcerate, and may become secondarily infected. Culture or biopsy shows specific diagnostic findings. Likewise, molluscum contagiosum produces characteristic lesions, palpable papules, 2–5 mm diameter, with central umbilication, flesh colored to slightly pink and usually clustered. HIV-associated lesions are rarely associated with chronic itching except for secondary fungal infections.

Fungal Infection

Smith et al.[12] found no instances of fungal infection in their investigation of pruritus ani where each of 75 patients had scrapings and fungus cultures. In contrast, Dodi et al.[16] found *C. albicans* had no relationship to pruritus (culture positive in 23% of control subjects, 26% of those with pruritus, and 28% of those without pruritus), but ten patients who cultured dermatophytes all had itching. None of these patients had exposure to steroids or antibiotics. Their conclusion was

that *C. albicans* was saprophytic in the absence of steroids, but that dermatophytes were always pathogenic. Prolonged courses of steroids are said to enhance pathogenicity of *C. albicans* and to mask Candida infection.[17]

Verbov[3] found 7 of 47 (15%) patients with pruritus ani had itching which was attributable to Candida. In a review of his dermatologic practice (3,000 patients surveyed on the basis of their primary complaint), Pirone et al.[18] reported that surgical treatment of anal disorders (hemorrhoids, fissure, spasm, mucosal prolapse) eliminated Candida and dermatophyte infections in all but 3 of 23 patients who were culture positive and symptomatic with itching before surgery. Two of these three failures responded to antifungal treatment, but the third patient continued to itch.

In another study of 200 patients evaluated by colorectal surgeons and dermatologists, thrush was found in 28 (14%), only one of whom was diabetic. Fourteen patients had Candida infection after local steroid therapy, and six occurred after a course of systemic antibiotics. Only one case of dermatophyte infection was found.[19]

Perianal dermatophyte infection, all *Trichophyton rubrum*, was reported to be infrequent by Alexander (four of nearly 300 cases).[17] Topical steroids may render direct scrapings negative for hyphae, though most frequently they facilitate dermatophyte growth.

Bacterial Infection

Several nonsexually transmitted bacterial infections are reported to cause longstanding pruritus. Weismann et al.[20] reported that 19 patients (16 males and 3 females) with pruritus of duration 1–20 years had beta hemolytic streptococci cultured (four also had *Staphylococcus aureus*) from the perianal area but not from nasal or throat swabs. Treatment with various regimen resulted in cure of 42% and amelioration of symptoms in the rest. Erythrasma was reported to cause pruritus in 15 of 81 (18%) patients who failed to respond to routine treatment.[21] Wood's light fluorescence (coral pink or red in the case of *Corynebacterium minutissimum*) was the most reliable diagnostic test, being positive in every case, whereas cultures for *C. minutissimum* were positive in only 4 of 15 cases. Groin, thighs, and toes were also involved in every case and cure was achieved in all patients with erythromycin. Smith et al.[12] found erythrasma in only one of their 75 patients, each of whom had Wood's light examination. *C. minutissimum* is probably present as normal skin flora, but moisture, diabetes, and obesity predispose to pathogenicity, which usually develops in the body folds (axillae, groin, intergluteal, inframammary) and toe webs.[22] The St. Mark's Hospital series found erythrasma in 16% of 200 cases, but in 27% of the patients who had been symptomatic for over 5 years *C. minutissimum* was identified.[19] These patients had disease in more than one site, in common with other quoted series.

S. aureus has been anecdotally implicated as a cause of treatable pruritus.[23] Intertrigo was reported in 27% of the St. Mark's Hospital series and was highly treatable with topical agents.[19]

Contact Dermatitis

Contact dermatitis may develop from a wide variety of preparations including topical anesthetics, topical antibiotics, topical antiseptics, topical antihistamines, nickel and topically applied steroids (discussed later).[19,24] Common sensitizing agents identified in the dermatologic literature are listed in Table 16-3. The role of feces and seepage as an irritant contact agent has been emphasized in almost every paper devoted to pruritus ani. Contact dermatitis may have an irritant or allergic basis but is recognized by being an eczematous inflammation characterized by erythema, scale, and vesicles.[25] Avoidance of contact with the inciting agent is the obvious treatment. Topical steroids may be useful unless secondary infection is present. It is preferable to avoid detergents and soaps. Bath oils and emollient creams may be useful for cleansing.

The cause of contact dermatitis is often obscure, requiring detailed history and examination to resolve. Dasan et al.[24] report one patient who had pruritus associated with bathing in a tub of water in which his wife shampooed her hair with paraphenylenediamine, a dye. When the patient's wife stopped shampooing her hair in the tub, his symptoms resolved.

A study of patch testing in 80 patients with pruritus ani in Sheffield, England emphasized the importance of allergic contact dermatitis as an aggravating factor in 55 patients who tested positive. Thirty-eight of the positives were to medicaments or their constituents including neomycin, fragrance mix, Balsam of Peru, and cinchocaine. After counseling, two-thirds of these 55 patients experienced improvement or resolution of their symptoms.[26] These authors disputed the recommendation to use "wet wipes" for cleansing due to possible sensitization. Bruynzeel[27] corroborates the potential sensitization from use of moist wipes containing methyldibromoglutaronitrile. Rohde[28] feels that excessive exposure

TABLE 16-3. Common sensitizing agents

Ethylenediaminetetraacetic acid
Formalin
Lanolin (wood wax alcohol)
Mercury ($Hg(NH_2)Cl$, thimerosal)
Neomycin
Nickel
Paraben mixtures
Paraphenylenediamine
Potassium dichromate
Rubber ingredients
Topical anesthetics (benzocaine, dibucaine)
Turpentine oil

to water and the act of excessive cleansing itself may incite symptoms, and recommends the use of oils for cleaning.

Alexander[17] found lanolin, neomycin, procaine, and parabens to be offending agents and emphasized the difficulty of identifying these types of products when incorporated with a local anesthetic or steroid because the anesthetic suppresses the itching and the steroid suppresses the inflammation giving paradoxical temporary relief. Temporary relief leads to increasing application of the offending agent over a wider area, escalating the process.

Psoriasis

Psoriasis has been an important underlying cause of itch in every published study on the subject of pruritus ani. In a combined colorectal dermatologic clinic established to prospectively evaluate patients with pruritus, 22 of 40 patients were found to have psoriasis.[24] Alexander[17] confirms that psoriasis may present as an isolated lesion in the perianal area, and emphasizes that lesions in this location may have an altered appearance secondary to maceration. Smith et al.[12] found six (8%) cases of psoriasis in his series of pruritus ani, five of which had not been previously diagnosed. The St. Marks Hospital series found 5.5% of their 200 patients had psoriasis.[19] They also emphasized the nontypical appearance of the perianal lesions. Lockridge[29] reported a series of 81 patients with pruritus ani who were ultimately diagnosed with psoriasis. All of his patients in this series responded to fluocinolone acetonide 0.025% (Synalar®) with normalization of the skin. He recommended a search for lesions elsewhere; including elbows, knees, ankles, extensor surfaces of the forearm, base of the scalp, ear canals, eyelids, nipples, penis, vulva, and navel. Biopsy was rarely diagnostic secondary to changes attributable to drugs or trauma and limited experience of pathologists with diagnosis of perianal skin. Psoriasis affects 1–3% of the general population.[30] Typical psoriasis involves the trunk and extensor surfaces such as knees, elbows, sacral area, and scalp, but psoriasis involving groin, genitals, axillae, umbilicus, and anus is referred to as inverse psoriasis because it involves the inverse of the usual distribution. The exact incidence is unknown, but a review of 709 patients with psoriasis in a Chinese dermatology clinic found 48 (6.8%) with this distribution and 54% of this group had involvement of the anus.[31] The National Psoriasis Foundation corroborates these figures and suggests that limited Type IB evidence supports short-term use of a low to mid-potency topical steroid (betamethasone valerate in one study) once daily for up to 4 weeks for induction of remission, with a switch to calcipotriene (Dovonex®; LEO Laboratories Ltd., Dublin, Ireland) or pimecrolimus, or tacrolimus for maintenance to avoid long-term side effects of steroids.[32] Calcipotriene may be used as a primary agent but may take 6–8 weeks for maximum effect to occur and may be accompanied by discomfort. A combination of these agents may be required.

Atopic Dermatitis

Atopic dermatitis or eczema may be the most common hereditary cause of pruritus ani. This disorder presents as nonspecific and diffuse erythema, often dramatically marked by evidence of excoriation. The probability of correctly diagnosing atopic dermatitis may be improved by documenting the associated findings of (1) keratosis pilaris (rough sandpaper-like texture over the posterior biceps and thighs), (2) Morgan's folds or Morgan–Dennie lines (redundant creases beneath the eyes), (3) "sniffers" or "snuffers" lines (a transverse often subtle crease across mid-nose), (4) urticaria, and (5) white dermatographism. Although generally informative and often helpful in making the diagnosis, biopsies are most frequently not diagnostic, showing a mixed inflammatory infiltrate with eosinophils.

This inherited disease has a frequency greater than psoriasis (15–20% of the population) and is caused by disruption of epidermal barrier function. The atopic diseases (hayfever, asthma, atopic dermatitis/eczema and the multiple sensitive/allergic patient) have direct genetic and epigenetic influences. Fillagrin appears integral to the development of the atopic diseases and the fillagrin gene (FLG) appears to have no expression rather than polymorphisms in atopic dermatitis.[33] Fillagrin (keratin filament aggregating protein) is the cement of the epidermis. Complete loss of FLG is seen in ichthyosis vulgaris,[34] a common keratinizing disorder frequently associated with atopic dermatitis and seen over the buttocks and on perianal skin. Polymorphisms of FLG are commonly seen in asthma and other "atopic" conditions. Absence of FLG results in a permeable epidermal barrier function which can be indirectly observed by following measurements of enhanced transepidermal water loss in affected patients.[35] With the loss of an adequate barrier bacterial growth and colonization increases, access to the dermis by irritants increases the inflammatory response.

Treatment of atopic dermatitis begins with providing a barrier such as Vaseline® (white petrolatum USP), use of aggressive moisturization techniques, and the use of anti-inflammatory agents (systemic and topical), antipruritic agents both topical and systemic (antihistaminics H1 and H2, leukotriene inhibitors, etc.). True allergies may be seen in association with atopic dermatitis, especially with longer duration of disease. Basically, the greater the risk of induction of allergy to topicals is seen with more frequent use of greater concentration of medicaments over a longer period of time (frequency, duration, and concentration). Suspicion of the development of truly allergic component in this process should be raised when in spite of the medications and therapy used, the condition continues to exacerbate.

Lichen Sclerosus

Lichen sclerosus (formerly lichen sclerosus et atrophicus) (LS) is a chronic disease of unknown cause, occurring more frequently in women (female/male: 10/1); when this process

occurs on the penis it is termed balanitis xerotica obliterans. In females LS has a predilection for the vulva and perianal area. Characteristic appearance is a gradual progression from erythema with mild induration to white, atrophic, and wrinkled to the end stage of loss of normal perineal and perianal architecture clinically and histologically consistent with nothing more than a scar, lacking the lymphocytic interface dermatitis and other changes.[25,36–39] Involvement of the labia gives this condition a characteristic distribution that makes recognition easier once the diagnosis is considered. Biopsy is characteristic and may be especially indicated in a lesion not responding to treatment because of rare occurrence of squamous cell carcinoma.[40–42] Patients with LS in the vulva probably have a 4–6% incidence of squamous cell carcinoma arising in or adjacent to the LS.[43] Women with lichen sclerosus have a 300-fold increase in the likelihood of developing cancer compared with those who do not, and treatment of the disease does not appear to modify this risk.[41] Although in the paper by Funaro[44] topical testosterone was a popular treatment, it has now been shown to be without benefit. Treatment of LS with a potent topical steroid (clobetasol propionate 0.05%, Temovate®) for 6–8 weeks is highly successful, often resulting in normalization of the skin.[4,37,38] Other recent reports suggest that tacrolimus ointment may avoid skin atrophy which may accompany potent steroid use.[45,46] Secondary to the increased risk of squamous cell carcinoma, these patients should be followed periodically for raised lesions or ulcers that fail to heal. The exact role LS plays in the development of cancer is not certain but is thought to be independent of human papilloma virus.[42]

Food Factors

No controlled trials have been done to examine food stuffs or diet as a cause for itching, but strong opinions have garnered a revered place in the literature. Friend states that virtually all patients with idiopathic pruritus ani consume enormous quantities of liquids, are almost never constipated, and usually have loose stools.[47] Because it helps their symptoms, patients with severe pruritus usually maintain good anal hygiene. Friend states that there are six common foods that unequivocally cause idiopathic pruritus: coffee, tea, cola, beer, chocolate, and tomato (ketchup) and that total elimination will result in remission of itching in 2 weeks. After a 2 week elimination period the food may be reintroduced to determine the threshold for appearance of symptoms. Thresholds are typically between two and three cups of coffee, four cups of tea, less than two cans of beer.

As we reviewed briefly earlier in this chapter, Smith et al.[12] demonstrated that coffee lowered anal resting pressure in 8 of 11 patients tested. An elimination diet gave partial or complete relief in 27 of 56 (48%) of their patients. Specific dietary items identified by elimination as a cause were coffee (eight), alcohol (five), peanuts (three), chocolate (two), milk products (three), cola (one), citrus (one). Alcohol was an equivocal factor in this study because 41% did not

consume alcohol and only a third of patients drank more than 1 ounce per day. Smith et al. confirm the importance of poorly formed stool and coffee which may contribute to seepage and recommend a bulk agent taken at the same time of day to promote regular, complete emptying of stool.[12]

Daniel et al.[2] reported that average coffee intake in patients with primary pruritus ani averaged six cups per day, compared to those with secondary pruritus who averaged about 3.5 cups per day. Akl[48] reported an 8-year-old boy with asthma, intolerant of milk with abdominal pain, whose pruritus ani disappeared after elimination of yogurt.

Coexisting Anal Disease

Coexisting surgical anal conditions (hemorrhoids, fissure, fistulas) may of themselves produce itching or aggravate any tendency to itch. Most authors agree that correcting these disorders in selected patients is indicated. Smith et al.[12] reported that 8 of his 75 patients required treatment of hemorrhoids (four operations, four Barron ligations) which by virtue of prolapse may induce soiling. These authors note, however, that correction of the hemorrhoids eliminated itching in only one patient. Another with scars from previous fissure surgery also had soiling not amenable to surgical correction. Murie et al.[49] in a study of 82 hemorrhoidal patients with and without pruritus felt that pruritus is more common in patients with hemorrhoids than in age- and sex-matched controls without hemorrhoids and that correction of the hemorrhoids usually eliminated itching along with the other symptoms of bleeding, pain, soiling, and protrusion. Bowyer and McColl[19] reported that hemorrhoids were the sole cause of itching in 16 of their 200 patients, contributory in 27 others, and that correction of fissure was required in five patients before symptoms were relieved. Five others had skin tags which when removed, eliminated symptoms. These patients could point to specific skin tag(s) as the source of their discomfort, raising the possibility of a causal relationship between skin tags and pruritus ani. Dasan et al.[24] in a study of 40 patients with pruritus found two that required surgery, one to remove complex skin tags and the other to correct a fistula. The St. Louis University group found that 52% of 109 patients with the sole presenting complaint of itching had anorectal disease as the cause.[2] The diagnoses included hemorrhoids, fissure, idiopathic proctitis, condyloma, ulcerative proctitis, abscess, and fistula.

Pirone et al.[18] as mentioned previously, believe that correction of hemorrhoids, fissure, mucosal prolapse and spasm can resolve fungal infection and the consequent pruritus.

Psychological Factors

Smith et al.[12] studied 25 of their patients who completed an Minnesota Multiphasic Personality Inventory (MMPI). They found no deviations on the clinical scales but a trend toward inhibition of aggression, and denial of feeling of social and

emotional alienation. Anxiety, stress, and fatigue, as well as personality, coping skills, and obsessive compulsive disorders, probably play a role in the exacerbation of pruritus ani.[50] Because of this, psychotropic drugs may play a role in its management in isolated cases supporting the use of Doxepin HCl with its strong H1 and H2 effects, amitryptiline, nortryptiline, and gabapentin.

Steroid-Induced Itching

Anogenital itching has been reported following bolus administration of intravenous dexamethasone.[51] More commonly, itching occurs as a rebound phenomenon after withdrawal of steroids, leading to their reinstitution and chronic use. This syndrome has been characterized as steroid addiction[52] and can lead to permanent deformity and dependence.[53] Experimental application of potent steroids under occlusion for as little as 3 weeks has been shown to produce an acute dermatitis resembling that seen with a blister that has been unroofed and exposed to air.[52] Steroids should only be used to achieve specific effects. Potency and dosing should be tapered in a planned fashion with the goal of eliminating steroids altogether from a maintenance regimen. Allergic contact dermatitis to topically applied steroids has been well documented and is chemical class specific. Switching to desoximetasone (a less commonly used agent in steroid class) may be a solution. The ideal solution would be elimination of the steroid, if, however, elimination is not possible, alternate day therapy or intermittent therapy once or twice a week is to be preferred. The calcineurin inhibitors (macrolide anti-inflammatories) tacrolimus and pimecrolimus offer excellent anti-inflammatory effect without steroids or steroidal side effects.

Skin Trauma

Trauma can arise from physiological processes such as diarrhea or frequent stools which may be associated with frequent wiping and maceration. Scratching either consciously or nocturnally while asleep may result in the classic lesion of lichen simplex chronicus. Alexander-Williams puts it nicely, "Perianal dermatitis is a cross between a nappy rash, athlete's foot, and a self inflicted injury. In most patients the problem is due either to inadequate cleansing of the anus or to over vigorous attempts to polish it clean."[54] There is controversy about the best way to clean the anus. Rohde takes issue with the standard method using water or wet wipes (which can induce irritant or allergic contact dermatitis) and advocates a smooth dry article with olive oil if necessary, feeling that water breaks down the barrier function of the skin.[28] Most authors agree that contact dermatitis is a contributing cause of perianal irritation and that attempts to discontinue over-the-counter preparations (OTCs), perfumed or scented products including toilet paper, should be made because of potential sensitizing agents (Table 16-3). Bland emollients, Acid Mantle creams, and waterless cleansing agents are reasonable

substitutes that may be used with tissue paper or cotton balls for cleansing and left on the skin. My own experience suggests that dilute white vinegar (one tablespoon in 8 ounces of water) and Burow's solution (Domeboro®, Bayer Corp.) are effective cleansing agents associated with little adverse reaction. Since Burow's solution and acetic acid have been found to be an effective antibacterial in chronic otitis externa with little toxicity, its use in perianal disease seems justified.[55–58]

Neoplasms

Perianal Paget's disease is rare and large series do not exist; however, more than half of patients with Paget's disease have itching, often lasting longer than 3 months.[59–61] Perianal Bowen's disease (intraepithelial squamous cell carcinoma in situ) is also rare, but in a series of 47 patients reviewed at the Cleveland Clinic, 28 (60%) had perianal itching as a presenting complaint.[62] AIN is the sequel to human papillomavirus infection (associated with itching) and refers to premalignant change in the area of the dentate line and anal transitional zone. Although pruritus has not been described in large series looking at AIN,[63,64] because of their study design it would seem prudent to be alert for neoplastic change in any patient with a history of warts who presents with pruritus. Itching was present either alone or with soreness in 77% of lichen sclerosus associated carcinoma and 73% of non-LS-associated vulvar carcinoma.[42] Higher grade tumors such as melanoma or squamous cell cancer usually present with bleeding or pain, not with pruritus.[65–67] Further discussion of neoplastic disease is provided in Chap. 20.

Diagnosis of Perianal Disease

Given the variety of possible diagnoses, it is important to identify the specific diagnoses that are treatable for cure, and to engage a strategy that will avoid mistakes. It is often helpful in the differential diagnosis of anal and perianal disease processes to divide them into the general classifications of mass (inflammatory or neoplastic), rash or fissure (primary or secondary). The morphology of a lesion is a starting point for diagnosis, but may not be specific, and the same disease may have several different appearances (Table 16-4). As an example, Candidiasis may be present as an erythematous lesion, a papular lesion, or as an ulcerative lesion. Specific techniques are necessary, therefore, to establish or eliminate a diagnosis. Bacterial culture is a time-honored technique for identification of organisms, but proper media and collection techniques must be used to avoid killing certain species.[68]

History and Physical Examination

History and physical examination are still the most basic maneuvers for diagnosis (see Table 16-5). Inquiry about other skin diseases, allergic conditions such as asthma or

  Ulceration
  Groin adenopathy
  Defined edge or margin

urticaria, or sites of involvement may the first clue to diagnosis of unrecognized psoriasis or atopic dermatitis. Patients may not relate the itch on their elbow to the itch around their anus. Erythrasma usually involves the groin and toes, usually is chronic and often associated with hyperpigmentation. Patients frequently do not consider over-the-counter or non-prescription preparations as medicines, though these may modify the appearance of a condition or even cause it.

Specific questions about the use of these products are necessary to uncover their use and patient exposure to unsuspected ingredients. Knowledge of a patient's allergies is important not only for avoidance but also may aid in uncovering an unsuspected exposure to an occult ingredient. Patients sometimes have had patch testing and allergy consultation, and may not volunteer that information unless specifically asked. Patch testing, dermatologic consultation, and withdrawal of medication may be in order. Specific questions about infections, colds, or diarrheal illnesses treated with pills may be necessary to uncover antibiotic use. Patients sometimes may not list prednisone in their list of medications until asked a question pertinent to an illness such as arthritis or asthma or myalgias. A condition that has come and gone for years or that has seasonal exacerbation may be a clue to anal fissure but could reflect dietary changes, type of clothes worn, or laundry practices.

Physical examination should specifically look for other sites of involvement. The groin is a classic intertriginous area that is easily accessible in the prone jack-knife or the lateral position and should be the first place one looks to confirm a suspected yeast or fungus diagnosis. Hyperpigmentation in the buttock cleft or other intertriginous area is a clue to a chronic inflammatory condition or the presence of chronically infected drainage or secretion. Effective treatment of a patient with changes in the groin as well as the cleft requires attention to each area of involvement. If a condition is infectious, steps to eliminate the infection will be more successful if the environment of the host is made inhospitable to the organism in each area of involvement. Broad areas of erythema with indistinct borders and findings suggestive of excoriation or chronic rubbing should generate thoughts of eczema or atopic dermatitis. A sharply defined border usually points to a definable diagnosis such as tinea, especially when accompanied by scale (Figure 16-1). Psoriasis usually has a sharply defined border but in the cleft may lack the classic scale seen in skin that is exposed to air and may, in fact, exhibit maceration. In the confined, occluded area of the cleft there usually is no scale (Figure 16-2). Neoplastic changes may appear sharply marginated, but margins may be microscopically involved, especially around the dentate line, even if grossly normal (Figure 16-3). Infiltrative processes may be less well defined as in Paget's disease of the anus with the same caveat about margins (Figure 16-4). Inflammatory changes of idiopathic nature often have borders that are indistinct and nondescript (Figures 16-5 and 16-6). Brilliant red erythema often is seen with perianal yeast (Figure 16-6), frequently "satellite" pustules will be present outside the main area of involvement. Erythema may be seen with chronic steroid use (Figure 16-7). Patient A had used hydrocortisone daily for 20 years or more and came in with recurrent warts and carcinoma in situ when the cortisone failed to control his symptoms. Treatment of his warts, carcinoma in situ, and withdrawal of his steroids resulted in resolution of his symptoms and normalization of his skin, with

FIGURE 16-1. Dermatophyte infection. Note the sharp border, the scale at the edges and its involvement of the groin crease. As this type of infection moves into the anal cleft, the characteristic edge at the border of the cleft and involvement of the groin may be the only clues.

FIGURE 16-3. Anal Bowen's disease or squamous cell carcinoma in situ may have a varied appearance and be indistinguishable from Paget's disease (Figure 16-5) by clinical examination. The *white pearls* on the *red* background are often present and are a clue to the diagnosis. Despite sharp appearing edges, the process often involves normal-looking skin and requires frozen section to confirm negative margins.
FIGURE 16-2. Psoriasis often appears atypical in the cleft and around the labia, lacking the silvery scale that is so characteristic. Isolated areas of involvement in the cleft occur and require biopsy confirmation by a competent skin pathologist.

FIGURE 16-4. Perianal Paget's disease may present as a nondescript rash that itches. This clinical appearance is not specific and requires biopsy to confirm the diagnosis. Unlike Paget's of the breast, there is rarely an underlying invasive adenocarcinoma, and local excision with clear margins is the treatment of choice. Margins of excision require frozen section confirmation because clinically normal skin may be involved.

FIGURE 16-5. Classic severe pruritus ani is marked by lichenification (leathery thickening of the skin), accentuation of folds, fissuring of the skin, and erosions and an indistinct border. Changes this severe require short-term aggressive therapy with high potency steroids for 4–8 weeks which then are rapidly tapered to a maintenance program, if possible without steroids. It is important to rule out secondary infection, which requires specific treatment.

no reoccurrence of disease or symptoms to date, 7 years later. Patient B had used Mycolog® (a combination of nystatin and triamcinolone acetonide) cream daily for several years, after having radiation therapy for prostate cancer; both Mycolog® and topical steroids were withdrawn. Acute, severe injury from prolonged diarrhea with frequent wiping produced lichen simplex chronicus (Figure 16-8), which was treated by controlling the patient's diarrhea, cleansing with Burow's solution, and application of topical silver sulfadiazine to which cortisone was added. Chronic infected discharge may lead to hyperpigmentation of the cleft (Figure 16-9). In the example shown this hyperpigmentation is due to chronic pilonidal disease, but it may also occur with fistulas, chronic yeast or fungus infection, or hidradenitis. Complications of treatment can result in a rash, in this example a patient with contact dermatitis from clotrimazole (Figure 16-10) is shown. Severe symptoms, especially paresthesias, coupled with scattered lesions may be a clue to Herpes virus infection (Figure 16-11). Lichen sclerosus characteristically involves the perineum and labia in the female and has a distinctive appearance with wrinkling of the skin (Figure 16-12). Biopsy is characteristic.

Inguinal lymphadenopathy, and the presence or absence of pain, tenderness, or other symptoms, can have specific relevance to diagnosis of perianal and anal disease (Table 16-6), especially sexually transmitted diseases.

Laboratory Examination

Ideally, infected material should be aspirated with a syringe and expelled into a sterile container; next best is a swab of exudate collected from a deep portion of the

FIGURE 16-6. Perianal yeast may present as a *bright red rash* without the cheesy exudate sometimes seen elsewhere and may follow treatment with antibiotics for some other condition. This infection is easy to treat but has a tendency to recur. Rendering the cleft environment inhospitable by drying with a hair dryer after bathing and using athletes foot powder to coat the skin and absorb moisture can help maintain remission.
FIGURE 16-7. Chronic steroid use may cause itching or mask other processes. **A** shows an elderly man who had used 1% cortisone daily for over 20 years but had worsening of his symptoms despite increasing use. Treatment of his warts and carcinoma in situ along with withdrawal of steroids resolved his symptoms. The erythema has disappeared and he had remained free of symptoms for over a year. **B** shows a similar erythema superimposed on radiation dermatitis from treatment of prostate cancer. Withdrawal of Mycolog®, which had been used for years without interruption and substitution of a barrier cream with menthol relieved his symptoms.

FIGURE 16-8. This man has classic lichen simplex chronicus with inflammation and erosion resulting from unremitting diarrhea of 3 weeks duration with wiping five times a day. Treatment of the patient's diarrhea and topical silver sulfadiazine with 2% cortisone achieved rapid healing and relief of symptoms.

FIGURE 16-9. Hyperpigmentation may result from chronic inflammatory changes in the skin for whatever reason. In this particular case, infected drainage from a chronic pilonidal sinus was the cause, but fistula disease, chronic dermatophyte infection, erythrasma may produce the same picture. This finding should emphasize the need to modify environmental conditions within the cleft and surrounding area as an adjunct to healing.

FIGURE 16-10. This patient had a reaction to topical clotrimazole in use for 1 week.

FIGURE 16-11. Scattered lesions, especially when accompanied by severe symptoms suggest Herpes virus infection. Herpes Simplex Type I was cultured from the base of these ulcerations that were 9 days old at the time of this picture. Treatment caused prompt resolution of symptoms.

lesion. Bacterial and fungal cultures should be placed into a bacterial transport medium and refrigerated if any delay in transport to the laboratory occurs. Anaerobic specimens require transport in a special anaerobic medium, and should not be refrigerated. Viral cultures require a viral transport medium and should be kept on ice. Vesicular lesions should be unroofed and cultures taken from the base of the vesicle. Microscope slides can be pressed against the base of the lesion for Tzanck smears, but inoculation of the fluid or exudate from the lesion base onto cell culture is more sensitive (viral culture).[68]

The office should have arrangements with a laboratory, which will supply culture swabs with transport media appropriate for aerobic, anaerobic, fungal, and viral culture. These become outdated and can result in rejection of specimens for processing. The practitioner should check the appropriateness of the media and its date before using it. Because staph and strep have been documented as causal agents, it is prudent to culture for pathogens in almost all cases whose treatment is not obvious. Conventional water soluble lubricant is bactericidal for some organisms (Neisseria gonorrhea).

Swabs should be lubricated with saline, if lubricated at all. Ulcerated lesions should have the base vigorously swabbed. Biopsy should be accomplished early with a representative lesion and should include an area of adjacent normal skin. Specific query should be made to the pathologist about suspected diagnoses, and if possible a pathologist with skin expertise should be consulted. Highly reliable histologic criteria exist for viral lesions, pyoderma, syphilis, and neoplastic lesions. EMLA® cream, applied as a lubricant at the time of examination, may facilitate injection of local anesthetic, and biopsy may conveniently be done with either an 11 blade or skin punch blades (Keyes dermal punches) that come in numerous sizes in separate sterile packages (Figure 16-13). Bleeding from punch biopsy holes is readily controlled with sliver nitrate sticks or GELFOAM® (Pfizer Inc., New York, NY) packing.

Skin scrapings may be submitted for fungus culture, and if available examined by KOH prep for hyphae. Most colorectal offices are not set up for KOH prep; rarely are we trained in this technique and in the United States CLIA certification may be required; therefore, culture is preferable.

FIGURE 16-12. Lichen sclerosis has a distinctive appearance with cigarette paper thinning and wrinkling of the skin. It almost always involves the labial skin and perineum, making it easy to recognize. Biopsy is characteristic and is especially indicated for any areas which are raised, ulcerated, or unresponsive to treatment because of a 5% risk of squamous cell carcinoma developing within its distribution.

Treatment of Pruritus Ani

A general strategy is presented in Table 16-7. Directed treatment for a specific, curable diagnosis is the ideal, and diagnostic efforts should be directed to avoid overlooking curable disease.

Many investigators have alluded to the importance of controlling seepage and fecal contamination of the skin. Diet may directly contribute to itching and it is prudent to give patients a list of potential foods implicated in itching for

FIGURE 16-13. Skin punch biopsy tools come in various sizes up to 1 cm in diameter (2, 3, and 5 mm pictured). They may be purchased as autoclavable sets which may be sterilized and reused, or for the occasional user, disposable punches are supplied in individually wrapped sterile packages. One advantage of the disposable instruments is that they are always sharp.

TABLE 16-7. Treatment of pruritus ani

1. Specific directed treatment for a diagnosis
2. Eliminate offending agent (contact irritant (perfume, soap, toilet paper), organism)
3. Eliminate scratching (especially noctural)
4. Control symptoms
5. Hygienic measures (Dove® soap, detachable showerhead, hair dryer to dry)
6. Withdraw inappropriate steroids
7. Treat infection (silver sulfadiazine cream, gentamicin or clindamycin topically, nystatin, clotrimazole)
8. Protect skin (barrier creams, powders (esp. athlete's foot powder))
9. Correct anal disease (fissure, hemorrhoids)
10. Judicious use of appropriate steroids
11. Emphasize control as a chronic condition
12. Reassess diagnosis if response to treatment is not appropriate
13. Anal tattooing in extreme cases

an elimination trial. Patients with loose stools may benefit from the addition of fiber to absorb moisture and add bulk and improve emptying with defecation. Many patients who have tried fiber without benefit may benefit from judicious use of Immodium® (McNEIL-PPC, Inc., Skillman, NJ) or Lomotil® (Pfizer Inc., New York, NY) to lessen frequency and firm up stools. Questran® (Bristol-Myers Squibb, Princeton, NJ), in varied doses, has been helpful in my practice to firm loose stools.

Environmental factors should be altered as much as possible with removal of irritants such as soaps, perfumes, dyes in clothes or wiping tissues, alcohol or witch hazel containing agents, moisture. Dove® (Unilever, London, UK) is free of conventional soap and is the preferred bathing agent. Bidets are not common in the USA, but detachable shower heads are

common and inexpensive and when equipped with long tubing and handle may be a useful item for cleansing the perianal skin and anal canal and eliminating soap residues by flushing with water in the squatting position. Subsequent drying with a hair dryer can eliminate moisture, and application of an athlete's foot powder or barrier cream will lubricate and prevent maceration of the skin in the cleft and anal canal. Zeasorb® (Stiefel Laboratories, Research Triangle Park, NC) is an alternate lubricating, drying agent in powder form. Cornstarch is to be avoided because it is culture medium for yeast. Cornmeal agar is used to identify different species of yeast in the laboratory.[57] Dilute white vinegar (one tablespoon in an 8 ounce glass of water) on a cotton ball is a cheap effective nonsoapy cleanser that can be kept at the toilet when bathing is not handy. Burow's solution, 1:40 (Domeboro® tablet one in 12 ounces water or one in six ounces for 1:20) is another nonirritating cleanser that can be kept refrigerated in a plastic squeeze bottle and used in lieu of soap or plain water. Burow's® may be used as an antibacterial soak for 5–15 min and then dried. Balneol® (Alaven Pharmaceutical, Marietta, GA) is a commercially available mineral oil-based preparation that can be kept in a pocket and squeezed onto toilet paper to make a soothing cleansing agent when using public facilities. Breaks in the skin caused by scratching or over vigorous cleansing efforts must be avoided, so an attempt to control symptoms with application of topical anesthetics, menthol, phenol, camphor, or a combination of ingredients may be appropriate. These agents may be used on combination with topical steroids, topical antifungal agents and topical antibacterials. Doxepin (Sinequan®, Pfizer, Inc., New York, NY – orally) is available topically as an effective antihistamine (Zonalon®, DPT Laboratories, Ltd. San Antonio, TX), but orally it is 1,000 times more potent that diphenhydramine (Benadryl®, McNEIL-PPC, Inc., Skillman, NJ) for elimination of itching and may a useful adjunct at bed time to avoid nocturnal scratching. Doxepin possesses both, anti-H1 and anti-H2 activity, a fact which may explain some of the enhanced effectiveness. Cimetidine, in 1 g/day dose, has been reported to eliminate itching induced by lymphoma and polycythemia vera, and oral gabapentin and paroxetine have been reported to have centrally acting antipruritic effects. Our combined experience with doxepin, cimetidine, gabapentin, and paroxetine has been quite rewarding.[7] Nocturnal scratching, of which the patient may be unaware, is probably a significant contributing factor in most cases of idiopathic pruritus ani. Patients who are awakened by the urge to scratch should be instructed to gently cleanse the area to eliminate any fecal seepage and reapply their steroid or barrier cream whichever is in effect at the time but not to scratch. Topical capsaicin may be useful in breaking the overwhelming urge to scratch by substituting a more powerful temporary burning stimulus.

No data exists on the influence of clothes or other formites on pruritus, but from a practical standpoint, loose underwear that allows air circulation and promotes dryness makes sense. Fresh clothes laundered without perfume or fabric softeners, perhaps with the addition of a small amount of chlorine bleach to secure lowered bacterial counts should be used daily.

Patients who come to the office with acute moderate to severe changes of the skin may be treated by application of Berwick's dye (combination of gentian violet and brilliant green) which has alcohol content and stings, often relieving the itch. The dye is dried with compressed air or a hair dryer. Benzoin tincture is applied over top of this as a barrier and dried similarly. This preparation will stay in place for several days if only water is used to cleanse and gives excellent temporary relief of symptoms and allows reepithelialization of broken skin. Berwick's is suitable as an office-applied remedy but is generally not for home application.

Patients who have mild to moderate symptoms with minimal skin changes will often respond to topical 1% hydrocortisone cream which can be combined with menthol, 0.5–1.0%, and topical antibiotics (gentamicin, clindamycin, or bacitracin) or antifungals (clotrimazole, nystatin). This preparation is applied at night and in the morning after bathing, being used daily until symptoms subside. Thereupon a tapering regimen is instituted, ending with substitution of a barrier cream such as Calmoseptine® (Calmoseptine, Inc., Huntington Beach, CA) to keep the skin covered. Elimination of the steroids and substitution of an innocuous agent to maintain attention to the hygiene is an important goal. Patients with thickened skin and chronic moderate or severe changes should be approached with higher intensity therapy, with a medium or high potency steroid for a limited, defined period of time (Table 16-8). When prescribing topical steroids, the use of brand name products allows control of both the delivery vehicle and specific active steroid salt (Table 16-8). The choice of solution, lotion, cream, or ointment is of major therapeutic importance. For instance, betamethasone as Diprolene® (Schering Laboratories, Kenilworth, NJ) is over 1,000 times more potent than Valisone® (Schering Laboratories, Kenilworth, NJ) cream, with Valisone® (Schering Laboratories, Kenilworth, NJ) ointment somewhere in between. These differences can lead to a great deal of confusion when prescribing by generic name without spelling out every tiny detail. It is important to emphasize to patients that a high potency steroid should be used for a limited period of time, generally 4–8 weeks. When normalization of the skin has been achieved, patients are switched to a mild steroid such as hydrocortisone 1% or Locoid® (Ferndale Laboratories, Inc., Ferndale, MI) 0.1% with tapering frequency of application down to once or twice a week or to total elimination. Patients who have frankly eroded or denuded skin may benefit from topical antibiotics. Silver sulfadiazine cream to which hydrocortisone or triamcinolone and menthol has been added may be soothing and promote regrowth of epidermis over ulcerated areas while suppressing the inflammation that can cause fissuring in the skin.

Skin atrophy is a serious problem with prolonged use of potent steroids, but each of the steroid preparations differs in

TABLE 16-8. Relative potency of topical steroids (descending order)

Group 1 (most potent)	Group 4
Betamethasone dipropionate 0.05% (Diprolene®)	Desoximetasone 0.05% (Topicort LP®)
Clobetasol propionate 0.05% (Temovate®)	Flurandrenolide 0.05% (Cordran®)

topically now approaches 17 years and anecdotally, safety has not appeared as a problem. These compounds may have some intrinsic antifungal activity as well.[74] I (COF) have had limited but very good clinical experience with these compounds. There is currently no published data on topical macrolide use in pruritus ani. Table 16-10 lists the potential complications of topical steroids, which are not to be taken lightly, and are all the more important as they are preventable complications of treatment.

Anal Tattooing

Every practice has a small number of patients who respond poorly to any treatment and whose symptoms are severe enough to alter life and happiness. These refractory patients may benefit from a technique originally described by a Russian surgeon, but espoused in the USA by Wollock and Dintsman[75] who described nine patients, eight of whom had relief after one treatment, one requiring a second injection to obtain a good result. Eusebio et al.[76] reported 23 patients: 13 with complete relief, 8 with incomplete relief but much improved, and 2 who were not improved but who had initially presented with burning, not itching. Three cases of skin necrosis resulted in modification of their technique and treatment of an additional 11 patients was without complication and with good result.[77] The modified technique consists of the intradermal and subcutaneous injection of the following solution with the patient under intravenous sedation in the prone jack-knife position: 10 ml 1% methylene blue + 5 ml normal saline + 7.5 ml 0.25% bupivacaine with epinephrine (1/200,000) + 7.5 ml 0.5% lidocaine. Farouk and Lee[78] reported six patients treated with a similar volume to Eusebio's modified technique. Five patients got substantial relief of symptoms with follow-up of 2–5 years. Three of the six required a repeat injection at 1, 3, and 5 years after the initial treatment.

The authors have personally used this technique on four patients, infiltrating the skin with the same solution as Eusebio et al. using a modified technique. I use a 30 or 27 gauge needle and infiltrate the skin as I would for cutaneous anesthesia with multiple injection sites sufficient to cover the perianal involved skin up to the dentate line (Figure 16-14). All four of my patients had positive results lasting at least 1 year, during which time all have had relative cutaneous hypoesthesia. They describe the sensation as similar to having the side of one's face numb after a dental block. Certain individuals have

its tendency to cause trouble. Creams cause comparatively greater atrophy than ointment preparations containing identical ingredients.[69] Newer, double-ester, nonfluorinated steroids may prove to be less atrophogenic than the older preparations,[70,71] but the FDA required informational inserts for prednicarbate and mometasone furoate still quote 8 and 6% incidence of mild skin atrophy for these compounds. Macrolide topical immune modulators (tacrolimus and pimecrolimus) appear to be free of the problem of skin atrophy, a fact that enhances their appeal for use on the opposed skin of the cleft.[72] Use of topically applied picolimus and tacrolimus has not been approved for skin diseases other than atopic dermatitis. As such, its use is off-label. Burning sensation after application has been relatively common in my experience, but tends to subside (Table 16-9). The FDA issued a black box warning regarding risk of lymphoma and skin cancer in 2005, but recent long-term safety data in large cohorts of patients with up to 4 years duration of treatment have not revealed an increase in either skin or internal cancer associated with topical use.[73] European and US use of these agents

Figure 16-14. Tattooing with methylene blue is a simple technique to treat intractable itching that does not respond to traditional vigorous therapy. Patients experience hypalgesia and numbness of the perianal skin that can be bothersome, but rapid resolution of itching occurs and the chronic skin changes normalize quickly.

found this sensation very disagreeable, so I am careful to warn them in detail before treatment. The skin changes of severe pruritus in all cases rapidly and dramatically regressed and resolved. One patient who initially responded to injection, experienced recurrence of much milder symptoms which then responded to institution of topical therapy and did not require repeat injection. The response of these patients during the time of hypalgesia lends some credence to the idea that some forms of pruritus ani may be a neurodermatitis resulting from noctural scratching of which patients are not aware.

Conclusion

Diseases of the perineum, anus, and perianal areas are laden with social stigma and a real reticence on the part of the patient to seek medical assistance. These skin conditions are nonetheless quite common and often poorly diagnosed and treated. This anatomic region represents only about 1% of the total body surface area, yet the discomfort both physical and psychological is immensely disproportionate. The colorectal surgeon should welcome the opportunity to provide relief from disease that all too often does not come to the attention of any other specialty.

The appearance of a lesion is rarely pathognomonic, a systematic approach to evaluation of disease in this area will lead to a successful outcome. Extension of physical examination beyond the peri-area, and expanded and often extensive past medical history, family history, social history, and review of systems, as well as follow-up of treatment plans, reevaluation of patients, and reconsideration of ongoing prescriptions, should be standard practice and will help to avoid misdiagnosis (or at least give a second chance at the correct diagnosis). The most important rule in evaluation or reevaluation is never believe anyone's diagnosis, least of all your own.

Sexually Transmitted Diseases

Charles B. Whitlow, Lester Gottesman, and Mitchell A. Bernstein

Introduction

There are over 25 diseases primarily spread by sexual means with an annual incidence of approximately 15 million cases in the USA.[1] In 1994, the overall cost related to major sexually transmitted diseases (STDs) was estimated to be 17 billion dollars. In the UK, the incidence of STDs has substantially increased over the past 6 years and has led to a new government strategy to counteract these increases.[2,3]

Site and route of infection determine the symptoms caused by STDs. Infections of the distal anal canal, anoderm, and perianal skin are similar to lesions in other parts of the genitalia and perineum caused by the same organisms. These infections are typically the result of anal receptive intercourse but in some instances represent contiguous spread from genital infections. Proctitis from sexually transmitted organisms is almost always acquired from anal intercourse. Direct or indirect fecal–oral contact produces infection with organisms which cause proctocolitis or enteritis but which are generally thought of as food or waterborne diseases instead of STDs. Included in this group are *Entameba histolytica*, *Campylobacter*, *Shigella*, *Giardia lamblia*, and hepatitis A. While it appears that male homosexual activity and the use of the anorectum for sexual gratification is increasing, data regarding the frequency of these behaviors both past and present are limited. Current estimates are that less than 2% of adult males regularly practice anal receptive intercourse while between 2 and 10% participate in homosexual activity at any point in their life.[4] Between 5 and 10% of females engage in anal receptive intercourse "with some degree of regularity" and females appear to be more likely than men to have unprotected anal intercourse.[4]

Difficulty in correct diagnosis and appropriate treatment of STD of the anorectum is caused by several factors. (1) The signs and symptoms of infection are more organ related than organism related so that no symptom or symptom complex or physical finding is diagnostic for many STDs. (2) The presence of more than one organism is not uncommon, especially with anogenital ulcerations. (3) Determining true pathogen from colonizing organism may be difficult. (4) Lastly, there is a lack of rapid sensitive diagnostic tests for many STDs so that empiric treatment is frequently required.

This chapter discusses the STDs that are most commonly seen by colorectal surgeons. Entire texts are devoted to STDs; however, we confine most of our comments to the diagnosis, treatment, and prevention of the anorectal component of these infections. Infections, which manifest as one of the colitides, are covered in Chap. 34.

Overview of Anorectal Immunology

The optimal state of health of the anus requires the integrity of the skin, which acts as the primary protection against invasive pathogens. The mucosa shed from the rectum contains IgA, which traps foreign antigens and expels them with stool, preventing them from reaching the rectal crypt cells.[5] Cellular immunity is controlled by the Langerhan's, or denditric cells which communicate with the T cells through a complicated mechanism and essentially prime the T cells to identify foreign cells.[6] This process allows the entire complement of cell-mediated immunity to destroy alien substances. Although study of anal immunology is still in its infancy, it appears that certain pathogens may alter the balance of cellular elements. It is known that while Human papillomavirus (HPV) increases Langerhan's cells, human immunodeficiency virus (HIV) may damage their effectiveness. In addition, pathogens like HPV and herpes simplex virus (HSV) invade into the host cell, combining with cellular elements or the genome, evading surveillance mechanisms. In addition, in the case of HPV, the identifying foreign antigens are placed onto the frame of the new virus near the epidermis, where the virus normally sheds and where an attack by the host has little value.[7]

HIV is known to impair cell-mediated immunity by depletion of T cells and destruction of Langerhan's cells. This process allows propagation of oncogenic processes such as HPV to become dysplastic. Although both exact switches and the

mechanism(s) have not yet been elucidated, they appear to be related to the coexistence of perhaps HSV and the highly active antiretroviral therapy (HAART) drugs.

Failure of the mucous complex to protect the rectum is seen in various diseases contracted through anal intercourse. The act of intercourse abrades the mucous lining and delivers pathogens directly to the crypt and columnar cells allowing for easy entry. Depending on their mechanism of action, they may burrow into the cells (ameba) or proliferate on the cells without damaging them (*G. neisseria*). Invasive pathogens (*LGV*) unleash nefarious cytokines which destroy the cell. The immune response is usually too late to contain an acute attack. In the case of recurrent viral attacks, it appears that the level of functioning T cells may have an impact on recurrence of warts or herpes outbreaks. The mechanics of anoreceptive intercourse, as compared to vaginal intercourse, almost demands denuding of the protecting cellular and mucous protection of the anus and rectum.

Latex allergies may also cause severe invasive and erosive proctitis and should be in the differential of a caustic burn to the rectum after protected sexual anoreceptive intercourse.

Diagnosis and Management of Bacterial Pathogens

Gonorrhea

Neisseria gonorrhea, the gram-negative diplococcus (Figure 17-1) responsible for gonorrhea was first described by Albert Neisser in 1879 from exudates from urethritis and cervicitis.[8] It is probably the most common bacterial STD affecting the anorectum. While gonorrhea rates decreased over the last several decades, in the mid-1990s the incidence slowly increased to the current rate of about 650,000 cases per year. Similar recent increases have been noted in Canada and the UK.[9] Peak incidence for all forms of gonorrhea is in the late teens for females and early 20s for males. African Americans have a 30-fold higher rate of infection than do white Americans.

Infection from *N. gonorrhoeae* occurs in columnar, cuboidal, or noncornified epithelial lined cells of the urethra, endocervix, rectum, and pharynx and is frequently asymptomatic. The incubation period ranges from 3 days to 2 weeks. Untreated infection may lead to disseminated gonococcal infection with transient bacteremia, arthritis, and dermatitis. Rare but severe sequelae include endocarditis and meningitis.

Anorectal transmission in homosexual males and in some females is by anoreceptive intercourse with an infected partner. Thirty-five to fifty percent of women with gonococcal cervicitis have concomitant rectal infection which is believed to be from contiguous spread from the genital infection.[10] Oral–anal sex has been suggested as another mode of anorectal gonococcal infection.[11] A large percentage of patients who culture positive for rectal gonorrhea are asymptomatic – up to 50% of males and 95% of females. Asymptomatic rectal infection constitutes the main reservoir of gonococcal disease in homosexual men.

Symptomatic anorectal gonococcal infection results in pruritis, tenesmus, bloody discharge, mucopurulent discharge, or severe pain. External inspection of the anus is generally unremarkable; however, nonspecific erythema and superficial ulceration may occur (Figure 17-2). Anoscopy reveals a thick purulent discharge, which classically is expressed from the anal crypts as pressure is applied externally on the anus. Nonspecific proctitis may be present with erythema, edema, friability, and pus. Diagnosis is confirmed by culture on selective media (Thayer-Martin or Modified New York City) incubated in a CO_2-rich environment and Gram's stain of directly visualized discharge.[12] The use of lubricants other than water may introduce antibacterial agents during anoscopy and decrease diagnostic yield. Nonculture detection of gonorrhea is being used more frequently especially in
FIGURE 17-1. Gram-negative intracellular diplococcus.

FIGURE 17-2. Anorectal gonorrhea.

TABLE 17-1. Treatment of anorectal gonococcal infection[14]

One of the following as a single dose:
Ceftriaxone – 125 mg IM
Ciprofloxacin – 500 mg orally
Ofloxacin – 400 mg orally
Levofloxacin – 250 mg orally
Cefixime – 400 mg orally

urethral and cervical infections. Nucleic acid amplification tests (NAATs), such as polymerase chain reaction (PCR), ligase chain reaction (LCR), and nonamplified DNA probes, provide sensitivities of greater than 95% but do not provide antibiotic susceptibility data. There are no NAATs currently licensed for the detection of rectal gonorrhea.[13]

Because of the prevalence of penicillinase-producing *N. gonorrhoeae* (PPNG) starting in the 1970s, penicillin G is no longer the drug of choice for gonorrhea. The most current recommended treatment regimen from the Centers for Disease Control (CDC) was published in 2002 and is listed in Table 17-1. Since publication of these guidelines cefixime has become unavailable in the US alternative regimens include spectinomycin (2 g as a single intramuscular injection), other cephalosporins (ceftizoxime, cefoxitin, and cefotaxime), and other quinolones. Only a few isolates reported by the Gonococcal Isolate Surveillance Report (GISP) in the past 10 years showed decreased susceptibility to the cephalosporins listed in Table 17-1.[15] Quinolone resistant *N. gonorrhea* (QRNG) have been detected in the past decade with increasing frequency in Asia and the Pacific. In the USA, this is particularly important in Hawaii (where QRNG may account for as much as 14% of gonorrhea isolates) and California. In the UK, the overall rate of QRNG was reported at 9.8% for 2002.[16] Concurrent HIV infection does not alter treatment for anorectal gonorrhea. Because of the high rate of concomitant infection with chlamydia, patients treated for gonococcal infections should be given appropriate treatment for chlamydia at the same visit or measures to exclude chlamydial infection should be taken.

Routine follow-up at 3 months is no longer necessary since current treatment provides near 100% efficacy. Patients with persistent symptoms after treatment should be followed and cultured as should those treated with nonstandard antibiotics. Sexual partners from the past 60 days should be treated and patient should abstain from intercourse until treatment is completed and symptoms resolved.

Chlamydia/Lymphogranuloma Venereum (LGV)

Chlamydia trachomatis is an obligate intracellular bacterium that is sexually transmitted and results in clinical infections that are similar to those caused by *N. gonorrhea*. Simultaneous infection with both organisms is common. Chlamydia is the most commonly reported STD in the USA with an annual incidence of about three million cases per year.[17] Aggressive screening programs have been credited with the decline of the Chlamydia infection rate from its peak of over four million per year in the early 1970s.

Anorectal transmission of chlamydia is through anoreceptive intercourse although secondary involvement can occur as a late manifestation of genital infection. Different serovars of *C. trachomatis* produce differing clinical illness. Serovars D through K (non-LGV) are responsible for proctitis and common genital infections. Lymphogranuloma venereum is caused by LGV serovars L1-L3. The incubation period for chlamydia is 5 days to 2 weeks. Non-LGV serovars are less invasive and cause mild proctitis (manifest by tenesmus, pain, and discharge) but asymptomatic infection is common. LGV serovars produce a much more aggressive infection with perianal, anal, and rectal ulceration. The proctitis produced can be difficult to distinguish from Crohn's disease (including microscopic findings of granulomas) with resulting rectal pain and discharge. Anoscopy and sigmoidoscopy demonstrate friable rectal mucosa, which is more severe in appearance (and extends above the rectum in some cases) in LGV strains.[18–20] Perianal abscesses, fistulas, and strictures may also occur. Lymphadenopathy develops in draining nodal basins, including the iliac, perirectal, inguinal, and femoral regions several weeks after initial infection. Large indurated matted nodes (Figure 17-3) and overlying erythema may produce a clinical picture similar to syphilis.

Diagnosis of chlamydia as the causative agent in proctitis can be difficult. Proper specimen collection increases diagnostic yield and consists of a cotton or Dacron swab with an inert shaft (plastic or metal). Specimen for tissue culture should be transported on specific medium and kept refrigerated or on ice until inoculated onto culture plates. Specimens that are to be tested by a nonculture technique are transported and stored in accordance with the test manufacturers guidelines. In patients with a clinical presentation consistent with chlamydia proctitis, rectal Gram's stain showing polymorphonuclear leukocytes without visible gonococci is presumptive for a diagnosis of chlamydia.[20]
FIGURE 17-3. Inguinal adenopathy of LGV; *LGV* lymphogranuloma venereum.

Tissue culture for chlamydia is relatively insensitive and is not widely available because of cost and technical requirements.[21]

Antigen detection by direct fluorescent antibody (DFA) or enzyme immunoassay DFA is highly specific, widely available and does not require rapid transportation or refrigeration. A trained microscopist is needed for interpretation. As with gonorrhea, newer NAATs are available. Their use is increasing in genital infection but unproven for anorectal chlamydia. A pilot study using both PCR and LCR techniques showed that these techniques can be effective for making this diagnosis but there are little additional data on the use of NAATs in anorectal chlamydia.[22]

The two recommended treatment regimens for rectal chlamydia (non-LGV) are azithromycin, 1 g orally as a single dose or doxycycline, 100 mg orally, twice a day for 7 days.[14] Alternative regimens include erythromycin (less effective, more GI side effects), ofloxacin (7-day course, more expensive), or levofloxacin (7-day course, no data on efficacy). Treatment of lymphogranuloma venereum is with doxycycline or erythromycin for 21 days. In patients with HIV and LGV prolonged therapy may be required. Management of sexual contacts is the same as for gonorrhea. Abstinence from sexual intercourse should last until 7 days after treatment with azithromycin or completion of 7 days of doxycycline.

Syphilis

Syphilis is an STD caused by the spirochete *Treponema pallidum* that can present in one of several progressive stages – primary (chancre or proctitis), secondary (condyloma lata), or tertiary. The incidence of syphilis had its recent peak of 107 cases per 100,000 people in the USA in 1991, but decreased to 2.2 per 100,000 in 2001, meaning that only 6,103 cases were reported. A slight increase in primary and secondary syphilis cases reported occurred in 2002.[23] These low rates have led to a national plan for eliminating syphilis.[24]

The primary stage of anorectal syphilis appears within 2–10 weeks of exposure via anal intercourse. The chancre begins as a small papule that eventually ulcerates. Anal ulcers are frequently painful (in contrast to genital ulcers) and without exudates. They may be single or multiple (Figures 17-4 and 17-5) and located on the perianal skin, in the anal canal or distal rectum. Differentiation from idiopathic anal fissures may be difficult. Painless but prominent lymphadenopathy is common. Proctitis from syphilis may occur with or without chancres.[18] Untreated lesions in this stage usually heal in several weeks.

Hematogenous dissemination of untreated syphilis leads to a secondary stage that occurs 4–10 weeks after primary lesions appear. Nonspecific systemic symptoms from this infection include fever, malaise, arthralgias, weight loss, sore throat, and headache. A maculopapular rash is seen on the trunk and extremities. Condyloma lata, another secondary manifestation, are gray or whitish, wart-like lesions that

FIGURE 17-4. Solitary anal chancre.

FIGURE 17-5. Multiple anal chancres.

appear adjacent to the primary chancre and are laden with spirochetes. Untreated, the symptoms of syphilis usually resolve after 3–12 weeks – of these patients, approximately one-fourth have a relapse of symptoms in the first year, a stage known as early latent syphilis.

Diagnosis in the primary or secondary stage is made by visualization of spirochetes on dark-field microscopic exam

FIGURE 17-6. Spirochetes demonstrated on dark-field microscopy.

of scrapings from chancres (Figure 17-6). Alternatively, spirochetes may be demonstrated on Warthin-Starry silver stain of biopsy specimens. A DFA test for *T. pallidum* (DFA-TP) is performed by some labs.[18,25] Serologic tests, rapid plasma regain (RPR) and Venereal Disease Research Laboratory (VDRL), have a false negative rate of up to 25% in primary syphilis and are called nontreponemal tests because they are not specific for *T. pallidum* infection. Positive nontreponemal tests should be confirmed by a treponemal test, such as the fluorescent treponemal antibody absorption test (FTA-ABS), which remains positive for life.

A single intramuscular injection of 2.4 million units of benzathine penicillin G is the treatment for primary and secondary syphilis. Penicillin-allergic patients are treated with doxycyline (100 mg orally, twice daily for 14 days) or tetracycline (500 mg orally, four times a day for 14 days). Follow-up serology (VDRL or RPR) should be checked at 6 months after therapy for HIV negative patients and every 3 months for HIV positive patients.[14] Treatment failures are retreated with the same dose of penicillin but at weekly intervals for a total of 3 weeks. Partner notification, testing, and treatment depends on stage at diagnosis of the index case. At-risk partners include sexual contacts (a) within the prior 3 months plus duration of symptoms for patients with primary syphilis; (b) within the prior 6 months plus duration of symptoms for patients with secondary syphilis and; (c) within the prior year for those with early latent syphilis.[26]

Chancroid

Chancroid is an ulcerating STD caused by the gram-negative, facultative anaerobic bacillus *Hemophilus ducreyi*. While there were approximately 5,000 cases reported per year in the late 1980s and early 1990s in the USA, there were fewer than 200 cases reported in 1999.[1] It is much more common in developing countries with a global incidence estimated at six million.[27]

Transmission of *H. ducreyi* is strictly via sexual contacts through breaks in the skin during intercourse and results in genital ulcers. The initial manifestation (hour to days after exposure) is as infected tender papules with erythema that subsequently develop into pustules and then (days to weeks) become ulcerated and eroded. Multiple ulcers are common and are generally painful, especially in males. While chancroid ulcers are most commonly located on the genitalia, perianal abscesses and ulceration may occur. Anal ulcerations in females may be the result of drainage from adjacent genital infections. Differentiation of other ulcerating STDs cannot be made on gross appearance in most cases.[28] Painful inguinal adenopathy accompanies half of cases in males and is usually unilateral. Females are less likely to develop adenopathy from *H. ducreyi* infection.[29] Abscess formation may result, necessitating drainage. Besides causing genital ulcers, *H. ducreyi* facilitates transmission of HIV and vice versa.

Diagnosis of chancroid is made by Gram stain and culture of *H. ducreyi* (on selective medium agar) from the base of ulcers. Gram stain is only 40–60% sensitive relative to culture and demonstrates nonmotile Gram-negative rods in small groups. *H. ducreyi* is difficult to culture and many labs in the USA are not equipped to perform this test. PCR is more sensitive than culture for detecting *H. ducreyi* but is not commercially available at this time.[30] Treatment for *H. ducreyi* is single dose treatment with azithromycin (1 g, orally) or ceftriaxone (250 mg, intramuscularly). Alternatively, regimens include ciprofloxacin, 500 mg orally twice a day for 3 days or erythromycin 500 mg three times a day for 1 week.[14]

Granuloma Inguinale (Donovanosis)

Donovanosis is an ulcerating infection of the genitalia and anus caused by *Calymmatobacterium granulomatis* (also called *Donovania granulomatis*). Transmission is believed to occur from both sexual and nonsexual contact. It is rarely seen in the USA but is common in parts of Africa, South America, and Australia. Morphologic manifestations include and ulcerogranulomatous form (nontender, fleshy, beefy red ulcers), hypertrophic or verrucous lesions, necrotic ulcers, or cicatrical. Genital involvement is most common but contiguous involvement of the anorectum occurs. Development of sclerotic lesions causes anal stenosis.[31]

C. granulomatis cannot be cultured by routine techniques. Diagnosis can be made by tissue smear or biopsy that reveals Donovan bodies (small inclusions) within macrophages. Several antibiotic regimens have been recommended, although the most recent CDC guidelines are doxycycline (100 mg orally, twice daily for 1 week) or trimethoprim-sulfamethoxazole (one 800 mg/160 mg tablet orally, twice a day for at least 3 weeks).[14] Alternative treatments include at least 3 weeks of ciprofloxacin, azithromycin, or erythromycin. Some authors believe azithromycin to be the preferred treatment.[31]

Diagnosis and Management of Viral Pathogens

Herpes Simplex Virus

HSV is a DNA virus of the family Herpesviridae that includes Varicella-Zoster virus, Epstein–Barr virus, and Cytomegalovirus (CMV). Herpes is the most prevalent STD in the USA with current the seroprevalence rate for HSV-2 estimated to be 20% for the general population.[32] Black females are the subgroup with the highest seroprevalence at 55%. Two serotypes of HSV are described. HSV-2 has been most associated with anogenital herpes infections. HSV-1 infection most commonly presents as labial oral or ocular lesions but accounts for about 30% of genital infections. Several recent reports have shown an increasing percentage of genital infections due to HSV-1;[33,34] asymptomatic infection with HSV is common.

Transmission is via close contact with an individual who is shedding the virus and infection results from penetration of mucosal surfaces or breaks in the skin. Productive infection causes viral replication within cells and cell death. Clinical infection presents first with systemic symptoms, such as fever, headache, and myalgias, followed by local symptoms, including pain and pruritis. Vesicles appear over the anogenital area, increase in number and size, and eventually ulcerate and coalesce (Figures 17-7 and 17-8). These vesicles and ulcerations generally heal over a mean time of 3 weeks.

Anorectal involvement by HSV-2 is acquired by anorectal intercourse and is second only to gonorrhea as a cause of proctitis in homosexual men. Herpetic infection of the anorectum results in severe anal pain, tenesmus, hematochezia, dysuria, and rectal discharge. The proctitis seen is typically limited to the distal 10 cm of the rectum with diffuse friability. Simultaneous with infection, HSV moves through peripheral sensory nerves to sensory or autonomic nerve root ganglia. Sacral radiculopathy of the lower sacral roots from this infection causes sacral paresthesias and neuralgias, urinary retention, constipation, and impotence. Tender inguinal adenopathy occurs in half of patients with HSV proctitis.[35]

Herpes has the ability to persist in their host because of latency – the viral genome maintained in a stable condition in host cell nuclei. For HSV, the site of latent infection is the sensory ganglia of nerves innervating the site of infection. Reactivation of latent virus results in recurrent infection but the stimuli for this process are poorly understood.[36] Recurrent attacks are generally milder, shorter in duration, and without the constitutional symptoms that occur with initial infection.

Diagnosis is frequently made by clinical evidence although cultures taken from ulcerations, rectal swabs, or biopsies confirm the diagnosis. Multinucleated giant cells with intranuclear inclusion bodies (ground-glass appearance) on Pap smear or Tzank prep are less sensitive than viral culture. Direct immunofluorescence has also been used for diagnosing HSV.[18] For cases in which cultures are not available, paired type-specific serology demonstrating seroconversion is diagnostic. In the past 5 years, the Food and Drug Administration (FDA) have approved several commercially available HSV serology tests. These tests have specificities and sensitivities greater than 90% and are sure to become more commonly used in the diagnosis of HSV.[37,38] It should be noted that seroconversion may take several weeks after initial infection and repeat testing intervals are dependent on the particular serology kit used.[39]

Treatment of patients with anorectal herpes includes comfort measures, such as warm soaks and oral analgesics. The only prospective randomized trial of antiviral treatment for herpes proctitis demonstrated a shortened duration of symptoms and period of viral shedding with oral acyclovir 400 mg, five times a day for 10 days.[40] A three times per day dosing has been shown to be effective for genital herpes but has not been evaluated for herpes proctitis.[41] Other antiviral agents, such as valacyclovir and famciclovir used for genital herpes, are most likely effective for HSV proctitis at
FIGURE 17-7. Perianal herpes.

FIGURE 17-8. Perianal herpes.

the same doses used for genitourinary infection but clinical studies for this indication are lacking. Severe mucocutaneous HSV infection in which the patient cannot tolerate oral medication warrants intravenous acyclovir. Topical acyclovir has limited efficacy and is not recommended. Treatment of initial episodes of HSV do not prevent latency, asymptomatic viral shedding, or the course of subsequent episodes. Recurrent episodes may be treated with oral antiviral agents. Valacyclovir (500 mg twice a day) and acyclovir (200 mg five times a day) have demonstrated equal efficacy in treating genitourinary HSV recurrences.[42] Prompt initiation of treatment at the onset of symptoms of HSV recurrence reduces the duration of symptoms and healing times. Patients who experience more than five recurrences per year are considered for suppressive treatment. Valacyclovir, acyclovir, and famciclovir have all demonstrated 70% or greater reduction compared to placebo.

As with all STDs, counseling of patients with HSV is an important part of treatment and prevention.[41,42] Specific items that should be addressed are (1) infectivity is not isolated to symptomatic outbreaks; most sexual HSV transmission occurs during asymptomatic periods; (2) latent infection and the risk of recurrence; suppressive therapy does not eliminate latent infection or viral shedding; (3) abstinence is recommended while lesions are present. Condoms are advised for all other times although they most likely provide incomplete protection. Most recently, once-daily administration of valacyclovir has been shown to reduce the risk of HSV-2 transmission between HSV-2 seropositive patients and there seronegative sexual partners.[43]

Human Papilloma Virus

HPV is a DNA papovirus. It is the most common STD in the USA with an estimated incidence of over five million cases per year.[1] There are over 80 subtypes of HPV, almost one-third of which cause anogenital warts. Subtypes 6 and 11 are the most common of the low-risk HPV subtypes while subtypes 16 and 18 have the greatest associated risk of anal dysplasia and anal cancer. Transmission is vial sexual contact with infected individuals with or without gross lesions and asymptomatic infection is common. Perianal involvement can occur in the absence of receptive anal intercourse.

Presenting complaints of perianal or anal condyloma accuminata include the presence of a growth, pruritis, bleeding, chronic drainage, pain, and difficulty with hygiene. Physical examination is generally all that is required for diagnosis and shows the characteristic gray or pink fleshy, cauliflower-like growths of variable size in the perianal region (Figure 17-9). Anoscopy is an integral part of the evaluation. In the anal canal, the lesions tend to be small papules and involvement above the dentate line is rare. Examination should focus on the genitalia, including vaginal speculum exam and Pap smear, as well as evaluation of the perineum and groin folds.
FIGURE 17-9. Perianal condyloma.

The goal of treatment of condyloma accuminata is destruction or removal of all obvious disease while minimizing morbidity, although this process does not ensure eradication of infection. Tangential excision, cryotherapy, or fulguration of small lesions can be performed as an office procedure with a local anesthetic, and causing little discomfort or inconvenience to the patient. Larger lesions are treated by electrodessication. The patient is placed in the lateral or prone jack-knife position. Depending on the size and number of lesions local, spinal, or general anesthesia is used. The superficial-most layer of the condyloma is fulgurated with the electrosurgery tip until the lesion takes on a gray–white appearance. This step is followed by curettage or simply abrading the fulgurated tissue with gauze. The process is repeated until the condylomas are completely removed without burning into the deep dermis or subcutaneous fat. Pedunculated warts are simply transected at their base. Tissue from HIV+ patients, recurrent lesions, flat lesions, or those suspicious lesions which may be ulcerated, friable, or hypervascular should be sent for histopathologic evaluation. Topical 5% lidocaine is helpful in decreasing postoperative pain. Oral analgesics

and daily cleansing with mild soap and water are all that is required for postoperative care in most patients. Silver sulfadiazine or mupirocin are applied in cases in which postoperative bacterial infection is suspected. Overall condyloma clearance rates for surgical techniques range from 60 to 90% with recurrence rates of 20–30%.[44]

The patient can apply topical agents like podofilox and imiquimod although neither agent is approved for use in the anal canal. Podofilox is the purified active component of the antimitotic plant resin podophyllin and is available as a 0.5% gel or solution. A treatment cycle consists of twice daily application for 3 days followed by no treatment for 4 days utilized for up to 1 month. Toxicity concerns are less than those issues with podophyllin while clearance rates for condyloma of 35–80% have been reported. Recurrence rates in patients treated with podofilox are 10–20%.[44–48] Imiquimod is an immune response modifier that increases local production of interferon. A complete response can be expected in 50% of patients treated with imiquimod with 11% of patients experiencing a recurrence.[44,49–51] It is applied at bedtime three times a week, left in place for 6–8 h and then removed by washing; treatment may take up to 16 weeks. One study demonstrated no benefit to increased dosing frequency from one to two or even three times daily.[52] Side effects of imiquimod include pain burning, itching, and ulceration which may require cessation of therapy. Imiquimod is used (1) as initial treatment with electrodessication reserved for those who have incomplete response or (2) following destructive treatment and epithelial healing to treat remaining disease or decrease recurrence (no randomized data to support this use). Currently, imiquimod is not approved for anal canal use but this application is being investigated.[53] Trichloracetic acid is applied topically and is useful for treating small lesions in the anal canal. Topical and intralesional interferon have been used to treat condyloma accuminata with mixed results. Other agents that have been used to treat anogenital condyloma but are not in widespread use include 5-FU cream, cidofovir and autologous vaccine.

Bushke and Loewenstein first described giant condyloma accuminata (GCA) in 1925.[54] They are most associated with HPV types 6 and 11 but histologically demonstrate some differences from ordinary condyloma – marked papillomatosis, acanthosis, thickened rete ridges, and increased mitotic activity. The substantial percentage of cases with in situ or invasive squamous cell cancers has lead to speculation that GCA represents part of a continuum from condyloma to invasive squamous cell cancer.

Wide local excision with a 1 cm margin is the treatment of choice for these lesions. Local tissue flaps or grafted skin may be required to repair surgical defects. Abdominal–perineal resection has been used for GCA involving the anal sphincters. Chemoradiation is also an option in the treatment of GCA, especially in those patients who are poor surgical candidates or in whom clear surgical margin are not attainable.[55] Complete regression of GCA with chemoradiation has been reported.[56]

HPV, Anal Intraepithelial Dysplasia, and Anal Cancer

While it is clear that HPV plays a significant role in the development of cervical cancer, its significance in the development of anal cancer (Figure 17-10) and its presumed precursor, anal intraepithelial dysplasia, is not as well defined. Parallels can be drawn between the anal canal and the cervical canal as they share embryologic and histologic features. Furthermore, both canals derive from the embryonic cloacal membrane and both are areas where ectodermal and endodermal tissues fuse to form a transition zone from columnar epithelium to squamous epithelium.

Epidemiologic parallels can be drawn as well. Studies prior to the HIV infection epidemic showed the incidence of anal cancer in homosexual males to be 12.5–37 per 100,000 in the USA[57] This incidence is similar to the incidence of cervical cancer prior routine Pap testing. The risk of anal cancer developing in an HIV+ homosexual male is estimated to be 38 times that of the general population and twice the risk of an HIV– homosexual male.[57,58] HPV infection has been reported in 93% of HIV+ homosexual males compared to 60% of HIV– homosexual males.[55]

Anal cytology has been suggested as a screening tool for detecting patients with anal dysplasia. Applying the current cervical cytology terminology specimens are designated normal, atypical squamous cells of indeterminate significance (ASCUS), low-grade squamous intraepithelial lesions (LSIL), or high-grade squamous intraepithelial lesions (HSIL). The benefit and best timing of this screening is undetermined. Evaluation and treatment algorithms as well as recommended testing schedules have been reported.[59,60] One such evaluation and treatment algorithm recommends high-resolution (with acetowhitening and staining with Lugol's solutions) anoscopy with biopsy.[60] Subsequent treatment is based on histologic findings which are typically reported as normal or anal epithelial neoplasia (AIN) I, II, or III. Options for treatment include local destruction (with topical agents,

FIGURE 17-10. Anal cancer in HIV-positive patient; *HIV* human immunodeficiency virus.

cryotherapy, or fulguration), excision, or observation. However, there are limitations of our understanding of the relationship between HPV, AIN, and anal cancer that prevent the dogmatic recommendation and widespread acceptance of such an approach. First, the incidence and predictability of the progression of AIN to invasive cancer is unclear.[61,62] The lack of inter- and intraobserver agreement in the interpretation of AIN no doubt contributes to this lack of understanding.[63] Second, data demonstrating efficacy, which is defined as long-term removal of AIN and prevention of anal cancer of treatment is lacking. The absence of established benefit combined with the morbidity of treatment leads us and others to the recommendation that AIN, regardless of grade, be observed unless there are gross visual or palpable lesions or ulcerations present.

Two additional comments with regard to the association of HPV, HIV, and AIN should be made. First, the use of HAART (discussed further later in the section on HIV) does not reduce the incidence of AIN.[64] The clinical implications of this fact are: (a) anal cytology screening should not be stopped just because a patient is treated with HAART and (b) with HIV patients living longer secondary to HAART, the incidence of anal cancers may increase. Second, the prevalence of HPV and AIN is high in HIV positive males with CD4+ counts less than 500×10^6 cells/L even in the absence of a history of anal intercourse.[65] These patients should also be considered for cytologic screening.

Molluscum Contagiosum

The molluscum contagiosum virus is a member of the poxvirus family and causes a benign papular condition of the skin. Transmission is by sexual and nonsexual contact. The incubation period is 1–6 months, followed by the development of 2–6 mm flesh-colored, umbilicated papules.[66] Symptoms are uncommon though pruritis or tenderness may occur. Immunocompromised hosts, such as those with HIV, are more prone to infection with molluscum contagiosum (compared to HIV negative) and may have a more severe form of the disease with hundreds of lesions. Diagnosis is usually made on clinical grounds but excisional biopsy demonstrates enlarged epithelial cell with intracytoplasmic molluscum bodies. Treatment is generally through eradication with curettage, electrodessication or cryotherapy. Podophyllotoxin (0.5%) and imiquimod (5%) have both been used as self-applied topical preparations with success,[67,68] although neither compound is FDA approved for this use.

HIV and the Acquired Immunodeficiency Syndrome

Infection from the HIV (originally called human t-lymphotropic virus) related to acquired immunodeficiency syndrome (AIDS) was first described in 1983.[69] The most current data available show that in 2005 there were approximately 433,760 people in the USA with AIDS and another 215,653 with HIV infection not meeting the criteria for AIDS.[70] Cumulative totals showed a total of 984,155 cases of AIDS in the USA through 2005 and a death rate of 51% in this group. While the incidence of HIV infection has apparently stabilized, the numbers of new AIDS cases and deaths from AIDS have decreased. This fact is in large part due to HAART – combinations of potent anti-HIV drugs which are nucleoside analogs, nonnucleoside reverse transcriptase inhibitors, or protease inhibitors. Table 17-2 shows the current classification system for patients who are HIV positive.

TABLE 17-2. Revised classification system for HIV and AIDS[72]

CD4+ T-lymphocyte categories
Category 1: greater than or equal to 500 cells/μL
Category 2: 200–499 cells/μL
Category 3: less than 200 cells/μL
Clinical categories
Category A: HIV positive; asymptomatic; persistent generalized lymphadenopathy
Category B: Symptomatic conditions not listed in clinical category C; are conditions that are attributed to HIV infection; or conditions that have a clinical course or require management that is complicated by HIV infection. Examples include: bacillary angiomatosis, oropharyngeal or vulvovaginal candidiasis, cervical dysplasia, diarrhea (greater than 1 month in duration), more than one episode of herpes zoster, pelvic inflammatory disease, peripheral neuropathy
Category C: Diagnoses included in the AIDS surveillance case definition – candidiasis (pulmonary or esophageal), invasive cervical cancer, Coccydiomycosis, extrapulmonary cryptococcosis, chronic intestinal Cryptosporidiosis, Cytomegalovirus disease (other than liver, spleen, nodes) or retinitis, HIV-encephalopathy, HSV (chronic ulcers, pulmonary or esophageal), Histoplasmosis (disseminated or extrapulmonary), Isosporiasis (chronic intestinal), Kaposi's sarcoma, Burkitt's lymphoma, immunoblastic lymphoma, primary brain lymphoma, Mycobacterium avium complex or any mycobacterium species other than M. tuberculosis (extrapulmonary or disseminated), Mycobacterium tuberculosis, Pneumocystis carinii pneumonia, progressive focal leukoencephalopathy, recurrent Salmonella septicemia, Toxoplasmosis of the brain, HIV wasting syndrome

CD4+ categories	Clinical categories		
	A1	B1	*C1*
	A2	B2	*C2*
	A3	*B3*	*C3*

Bold italic groups are defined as AIDS.

Surgery for anorectal diseases is the most common indication for surgery in HIV infected patients and in 5% of patients, their anorectal complaint is the presenting symptom of their HIV infection.[71] Most of the indications for surgery are common to the population at large but some are unique to AIDS patients. Several studies demonstrate poor wound healing and increased morbidity in the surgical treatment of anorectal disease in AIDS patients.[72–74] Delayed or failed wound healing has been associated with the presence of AIDS, decreased absolute leukocyte count, and decreased CD4 count. Morandi et al. found that at 32 weeks after hemorrhoidectomy, 50% of AIDS patients had incompletely healed wounds. The overall complication rate was significantly higher in the AIDS group than in HIV+ patients without AIDS.[73] Conversely, Lord reported decreased wound healing in HIV+ patients with T-lymphocyte count of less than 50.[75] Others have shown longer interval and decreased complete wound healing in HIV+ patients with CD4+ T-lymphocyte counts of less than 200.[74] The studies reviewed above describe patients who were not treated with HAART. There is a lack of data describing wound healing in anorectal surgery since the widespread use of HAART; however, the observation of the authors is that compensated HIV+ patients are at no significant risk of increased complications from anorectal surgery. Other factors to be considered in selecting appropriate treatment include any untreatable diarrheal conditions, degree of existing fecal incontinence, and the effect of the proposed surgical procedure on incontinence.

Anal fissures that occur in HIV+ patients must be distinguished from idiopathic AIDS-related anal ulcers (Figure 17-11) and ulcerating STDs, such as HSV or syphilis. Anal fissures in this patient population are indistinguishable from those in the general population and their treatment is similar – initial conservative management with surgery for treatment failures.[76,77] Treatment of fissures in HIV+ patients is modified by the factors described previously and include controlling diarrhea when possible and encouraging abstinence from anoreceptive intercourse.
FIGURE 17-11. AIDS and ulcer.

While data on the incidence of AIDS-related anal ulcers is lacking, it appears that they are less common with HAART because the lesions are most frequently associated with clinical AIDS and lower CD4+ counts. These ulcers can be distinguished from typical anal fissures because they are more proximal in the anal canal (frequently above the dentate line or anorectal ring), broader based, deeply ulcerating with the destruction of sphincter planes, and may demonstrate mucosal bridging. Debilitating pain is a common presenting symptom of these ulcers. Surgical debridement allows for adequate drainage of feculent or purulent material trapped in the ulcer and removal of necrotic debris. Biopsy and culture identifies potentially treatable causes for ulceration – malignancy, acid-fast bacilli, HSV, *H. ducreyi*, *T. pallidum*. CMV has been cultured from these ulcers by some authors but is apparently not causal and therefore does not require treatment. Intralesional injection with steroids (methylprednisolone 80–160 mg, in 1 cc 0.25% bupivacaine) provides relief in the majority of patients but not healing.[78] Patients who have persistent pain are reinjected at their ulcer sites.

Perianal suppurative diseases are common conditions in AIDS patients. Abscesses should be drained using small incisions and the placement of a mushroom catheter lessens recurrent sepsis. Broad spectrum antibiotics should be given in immune compromised especially if cellulitis is present. Culture (to include mycobacterium) and histopathologic evaluation identifies infection from atypical organisms and malignancy.

Naldal et al. reported on fistulotomies performed in 31 HIV+ patients. Seven patients had failure of wound healing and all had clinical AIDS, CD4+ counts of less than 200, and absolute leukocyte counts of less than 3,000/mm³.[74] Based on this, the authors treat anal fistulas in AIDS patients with high viral loads and low CD4+ counts similar to Crohn's patients. Draining setons are placed liberally with selective use of fistulotomy for low uncomplicated fistulas. Fistulotomy in HIV+ patients with AIDS and normal CD4+ counts is based on criteria similar to HIV− patients.

Thrombosed external hemorrhoids in patients with AIDS are treated the same as for HIV− patients. Acute thrombosis (24–48 h after onset of symptoms) is treated with excision. Subacute thrombosis (longer than 48 h from symptom onset) is treated conservatively with Sitz baths and oral analgesics.

Internal hemorrhoids present with symptoms of bleeding or prolapse. Initial treatment in patients with AIDS is with a high fiber diet and bulking agents. Proximal colonic sources of bleeding should be excluded via colonoscopy. Patients who fail initial conservative measures are treated with rubber band ligation or infrared coagulation. Other nonoperative techniques, such as bipolar coagulation, cryotherapy, or injection sclerotherapy, are acceptable. There are conflicting recommendations for operative treatment of hemorrhoids published within the last decade. In a retrospective study, Hewitt et al. found no difference in wound healing between HIV+ and HIV− patients.[79] The mean CD4+ count was 301 but they classified 81% of patients as having AIDS based on

symptoms or CD4 count less than 200. In the discussion, the authors comment that the majority of their patients were well nourished and otherwise healthy. They conclude that HIV status should not alter the indications for surgery in patients with symptomatic hemorrhoids. In contrast, as mentioned, Morandi et al. prospectively evaluated healing time after hemorrhoidectomy.[73] Functional status and the presence of AIDS were the two factors that correlated with poor wound healing. AIDS patients with nonhealing had a mean CD4+ count of 79. Unfortunately, they do not comment relief of hemorrhoid symptoms. It appears that asymptomatic HIV+ patients and who do not meet the clinical or CD4+ count diagnostic criteria for AIDS (Table 17-2) can be treated with hemorrhoidectomy with the expectation that they have good symptomatic relief and normal wound healing. AIDS patients with more advanced disease (clinical category C) or low CD4+ counts (especially less than 100) are at increased risk for wound healing problems. The benefit of symptomatic relief may still warrant performing surgical treatment in this group.[76]

Fecal Incontinence

Dana R. Sands and Mari A. Madsen

Introduction

Fecal incontinence is a socially devastating condition, affecting between 1.4 and 18% of the population and up to 50% of all nursing home residents.[1,2] It has been defined as "recurrent uncontrolled passage of fecal material for at least 1 month,"[3] while partial incontinence is typically described as inability to control the passage of flatus and fecal soiling.

Populations at risk for fecal incontinence include: parous females, patients with cognitive impairment, neurologic disorders, and nursing home residents.[4,5] In fact, fecal incontinence is the second leading reason for admission to nursing homes.[6] As a result of the social stigma and the fear for loss of autonomy, the true incidence of this problem is believed to be vastly under reported. It has been dubbed the "silent affliction."[7]

Etiology

It is important to realize that fecal incontinence is not a diagnosis, but a symptom of which there are multiple causes. Normal bowel continence requires a complex integration of function between the anal sphincters, pelvic floor, stool volume/consistency, rectal compliance, and neurologic function. It is first necessary to determine if the patient is having true fecal incontinence. Pseudo incontinence can be caused by a variety of anorectal conditions including hemorrhoidal prolapse, incomplete evacuation, poor hygiene, fistula-in-ano, dermatologic conditions, anorectal sexually transmitted diseases (STDs), and anorectal neoplasms. Fecal urgency from a noncompliant rectum can also cause incontinence. Consideration should be given to other disease states such as inflammatory bowel disease and radiation proctitis. The diagnosis of overflow incontinence from incomplete rectal evacuation should also be entertained in patients whose history indicates this condition.

A thorough history will allow the examiner to diagnose a diarrheal state as the etiology of the incontinence. Any change in bowel habits with diarrhea should be excluded.

Various systemic disease states can affect continence. In the appropriate patient, central nervous system pathology including spinal cord injury and neoplasm should be part of the differential diagnosis. Autonomic neuropathies such as diabetes can also cause derangements in continence.

Perhaps the more common etiologies of incontinence treated by the colorectal surgeon are those that pertain to abnormal pelvic floor function. Anal sphincter injury can be the result of obstetric injury, direct trauma, neoplasm, or rectal prolapse. Obstetric injury is a common occurrence with occult tears of the anal sphincter reported in 25–35% of women after vaginal delivery.[8,9] The incidence of obstetric tears has been reported from 0.6 to 9% in the literature.[10,11] Factors that affect the risk for developing obstetric tears are use of forceps, mediolateral episiotomy, and primiparity.[12,13]

Denervation injuries to the pelvic floor are also common sequelae of childbirth; 60% of patients with an obstetric tear also have evidence of pudendal nerve damage.[14,15] The mechanism of pelvic floor denervation appears to be a result of compression or traction injury to the pudendal nerves during vaginal delivery, particularly when it is prolonged or requires forceps assistance. High birth weight is also a risk factor for compression injury. The end stage of denervation injury is pelvic floor failure and descending perineum syndrome.

Iatrogenic injury to the anal sphincter musculature is also a cause of fecal incontinence. Incontinence after surgery for fissure with lateral internal sphincterotomy is not uncommon.[16,17] Fistulotomy is also associated with seepage and soiling and incontinence rates reported as high as 35–45%.[18,19] Local sphincter lesions and intra-anal scarring (keyhole deformity) are not the sole explanation for the high incidence of incontinence since it also occurs after non-muscle-cutting anorectal surgery such as anal stretch,[20] hemorrhoidectomy,[21] and transanal advancement flaps.[22]

Patients who have suffered from congenital malformations including spina bifida, imperforate anus, and myelomeningocele often have severe alterations of continence and evacuatory function. The difficulty is related not only to the function of the pelvic floor musculature but also to the

proprioceptive response of the rectum. Radiation therapy can result in fecal incontinence from both a direct damage to the anal sphincter as well as through its effect on the compliance of the rectum.

Diagnosis

History

The first step in the evaluation of any medical condition is to attain a thorough patient history. Patients with fecal incontinence are often embarrassed and reluctant to provide details of the problem unless specifically asked. It is important to create a comfortable environment for the patient during the history and physical examination. The onset of the symptoms can provide useful insight into the etiology of the problem. A thorough obstetric and surgical history is imperative. Other neurologic conditions should be considered as well. Changes in bowel consistency are a common cause of fecal incontinence which can be overlooked by many physicians. Any cause of diarrhea should be explored as a potential etiology of the patients' symptoms especially if there is a temporal relationship.

After appropriate questioning, the physician will often be able to determine if the patient has active or passive incontinence. Active (urge) incontinence, or the loss of stool despite the patients' best efforts to control it, will lead the physician to consider etiologies which involve an intact sensory mechanism with a derangement in the external anal sphincter function.[23] Passive incontinence, or the loss of stool without the patient's awareness, will lead the examiner to consider internal anal sphincter pathology or neurologic etiologies.

It is helpful to quantify the degree of the fecal incontinence. Numerous scoring systems have been used to evaluate incontinence. When utilizing these tools, it is important to take into account the impact of the patient's perception of the severity of their symptoms and their response to treatment.[24] The Cleveland Clinic Florida Fecal Incontinence Score (CCF-FIS) is an independently validated tool which has the benefit of ease of use combined with incorporation of a quality of life component (Table 18-1).[25]

An often overlooked component of the history of the patient suffering from fecal incontinence is the presence of other pelvic floor complaints. Physicians should be sure to inquire about the presence of any form of rectal prolapse as well as the presence of urinary incontinence or genital organ prolapse. It has been noted that there is a significant overlap of symptoms in this complex patient population.

Physical Examination

A complete physical examination will include inspection of the perianal skin for scars from prior surgeries, trauma or birthing injuries, fistulae, excoriation from chronic soiling,

TABLE 18-1. Cleveland Clinic Florida Fecal Incontinence Score (CCF-FIS)

Type of incontinence	Frequency				
	Never	Rarely	Sometimes	Usually	Always
Solid	0	1	2	3	4
Liquid	0	1	2	3	4
Gas	0	1	2	3	4
Pad usage	0	1	2	3	4
Lifestyle impact	0	1	2	3	4

0 = perfect continence.
20 = complete incontinence.
Never = 0, rarely = <1/month, sometimes = >1/month, <1/week, usually = >1/week, <1/day, always = >1/day.

or large prolapsing hemorrhoids. A specific evaluation of the perineal body in parous females should include palpation to determine if it is thinned. At rest, the anal canal should be well approximated, not patulous. A patulous anus suggests a possible rectal prolapse, which is best reproduced by asking the patient to Valsalva while sitting on a toilet or squatting. Checking the perianal sensation to pinprick as well as the anocutaneous "wink" reflex will serve as a simple assessment of neurologic function.

Digital rectal examination can reveal masses or a fecal impaction. It also provides a gross assessment of both resting tone and voluntary squeeze. With some attention, it is possible to discern contraction of the puborectalis in the upper canal versus constriction of the external anal sphincter. Lastly, anoscopy or potentially a rigid vs. flexible proctosigmoidoscopy may reveal inflammatory bowel disease, infectious proctitis, or neoplastic process if suspected.

Diagnostic Studies

Endoanal Ultrasound

Endosonography has become the diagnostic cornerstone of the anorectal physiologic evaluation of fecal incontinence. Endoluminal ultrasonography has been utilized extensively to delineate anal canal anatomy. Pulsed sound waves emitted from a luminally placed transducer create transverse images of the anal canal. The efficacy of this technique was demonstrated by Sultan et al.[26] who have used cadaveric and surgical specimens to correlate ultrasonographic findings with anatomic dissection. Their findings were further confirmed with histopathologic evaluation of the dissected specimens. This test is well tolerated and provides physicians with important information about the anatomy of patients suffering from incontinence, fistulous disease, and anal pain. The ultrasound provides excellent imaging of the internal anal sphincter which appears hypoechoic (Figure 18-1). The external sphincter is hyperechoic and scar tissue often has a mixed echogenecity appearance. Obviously, the most important parameter is to determine if the musculature is intact or if there are traumatic defects present. When present, defects
FIGURE 18-1. Normal endoanal ultrasound. The *red line* illustrates the lateral border of the external anal sphincter (hyperechoic) while the *yellow depicts* the lateral border of the internal anal sphincter (hypoechoic).
FIGURE 18-2. Endoanal ultrasound with anterior sphincter defect (internal and external).

in the musculature should be measured. Additionally, the perineal body thickness (PBT) should be measured. PBT less than 10 mm is considered abnormal, and those patients with PBT greater than 12 mm are considered unlikely to have a sphincter defect in the absence of prior reconstructive surgery (Figure 18-2).[27]

Anorectal Manometry

Anorectal manometry provides important information about the functional status of the anal sphincters and distal rectum. There is no standardized method of manometric evaluation.

Several methods have been described.[28] Microtransducers can be used in the anal canal and are well tolerated by patients. Multichannel water-perfused catheters are perhaps the most common tool used to perform anal manometry. Flow rates of 0.3 mL per channel per minute are required to adequately measure outflow pressure.[29] Higher flow rates can result in accumulation of fluid and distortion of the measurements.

The resistance of flow of fluid from the catheter determines pressure measurements. Measurements can be taken in a continuous fashion (continuous pull through) or at set levels within the anal canal (station pull through). The continuous pull-through technique requires the catheter to be removed at a continuous speed from the anal canal. A computerized motor is used for this purpose. This technique can provide a detailed recording of both the radial and longitudinal pressure profiles. Computer analysis can then generate a three dimensional representation of the anal canal. The stationary pull-through technique measures anal canal pressures at 1 cm increments in the anal canal. It has been theorized that this method provides a more accurate assessment of anal pressures because there is a stabilization period before each reading, thereby reducing artifact.[30]

Measurements

Resting Pressure. The mean resting pressure in healthy volunteers ranges from 40 to 70 mmHg. The internal anal sphincter generates the majority of the resting pressure.[31] This smooth muscle is in a continuous state of maximal contraction accounting for 55–60% of resting tone. The external anal sphincter contributes less to the resting anal tone. The final determinant of resting anal tone is the contribution of the hemorrhoidal plexi. Patients with alterations in continence related to the internal anal sphincter often have low baseline resting pressure.

Squeeze Pressure. The maximal squeeze pressure in healthy individuals is two to three times the baseline resting value. The external anal sphincter is the main contributor to the generation of these pressures. Traumatic defects of the external anal sphincter, whether from obstetric or surgery, often result in decreased squeeze pressures.

High-Pressure Zone. The high-pressure zone is defined as the length of the internal anal sphincter, through which pressures are greater than half of the maximal resting pressure. The high-pressure zone is approximately 2–3 cm in women and 2.5–3.5 cm in men.[28]

Rectoanal Inhibitory Reflex. The rectoanal inhibitory reflex (RAIR) is thought to play a role in the fine adjustments of continence. Rectal distension, usually with small volumes (10–30 mL), causes a contraction of the external anal sphincter followed by a pronounced internal anal sphincter relaxation. This reflex enables the sensory mucosa of the anal canal to "sample" the contents of the distal rectum and the patient to distinguish between gas, liquid, and solid stool. This reflex is

absent or abnormal in patients with Hirschsprung's disease, Chagas' disease, dermatomyositis, and scleroderma.

Rectal Sensation. Alterations in rectal sensation can lead to decreased fecal continence. Rectal sensation is measured with an intrarectal balloon and incremental instillation of known volumes of air. Sensation is generally achieved with 40 mL air. Overflow incontinence can result from a decrease in rectal sensation and subsequent fecal impaction.

Rectal Compliance. Compliance is determined by the change in pressure associated with a change in volume ($C = V/P$). This is calculated by subtracting the volume of first sensation from the maximum tolerable volume and dividing by the change in pressure at these two points. A noncompliant rectum can contribute to fecal incontinence as the patient is not able to accommodate the amount of stool presented to the rectum. This is common in conditions which cause proctitis.

Pudendal Nerve Terminal Motor Latency

Pudendal neuropathy has been implicated in the etiology of fecal and urinary incontinence. Assessment of the pudendal nerve terminal motor latency (PNTML) is an important component to the evaluation of the patient with fecal incontinence. A disposable electrode is attached to the examiner's finger which is then directed toward the ischial spine and electrical impulses are delivered to the pudendal nerve. The time for response at the level of the external anal sphincter is measured. Normal response is within 2.0 ± 0.2 ms. Pudendal neuropathy has been implicated in poor outcome after anterior overlapping sphincteroplasty.[32,33] The presence of pudendal neuropathy in the setting of an external anal sphincter defect does not preclude repair[34]; however, the patient can be appropriately counseled in the preoperative and the possible need for future intervention can be discussed.

Electromyography

Anal electromyography (EMG) relies on the use of a concentric needle electrode to record electrical activity generated by the anal sphincter muscle fibers. Sequential recordings of the motor unit potentials are taken circumferentially around the anal canal. This technique is used to "map" the external anal sphincter and document neuromuscular integrity.[35] While this test is more uncomfortable than anal ultrasound, it can provide useful data about the physiologic status of the specific portions of the anal sphincter. This is a useful adjunct when there is excessive scarring on the anal ultrasound.[36]

Defecography

Defecography is the radiological visualization of the act of defecation. It provides a picture of the successive phases of defecation and gives a dynamic impression of pelvic floor activity during these actions. Changes in the rectal configuration and the anorectal angle become visible and the degree of evacuation can be studied. It has become evident that it can demonstrate abnormalities that were unsuspected on clinical examination. While typically utilized in the evaluation of patients suffering from constipation, the value of defecography in the evaluation of fecal incontinence is to demonstrate the presence of incomplete evacuation thereby leading the physician to consider overflow incontinence as the cause of the patient's symptoms.

Colonoscopy

Endoscopic evaluation of the colon can rectum should be undertaken in the evaluation of patients suffering from fecal incontinence. This will allow for the exclusion of any lesions within the lumen of the bowel as well as to ensure that there is no evidence of any inflammatory conditions which could be causing a change in the stool consistency or rectal compliance.

Treatment

Nonoperative Management

Medical Therapies

There are a variety of pharmacotherapies available for the medical management of fecal incontinence, but ultimately the number of randomized, placebo-controlled trials is limited. In fact, the Cochrane Database systemic review on the subject stated "there is little evidence with which to assess the use of drug therapies for the management of fecal incontinence."[37] That said, medical management therapies are broadly broken down into the following categories: bulking agents, constipating agents, and laxative regimen with scheduled disimpactions.

As is suggested by the wide differential diagnosis leading to fecal incontinence, the first step for controlling the incontinence is determination of the underlying cause. Certain etiologies, such as chronic diarrhea, chronic constipation, certain neurologic conditions and systemic diseases, such as diabetes, are best targeted through medical management. At a minimum, use of medical therapies is an important adjunct to mitigate the impact of fecal incontinence.

Bulking Agents

Fiber, both natural and synthetic, has long been a staple in treatment of minor fecal incontinence. It has the benefit of adding bulk and has the ability to absorb additional fluid, providing a more solid stool in the face of mild chronic diarrhea. In laboratory studies calcium polycarbophil (Konsyl®, FiberCon®) a synthetic, insoluble fiber was able to absorb 70 times its weight in fluid, thereby reducing fecal water content.[38] Conversely, in constipation, calcium polycarbophil increases stool frequency and weight without

leading to diarrhea.[39] Bliss et al.[40] were able to demonstrate a 50% reduction in incontinence episodes by adding daily fiber supplementation in 39 patients for 1 month.

Constipating Agents

In patients with chronic diarrhea, up to 50% also suffer from incontinence.[41] In patients with diarrhea-predominant irritable bowel syndrome, it is estimated that 20% have associated fecal incontinence.[42] It therefore stands to reason that use of constipation inducing drugs, such as loperamide, codeine, dephenoxylate plus atropine, difenoxin plus atropine, and amitriptyline, are of utility for this group of patients. Loperamide is a synthetic opioid which inhibits small and large intestinal peristalsis via the m (Mu) receptors in the gut. It has also been shown to increase anal resting sphincter pressure, improve rectal sensation, and retention of fluid load, as well as increase the RAIR.[43,44] Amitriptyline has also been suggested as therapy based on its anticholinergic properties leading to a reduction in the frequency and amplitude of rectal motor complexes.[45]

Laxative Regimen with Scheduled Disimpactions

In contrast to patients with diarrhea, patients with constipation and fecal impaction experience fecal incontinence secondary to overflow incontinence. Chassagne et al.[46] compared a regimen of 30 g lactulose daily to 30 g of lactulose daily with the addition of a daily glycerin suppository and a weekly tap-water enema in 206 institutionalized elderly patients with a history of prior fecal impaction and at least weekly episodes of fecal incontinence. The patients receiving the suppositories and weekly enemas in addition to the lactulose had a 35% reduction in fecal incontinence episodes and a 42% reduction in soiled laundry.

Biofeedback

The goal of biofeedback is to use visual, auditory, or other forms of sensory information to improve a patient's ability to sense rectal distention and reinforce appropriate sphincter contraction. In 1974, Engel et al.[47] pioneered the technique and published their results on six patients with fecal incontinence using a Miller–Abbott balloon as a sensor attached to a polygraph to improve the quality of Kegel exercises. Heymen et al.[48] designed a randomized controlled trial in three phases comparing manometric biofeedback to pelvic floor exercises for fecal incontinence, with the aim of reducing the impact of confounding factors by providing all patients with a 4-week pretreatment education and a similar schedule of training visits for both groups. At the completion of the study 44% of patients in the biofeedback group were able to achieve complete continence vs. 21% in the pelvic floor exercise group ($P=0.008$). A greater increase in anal canal squeeze pressure was seen in the biofeedback group

($P=0.014$) and at 3 months 76% of patients treated with biofeedback compared to 41% of patients treated with pelvic floor exercises reported adequate relief of their fecal incontinence ($P<0.001$). It is interesting to note that both groups showed a significant improvement in episodes of fecal incontinence after the 4-week pretreatment phase ($P<0.001$) and only a trend in favor of the biofeedback group at 3 month posttreatment follow-up ($P=0.083$).

Published studies typically demonstrate improvement in continence for both adults and children[49,50] as a result of biofeedback in over 70% of the patients.[51–54] Current described methods are widely variable and include weekly or bi-weekly sessions of 30 or 60 min, use of home practice machines, EMG, manometry, and even ultrasound.[55] The Cochrane Database systemic review of the subject included 11 randomized controlled trials and concluded that there is no one method of biofeedback which has been demonstrated superior over the others, nor that biofeedback is conclusively better than conservative measures such as pelvic floor exercises, dietary measures, and pharmacologic agents.[55]

Long-term, the benefits of biofeedback are less clear, with many authorities suggesting an attenuation of results and the need for "refresher" training sessions. Regardless, a trial of biofeedback is considered an important noninvasive, first-line therapeutic option for highly motivated patients who have failed medical management.[56] Factors associated with short-term treatment success are completion of a full six training sessions, female gender, older age (<61), and more severe incontinence.[54]

Secca® Procedure

The Secca® procedure involves the use of radiofrequency delivered as an alternating current at high frequency leading to frictional movement of ions and generation of heat, or thermal energy. As a result of the delivered thermal energy, there is immediate contraction of collagen fibers which are then permanently shortened via remodeling resulting in a tightening of the muscle.[57] Radiofrequency has been used for treatment of gastroesophageal reflux disease (GERD),[58] joint capsule instability,[59] benign prostatic hypertrophy,[60] and even sleep apnea.[61]

The technique is a modification of the Stretta procedure, developed for the treatment of gastroesophageal reflux. In Secca®, the radiofrequency is delivered to the anal sphincter under constant monitoring of the temperature and tissue impedance while simultaneously cooling the probes at the surface to minimize mucosal damage. The current is automatically ceased if the tissue temperature rises above 85°C at the electrode tip or above 42°C at the anoderm surface.

The patients selected are generally those with mild to moderate complaints of fecal incontinence who have failed conservative measures including dietary modification, pharmacotherapy and biofeedback, and do not have a demonstrable

TABLE 18-2. Secca® procedure for treatment of fecal incontinence

| Author (year) | No. of patients | CCF-FIS | | P value | Duration of follow-up (months) |

CCF-FIS = Cleveland Clinic Florida Fecal Incontinence Score.

sphincter defect. To date, the studies have been limited by either small sample size or length of follow-up. Complications have been minor, and include bleeding and ulceration at an application site which can be immediate or delayed requiring a return to the operating room for oversewing.[62]

The Secca® procedure is typically performed in an outpatient, ambulatory setting under intravenous sedation with local anesthetic. Prophylactic antibiotics are given. The patient is positioned in either prone jack-knife or lithotomy, following which, the handpiece is inserted into the anal canal and lined up so the four needle electrodes will be deployed at the level of the dentate line. Radiofrequency is then delivered for 90 s to one quadrant. The process is then repeated for each of the four quadrants and at 5 mm level increments proximal to the dentate line. Dependant on the length of the anal canal, there should be 16–20 application sites.

Takehashi et al.[62] recently published their results on 19 patients at 5 years of follow-up, showing a durable improvement in mean CCF-FIS from 14.37 to 8.26 ($P < 0.00025$). In 16 of the patients there was a >50% improvement in their incontinence score. The results are encouraging, but additional studies are warranted. Table 18-2 summarizes the results of the Secca® procedure for fecal incontinence.[62–65]

Injectables

Injection of a biocompatible bulking agent has been adapted from its initial reported successful application in the treatment of urinary incontinence.[66] Its chief application is for the treatment of minor fecal incontinence due to internal anal sphincter dysfunction.[56] This option gains significance because surgical repair of the internal anal sphincter has not been shown to be effective,[67–69] whereas more aggressive operations and their attendant complications are typically out of proportion to the complaints of this specific patient population. Proponents of this therapy cite the fact that it is a safe, minimally invasive therapy, typically administered on an outpatient basis, in some instances in an office setting with minimal complications under local anesthetic alone or with intravenous sedation.[70–73]

The technique involves injection of a bulking agent either into the anal submucosal or intersphincteric space. Currently the two most studied materials are silicone biomaterial and carbon-coated microbeads. The mechanism of action is not fully understood, but Davis et al.[74] suggested an increase in anal resting pressure secondary to augmentation of the anal cushions and restoration of anal canal symmetry. Other proposed mechanisms include bulking of the anal canal providing increased resistance to the passage of stool, allowing for improved sensation and that fibrosis over time contributes to increased sphincter muscle volume. Typically, the maximal improvement in fecal continence is observed within the first 1–6 months and appears durable up to 1–2 years later.[74–76] Because of concerns of absorption and migration of the bulking agent, further long-term data are still needed. Additionally, the ideal number and location of injections, utility of ultrasound guidance for said localization as well as which materials and volume are most suitable for injection have yet to be definitively determined. Table 18-3 summarizes the results of the use of injectables for the treatment of fecal incontinence.[77–81]

Operative Procedures

Anterior Overlapping Sphincteroplasty

Anterior overlapping sphincteroplasty is the mainstay surgical treatment for patients suffering from severe fecal incontinence in conjunction with an external sphincter defect (Table 18-4).[82–87] The patient is given a full mechanical bowel preparation. After induction of anesthesia, the patient is placed in the prone jack-knife position. Tapping of the buttocks provides excellent exposure. A transverse incision is made on the thin or absent perineal body. Lateral dissection allows for identification of the normal ends of the external anal sphincter musculature. Care should be taken not to proceed too far posterior due to the potential for injury to the nerves entering in this location. Once the muscle is isolated on each side, the dissection should proceed medial to the anterior aspect of the anal canal. Preservation of the scar tissue in this location is important for the ensuing repair as it is helpful in holding the sutures. There has been suggestion that the presence of overlapped scar tissue correlates with improved short-term outcome as well.[82] Care should be taken to avoid injury to either the vaginal wall or anal canal. At the proximal extent of the dissection, the levators are identified and plicated anteriorly. Following this, the medial scar is divided and the external anal sphincter muscles are

TABLE 18-3. Injectable anal sphincter bulking agents for treatment of minor fecal incontinence

2009	Oom et al.[87]	120	69	37% "Good or excellent"

overlapped in the anterior midline (Figure 18-3A–C). Outcome after end-to-end repair is somewhat inferior to overlapping repair, whereas overlapping repair might be associated with more evacuation difficulties.[83] The initial results of anterior sphincteroplasty are promising; however, numerous authors have noted diminishing efficacy over time with disappointing long-term continence.

Parks Posterior Anal Repair

The Parks posterior anal repair has been described for the treatment of neurogenic fecal incontinence in those patients without a sphincter defect. The initial premise was that it lengthened the anal canal and corrected the anorectal angle.[88] A curved incision is made behind the anus and an anterior skin flap is dissected. The intersphincteric space is identified and dissected free up to the upper part of the anal canal where Waldeyer's fascia, a dense fibrous structure, is encountered. Division gives access to the pelvis. The rectum can be dissected free from the levator ani by blunt dissection. A lattice is constructed by plicating the pubococcygeus and, in a second layer, the puborectalis. Additional sutures are placed in the deep and superficial part of the external sphincter (Figure 18-4). Part of the skin is left open to prevent sepsis. This operation has not gained widespread support in the

USA, possibly because of the published poor long-term results with continence rates of only 33% at 5 years.[89]

Sacral Nerve Stimulation

Sacral nerve stimulation (SNS) or neuromodulation was initially developed for the management of urinary incontinence. It was subsequently noted that in patients with fecal incontinence treated with SNS for urinary incontinence the fecal incontinence also improved. This observation prompted Matzel et al.[90] to successfully attempt treatment of three patients with fecal incontinence using SNS.

Unlike other therapeutic modalities, SNS is a staged procedure. The first stage is the percutaneous nerve evaluation (PNE) which serves as feasibility trial period lasting 2 weeks. Patients who experience an improvement of 50% or greater decrease in the number of incontinence episodes progress to the final stage and are offered placement of a permanent stimulator.

The electrode placement is performed under sterile conditions with fluoroscopic guidance. Stimulation of the S2, S3, and S4 nerve roots via their sacral foramina is tested. The goal is to elicit contraction of the levator ani and external anal sphincter with plantar flexion of the first two toes, seen with stimulation of S3. The purpose of direct stimulation of the sacral nerves is to recruit additional inactive motor
FIGURE 18-3. **A** Anterior overlapping sphincteroplasty. Overlapping and suturing of the external anal sphincter in the *midline*; **B** anterior overlapping sphincteroplasty. **C** Final repair with recreation of the perineal body.

units to improve muscle strength, resulting in an increase in resting anal pressure as demonstrated by Kenefick et al.[91] Additionally, SNS has been shown to improve the rectal sensory threshold and balloon expulsion time.[92]

Both the initial PNE and subsequent placement of the permanent stimulator are performed on an outpatient basis. Complications are rare and have all been minor with lead migration being most typical. Other complications include infection leading to explantation of the stimulator and pain attributed to either the leads of the stimulator.[93]

The obvious benefit of sacral nerve stimulation is that it avoids creation of an incision around or near the anal canal. This is important because it avoids further anal scarring as well as significantly decreases the risk of infection. When comparing sacral nerve stimulation to the artificial bowel sphincter, it has been proposed that SNS should be considered the first-line option due to the observed improved continence and decreased rate of outlet obstruction.[94]

Most recently, the results of the largest prospective randomized trial of the use of sacral nerve stimulation have been published. Sixteen centers in North America and Australia participated in the trial which included 129 patients who underwent the subchronic stimulation phase. Of the 129 patients, 120 qualified for permanent implantation by achieving a decrease in the incontinent episodes by at least 50% during the test phase. The mean follow-up period was 28 months. Persistent benefits of a 50% decrease in the weekly incontinence episodes, incontinent days and urgent incontinent episodes were noted in over 75% of the patients at all follow-up periods up to 36 months, with most of interval measurements over 80% success.[95] There was also a consistent improvement in quality of life throughout the study period.

While the device has still to obtain FDA approval in the USA, it has been used extensively in other countries. Promising short and long-term success has been reported with significant and sustained decreases in the CCF-FIS. The results of sacral nerve stimulation and summarized in Table 18-5.[96–104]

Artificial Bowel Sphincter

The artificial bowel sphincter was first reported in 1987.[105] A man with neurogenic incontinence had an artificial urinary sphincter inserted and he was able to have "complete control of defecation." The device was subsequently modified for the use around the anus. The procedure involves creating a subcutaneous tunnel around the anus, typically through a transverse perineal incision. The cuff is situated around the anus. The pump is tunneled through a pfannensteil incision down to either the labia or scrotum, while the reservoir is placed in the space of retzius (Figure 18-5A and B). All of the tubing is tunneled subcutaneously. The device provides continence by keeping the perianal cuff full in the resting state. When the patient needs to evacuate, he/she needs to actively pump fluid from the cuff to the reservoir. The cuff will then passively refill. When considering a patient for artificial bowel sphincter, it is important to ensure that there is not a significant soft tissue loss on the perineum which could preclude adequate coverage and guarantee erosion. It is also imperative to ensure that the patient will have the manual dexterity to activate the device.

Infection has been the greatest challenge for patients and surgeons utilizing the artificial bowel sphincter. The results of a multicenter trial were published by Wong et al.[106] in 2002; 112 patients were implanted. There were 384 device-related adverse events in 99 patients. 246 required either no or noninvasive intervention. 73 revisional operations were performed in 51(46%) patients. Twenty-five percent of patients developed infection requiring surgical revision and 41(37%) patients had devices completely explanted. While the intention to treat success rate was low at 53%, 85% of patients with a functional device had a successful outcome. Recent reports of the long-term outcome for patients with the artificial bowel sphincter have been published.[107] Seventeen consecutive patients underwent sphincter implantation. The mean follow-up was 68 months (range: 3–133). All of the patients had some complication and 65% required at least one reoperation. As with other published series, 53% of the patients had an implanted device at follow-up. Those patients enjoyed the benefit of improved quality of life and significantly decreased fecal incontinence scores. Some factors associated with failure have been proposed. The experience from the Cleveland Clinic Florida suggested that early failures were more common with patients who had an early first postoperative bowel movement and who had a history of perineal sepsis. Early failure was more often related to infectious complications, while late failure was related to device associated mechanical complications.[108] There was a 41% infection rate noted in the series of 51 implantations, of these, 35% were early and 6% late. The major challenge of this treatment for fecal incontinence is infection followed by late device-related complications.

Muscle Transposition

The concept of substituting the anal sphincter was first reported by Chetwood in 1902[109] using the gluteus maximus. The ideal muscle for substitution of the sphincter complex should have a negligible role in movement and posture, yet it should be able to provide sufficient bulk. The muscle itself must have a reliable neurovascular bundle, so that it will not be damaged in the process of dissection.

The advantages of the gluteus maximus muscle are that it has a location in close proximity to the anal canal and provides excellent strength and bulk to the anal canal; however, its use poses significant functional impairment to the patient while standing or climbing stairs. The majority of data are case series, wherein a bilateral gluteus flap is performed; however, Devesa et al.[110] have suggested that a unilateral gluteus flap is simpler and yields superior results because of reduced tension on the muscular neosphincter. The major technical difficulty of this procedure is obtaining sufficient length to adequately encircle the anal canal.[111]

Gracilis Muscle Transposition

Gracilis muscle transposition was first reported by Pickrell in 1952[109] for the treatment of children with fecal incontinence due to neurologic and congenital anomalies. It is generally a treatment option best for those patients whose incontinence results from either trauma or congenital anomaly, where the additional muscle bulk can supplement deficient native tissue. A history of diarrhea, severe refractory constipation, obstetric injury, and advanced age generally predict a poor outcome and therefore are relative contraindications for this technique.

The essence of the operation is mobilization of the gracilis muscle followed by transposition of the muscle around the anus and fixation to the contralateral ischial tuberosity. In concept the gracilis acts as a barrier to the passage of stool by acting as a living Thiersch. The patient is placed in the lithotomy position and prepped beyond the knee. Because the blood supply for the gracilis is based proximally, the distal end of the gracilis can be freely mobilized. The gracilis is first identified by palpating and marking its course from the pubic arch to the upper medial tubercle of the tibia. Generally the muscle is mobilized via three separate incisions over the course of the muscle, with division of the gracilis tendon at its insertion on the tibia. Special care is taken at the cephalad dissection to identify and preserve the neurovascular bundle, which defines the proximal limit of dissection. A tunnel is then created between the proximal incision and two incisions placed approximately 1.5–2.0 cm from the anal verge located anteriorly and posteriorly. A circumferential tunnel is also created in the ischirectal fossae between the perianal incisions. The distal portion of the gracilis is then passed around the anus, under the anterior and posterior raphe and encompassing any existing native sphincter muscle. The muscle is then anchored to the contralateral ischial tuberosity with a nonabsorbable suture. The completed graciloplasty should admit one finger snugly.

Functionally, most patients are only able to control the passage of solid stool. The additional limitation is that skeletal muscle is more easily fatigued, leading Salmons[112] to suggest use of a stimulator to convert fast-twitch (type II) muscle fibers in the gracilis into slow-twitch (type I) that comprise 80% of the external sphincters found in cadavers.[113] Complications associated with graciloplasty include evacuatory dysfunction, pain in the perineum or with contraction of gracilis, and infection. Additional complications specific to the stimulated graciloplasty include lead displacement and erosion, nerve fibrosis, and implant infection. A randomized, controlled trial comparing unstimulated to stimulated graciloplasty has not been done. In the USA, the stimulator is not available for implantation; however, it remains a viable option for a highly selected group patients in other countries.

Fecal Diversion

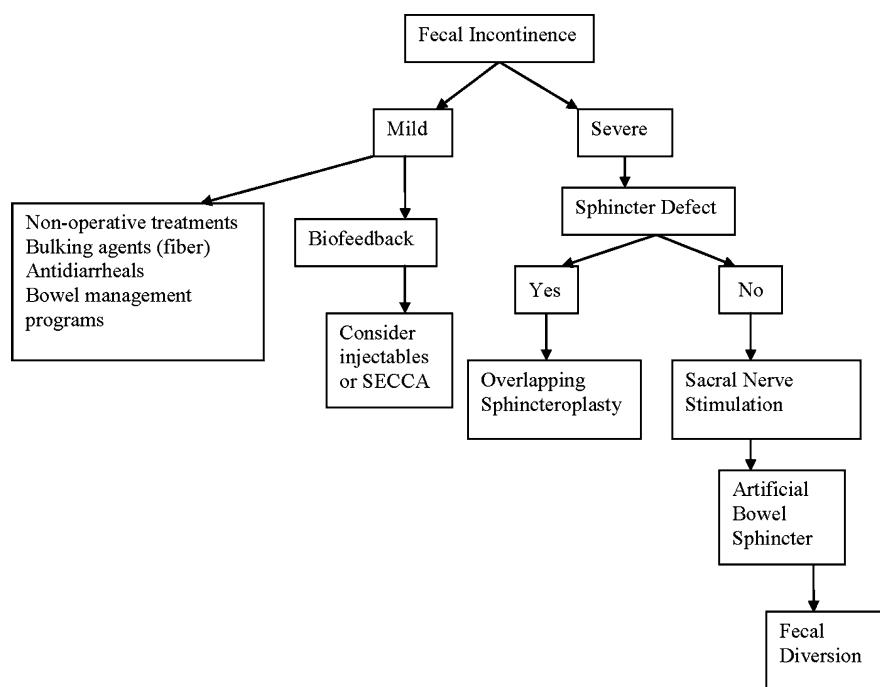
Creation of a colostomy or ileostomy is typically the therapeutic option of last resort, when all other reasonable options have been exhausted. The majority of patients will be best


FIGURE 18-6. Algorithm for the management of fecal incontinence.

served with an end sigmoid colostomy, but some patients with chronic constipation and slow transit may be best served with an ileostomy. Predictably, strong resistance even in the face of severe and debilitating incontinence is common. Patient education in the form of a visit with an enterostomal therapist and perhaps a patient already living with an ostomy can greatly ease anxiety. It is important to emphasize there is no time-limit for the decision to convert an uncontrolled perineal stoma to a more easily managed abdominal one.

Conclusion

Fecal incontinence is a socially devastating condition which is extremely common and under reported. There are many options available for patients who can treat or significantly improve their symptoms. The first step for the physician is to diagnose the problem. This will often not take place until the examiner specifically asks the patient as they will often not offer the information. Through a detailed history, the physician can formulate a differential diagnosis. Anorectal physiologic testing can add specific information with regards to the functional status to the sphincter musculature. Many patients quality of life can be improved with noninvasive modalities focused on improving stool consistency and strengthening of the musculature with biofeedback.

If there is a significant impact on quality of life and the patient is a candidate for invasive therapy, surgical intervention should be considered. The overlapping sphincteroplasty remains the mainstay of surgical treatment when a

sphincter defect is present. When a defect is absent or the sphincteroplasty has failed, sacral nerve stimulation and the artificial bowel sphincter are options. For less severe forms of incontinence, injectables and SECCA may be of benefit. Figure 18-6 provides a generalized algorithm for the management of fecal incontinence.

Pelvic Floor Disorders

Patrick Y.H. Lee and Guillaum Meurette

Pelvic floor disorders are mostly a continuum of a disease process resulting from the loss of pelvic floor support. Although these diseases are commonly believed to afflict primarily women, the ease in examination of the pelvic floor in women makes the identification of pelvic floor disorders easier in women than in men. Anatomical differences in the size of the genital hiatus between the sexes also make women more prone to pelvic floor prolapse. Epidemiologic studies on pelvic floor prolapse suggest that it is a disease that will become more prevalent as the population ages. Olsen et al.[1] reported the findings of pelvic organ prolapse on 149,554 women aged 20 years or older at Kaiser Permanente; their study showed that 11.1% of these women will have a lifetime risk of undergoing an operation related to pelvic prolapse or incontinence by the age of 80. Surgical repair related to the rectum or posterior compartment constituted 45% of the operations. Reoperation for prolapse was 29.9%, and the time interval between repeat procedures decreased with each successive repair.[1] According to the government census, the population in the USA is projected to reach 440 million by 2050, and the population of 75 years old or older is projected to increase from 6% to 11%.[2] These findings and trends help highlight the importance of pelvic floor disorders and the role of the colorectal specialist in the management of pelvic floor disorders.

Despite the incomplete knowledge on the etiology of pelvic floor laxity and prolapse, surgical management is one of the most important modalities in the repair of the pelvic floor in women. Hence, successful repair of the pelvic floor requires a good understanding not only of the pelvic floor anatomy, but also of the dynamic interaction between pelvic floor muscles and organs. The anatomy discussed here will primarily focus on how pelvic organs are supported and the pathologic changes of pelvic floor prolapse. The pelvic floor disorders that will be discussed are rectocele, defecatory dysfunction, and rectal and genital prolapse. The disease processes will be correlated with the anatomic changes seen on physical exams and radiologic studies. Restoration of function is the ultimate goal in any treatment, and how that is accomplished with the current surgical techniques will be discussed.

Grant's Atlas and Netter's anatomic drawings of the pelvis need no introduction,[3,4] but they provide very little in the understanding of the dynamic interaction between pelvic musculature and ligamentous connective tissue in the stabilization of pelvic organs. The levator ani complex and the supporting or endopelvic fascia are the two most important dynamic structures of the pelvis that are extensively discussed in the gynecologic, urologic, and colorectal literatures. In the resting state, the levator ani muscle group (puborectalis, pubococcygeus, and iliococcygeus) is in a constant state of contraction.[5] Magnetic resonance imaging (MRI) of the normal pelvic floor in a woman shows the levator ani complex to have a hyperbolic or biconcave shape posteriorly and a sling-like appearance around the rectum, vagina, and urethra anteriorly (Figure 19-1A and B).[6,7] Anatomically, the iliococcygeus forms the posterior biconvex shape on the MRI and functions to support the rectum. The puborectalis slings around the rectum, vagina, and urethra. Singh et al.[8] describe the puborectalis as a belt, which encases the pelvic organs and contracts in a dorsoventral direction to close the levator hiatus and thus maintain continence. Lawson[9] in his dissection of the pelvis of neonates and infants, describes the pubococcygeus as a vertical sling, which has very little fiber going to the coccyx and has muscle fibers which interdigitate with the anorectum, vagina, urethra, and perineal body.[10] The exact etiology of the loss of the levator ani muscle integrity resulting in pelvic floor prolapse is unclear. Animal models show that chronic stretching of the pelvic muscles leads to myopathic injury.[11]

The supporting or endopelvic fascia is a more complex and controversial structure than the levator ani. Located between the visceral peritoneum and parietal fascia of the levator ani is fibroareolar tissue containing neurovascular bundles, smooth muscles, collagen, and elastin, which is often called the endopelvic or endovisceral fascia.[12] In Figure 19-2, the endopelvic fascia is drawn as a layer which fans out to envelop the pelvic organs and anchors them to
FIGURE 19-1. **A** and **B**. Digitally enhanced MRI reconstruction of the levator ani at rest in a 23-year-old nulliparous woman. The levator ani gives a biconcave shape posteriorly and the puborectalis show as a sling imbedded in the muscle of the pelvic floor. the surrounding pelvic side wall structures such as the uterosacral ligament, arcus tendineus fascia pelvis, and perineal body.[6] DeLancey calls the endopelvic fascia the viscero-fascial layer because it is a combination of the pelvic viscera and endopelvic fascia and plays a key role in the support of the vagina and uterus.[10,13,14] Norton[15] has described the interaction between levator ani and endopelvic fascia as the "boat in the dry dock." The levator ani is like the water in a dry dock that floats the boat, and the ligaments are like the mooring that holds the boat in place. When the water in the dock begins to recede, the moorings are strained to hold the boat in place. Similarly, as the levator ani begins to lose its integrity, the ligaments are stretched and at some point will lose their ability to hold the pelvic organs in place. Norton postulated that collagen composition changes with injury and results in a higher concentration of the weaker type III than stronger type I collagen. It is unknown if this transformation

of collagen type is permanent. The replacement of collagen type and the loss of elasticity in the endopelvic fascia are believed to result in the loss of fascial ability to return the pelvic organs to their appropriate anatomic alignment.

Clinical studies of patients with collagen and elastin defects like those found in patients with Marfan and Ehlers–Danlos syndrome show a 42 and 50% incidence of urinary incontinence and a 33 and 75% incidence of pelvic organ prolapse, respectively.[16] Similarly, patients with hypermobile joints have a higher prevalence of cystocele, 89% versus 58% ($p = 0.001$); rectocele, 84% versus 48% ($p = 0.0002$); and uterine or vault prolapse, 66% versus 29% ($p = 0.0002$).[17] Soderberg et al.[18] showed that women younger than 53 years of age with genital prolapse had a 30% lower collagen concentration than age-matched controls ($p = 0.01$). In patients with complex multiorgan prolapse, Sullivan et al.[19] found a 44% incidence of arthritis in women with pelvic floor prolapse, suggesting an underlying collagen vascular disease. Their findings are supported by epidemiologic studies of women in Sweden which showed that genital prolapse, urinary and fecal incontinence were associated with obesity, chronic bronchitis, vaginal delivery, age, heredity, and diseases suggestive of collagen vascular disorders.[20]

Despite a well-established consensus in the gynecologic literature that the endopelvic fascia exists, there remains controversy over its existence or significance. Berglass and Rubin[21] in 1953 confirmed the works of earlier anatomists that there are no histologic findings to support a well-defined sheath around the rectum, vagina, and bladder to be termed "fascia." In 2004, Fritsch et al.[22] published their extensive anatomical and histologic study of the pelvis of 11 adults (6 female and 5 male), 7 newborns, and 79 fetuses and concluded that the endopelvic fascia does not exist. They concluded that pelvic floor support is dependent on intact pelvic floor muscles, undisturbed topography of the pelvic organs, and intact perineum. Regardless of the controversies on the existence and significance of the endopelvic fascia, all anatomists and surgeons agree that lying between the rectum and vagina or prostate is a fascial septum that is attached to the perineal body; in women that is known as the rectovaginal fascia and in men Denonvilliers' fascia. The importance of this fascia and the perineal body will become apparent in the findings and repair of pelvic organ prolapse.

Equally important to the understanding of pelvic anatomy is an understanding of the dynamic changes of the pelvic organs. Visualization of the dynamic changes between pelvic floor and pelvic organs was first described by Burhenne in 1963,[23] when he performed cinefluorography on the rectum during defecation. These studies have evolved to include evaluation of the bladder, vagina, and small bowel during evacuation. Kelvin and associates[24] popularized the use of four-contrast study to outline the small bowel, bladder, vagina, and rectum. The dynamic evaluation of the pelvic floor before, during, and after evacuation of the contrasts in the rectum and bladder not only yields a tremendous amount
FIGURE 19-2. Illustration of the endopelvic fascia as it fans out to cover the pelvic floor and provide support to the surrounding organs. The levels 1, 2, and 3 depict the vaginal support (Reprinted with permission from Cleveland Clinic Center for Medical Art and Photography© 2004–2009 and Matthew Barber, MD).

of information about the function of the pelvic organs and the surrounding structures which support them, but it also complements physical examination for enterocele, one of the findings in advanced pelvic floor prolapse.[25,26] Kelvin et al.[24], using their four-contrast study to evaluate 74 women with pelvic floor prolapse, found 14 (19%) to have enteroceles, 50% of which were missed on physical exam. These dynamic studies also helped to identify other pelvic organ dysfunctions. In a study of 100 women referred for evaluation of pelvic floor prolapse, dynamic cystoproctography or cystodefecography found that of the 20 patients with anterior compartment systems (urinary), 45% had middle compartment findings of vaginal vault prolapse; of posterior compartment findings, 90% had rectocele, 40% had enterocele, and 35% had rectal intussusception. Similarly, of the 45 patients with symptoms of middle compartment defects (genital), 91% had anterior compartment findings of cystocele and 56% of hypermobile bladder neck; of posterior compartment findings, 82% had findings of rectocele and 58% of enterocele. Of the 17 patients with posterior compartment symptoms (anorectal), 71% had cystocele, 65% had hypermobile bladder neck, and 35% had vaginal prolapse. Their study concluded that 95% of the women with pelvic floor dysfunction had abnormalities of all three compartments.[27]

This study underscores the global nature of pelvic floor disorders and the need to understand the pelvic floor as a unit rather than as compartments.[27] The usefulness of cystodefecography was further validated by Mellgren et al.[28] who evaluated the defecation complaints of 2,816 patients and found 31% with rectal intussusceptions (13% rectal prolapse), 27% with rectocele, 19% with enterocele, and 21% with two or more of these combinations. Halligan and Bartram,[29] in a study to determine the usefulness of evacuation proctography in the management of patients with rectal dysfunction, found a change of diagnosis in 18%, a change of surgical to nonsurgical management in 14%, and a change from nonsurgical to surgical management in 4%. Hence, it is imperative that a patient who presents with symptoms of defecation dysfunction, anal or urinary incontinence, and/or prolapse of the rectum, bladder, or vagina and unexplained PELVIC pressure undergo a cystodefecography to evaluate their pelvic floor and organs.

The loss of pelvic organ alignment as seen on cystodefecography of the bladder, vagina, uterus, and rectum is obvious, but the significance of an enterocele remains controversial. Kinzel[30] described an enterocele as a "true" hernia because it contains a hernia sac (the pouch of Douglas), neck and contents. Delancey[31] postulates that enterocele sac develop as a result of the loss of suspension of the upper vagina and muscle integrity of the levator ani muscles that leads to the herniation of the cul-de-sac between the rectum and vagina. Enteroceles are often classified as congenital,

pulsion, traction, and iatrogenic. A congenital enterocele is a result of the failure of the fusion of the anterior and posterior peritoneum during fetal development, resulting in a deep pouch of Douglas. Pulsion type is caused by chronic increase abdominal pressure. While traction type is caused by the loss of pelvic floor support and resulting in the pulling or traction of the pelvic organ on the surrounding structures out of the pelvis such as the vagina. Iatrogenic is caused by surgical injury.[32] Except for the congenital and iatrogenic types of enterocele, pulsion and traction enteroceles are probably a reflection of the degree of pelvic floor laxity rather than of a different etiology. The clinical presentations of an enterocele are dependent on the extent of the herniation and may present from no physical findings to bulging of the perineum or posterior vagina during strain. Clinical examination of the vagina, or bidigital exam of the rectum and vagina during maximum strain can help detect the spreading of the rectovaginal plane between the fingers as the enterocele enters into the rectovaginal plane, however, physical examination is unreliable in detecting enterocele. Kelvin et al.[33] reported their findings on 170 patients with symptoms of pelvic floor dysfunction who were evaluated by urogynecologist, and found 47 patients (28%) with an enterocele, only 24 (51%) of these patients were found by physical exam.

Others have advocated the use of peritoneal contrast, peritoneography, to increase the sensitivity of detecting significant pelvic floor prolapse. Peritoneocele, as defined by Bremmer et al.[34] is an extension of the pouch of Douglas below the upper third of the vagina, and are classified as rectal, septal, or vaginal depending on their location. Peritoneocele can be further classified into small (<100 cc), medium (100–300 cc), and large (>300 cc). Bremmer et al.[34] reported their findings on the formation and transformation of peritoneocele and enterocele on 46 patients with defecation disorder symptoms with known peritoneocele on defaeco-peritoneography. Thirty two patients (70%) had no peritoneocele at the start and developed them during maximum strain. None of the patients had an enterocele at the start, but during maximum strain, 21 patients (45%) developed an enterocele, and 15 of these patients (71%) had a persistent enterocele after evacuation at rest. Their study suggests that peritoneocele precedes the development of enterocele and that peritoneogram is more sensitive in detecting the early transformation of the herniation of the pouch of Douglas than the findings of enteroceles found on defecography. These findings are supported by Halligan et al.[35] who evaluated 47 patients with constipation symptoms using simultaneous proctography and peritoneography, and found peritoneal descent to be greater compared to controls during strain ($p < 0.0001$), 42% had peritoneal sac without enteric content.[35] Interestingly, their study showed that patients with enterocele, evacuated better ($p < 0.008$) than those with peritoneocele.[35] The degree of the peritoneocele and the presence of enterocele not only reflects on the herniation of the pouch of Douglas, but also on the association of pelvic organ prolapse. Baessler and

Schuessler[36] found that when the percentage of the depth of the pouch of Douglas, as calculated as the percentage of the depth of the pouch to the total vaginal length, is greater than 50%, the odds of posterior vaginal wall prolapse is 14.2. Mellgren et al.[37] found a 93% association of rectal intussusception, or rectal prolapse in patients with enteroceles. Similarly, Takahashi et al.[38] found concomitant abnormalities such as perineal descent, rectocele, and rectal intussusception in 76% of the patients with enteroceles. It is not clear how the detection of a peritoneocele or enterocele changes the surgical management.

There are, however, controversies about the significance of enterocele containing small bowel versus sigmoid colon. Wexner[39] in his letter to the editor of Diseases Colon and Rectum about the study by Gosselink et al.[40] on the treatment of enterocele by mesh obliteration of the pelvic inlet, contends that enteroceles containing sigmoid colon results in defecatory dysfunction whereas enteroceles containing small bowel are more reflective of pelvic floor prolapse. Wexner's group[41] reported their findings on 24 patients with sigmoidoceles, representing 5.2% of the total cinedefecography studies, and found that patients who had enterocele containing sigmoid colon classed as second and third degree sigmoidoceles did better with sigmoid resection than medical management 100% versus 33%, with a mean follow-up of 23 months. It is not clear why the resection of the sigmoid colon without realignment of the rectum in the pelvis improved the defecatory symptoms. Was the obstructive effect of the sigmoid colon anatomical, or functional, and did the enterocele cause or a result of the sigmoid dysfunction? Their findings highlight some of the difficulties encountered in understanding the interrelationship between colorectal function and pelvic floor prolapse. Answering these complex questions may require the use of radiopaque marker and cystodefecography before and after surgical interventions.

MRI has been reported to be useful in the detection of enteroceles. Gousse et al.[42] reported that MRI had a sensitivity of 87%, specificity of 80%, and a positive predictive value of 91% compared to intraoperative findings. Typical findings of the pelvic floor on MRI of patients with pelvic organ prolapsed are shown in Figure 19-3. The MRI pictures illustrate the difference in the area of the levator hiatus between normal and prolapsed states. An angle can be measured when two lines drawn along each side of the puborectalis, bisects in the posterior midline, forming what we call the levator hiatus angle. This angle can also be measured by endorectal ultrasound (ERUS). The authors have found that when the levator hiatus angle measured by ERUS is greater than 75 degrees, we begin to see enterocele and other findings of pelvic floor prolapse on MRI and cystodefecography.[43]

MRI is helpful in evaluating not only the size of the levator hiatus in prolapse, but also changes in the anatomy of the levator ani muscle. Singh et al.[7] used a three-dimensional MRI reconstruction to assess the size of the levator hiatus and morphology of the levator ani muscle. They found that
FIGURE 19-3. MRI of the levator hiatus, normal on the *left* **A** and enlarged on the *right* **B**. The angle between the two lines drawn along the puborectalis muscle and bisecting in the posterior midline of the levator ani defines the levator hiatus angle. This angle can also be measured by endorectal ultrasound and is found to correlate with findings of enterocele and pelvic floor prolapse findings on MRI and cystodefecography.

increasing stage of prolapse correlated with increasing size of the levator hiatus, but not with the morphology of the levator ani. They proposed that patients who have pelvic organ prolapse with normal levator ani morphology may only need fascial repair, compared to those who show morphologic changes of muscle injury.[7] Pannu et al.[44] showed that levator hiatus enlargement is best obtained during strain. Eguare et al.[45] using dynamic MRI in the evaluation of 85 patients with combined urinary and fecal incontinence, showed statistically significant findings of increase in the width of the levator hiatus compared to control (48.3 ± 8 mm versus 46.5 mm± 8 mm, $p = 0.001$). Comparisons of MRI versus cystodefecography by Kelvin et al.[46] showed similar detection rates for pelvic floor prolapse, but MRI underestimated the extent of cystoceles and enteroceles though it was better at delineating the pelvic floor musculature. Kaufman et al.[47] showed that dynamic MRI, when combined with cystocolpoproctography (CCP) or cystodefecography, resulted in a change of the initial operative plan in 9 of 22 patients (41%); MRI accounted for 5 of the 9 patients (55%) and CCP for 4 of the 9 patients (44%). Currently, the MRI remains the best imaging technique in looking at the anatomy of the pelvic floor, while cystodefecography provides for dynamic images of the pelvic organs during defecation and urination. The increasing use of open-configuration MRI to allow the patient to assume a sitting position has shown this to be equivalent to the supine MRI in the evaluation of pelvic

floor laxity.[48] In the future, the open-configuration MRI may offer superior imaging findings compared to cystodefecography.

The MRI and cystodefecography studies have helped confirm what is already clinically known about the enlargement of the levator hiatus in pelvic organ prolapse. What is not known is at what point in the levator hiatus enlargement does pelvic organ dysfunction or prolapse occur, and why. Such questions can only be answered in the future with longitudinal studies. The mechanism of enlargement of the levator hiatus was shown by Berglas and Rubin[49] in 1953 with the use of barium injected into the levator ani, called levator myography. Their studies showed that the degree of uterine prolapse was associated with the incline of the "levator plate": the greater the incline, the greater the longitudinal diameter and the total area of the levator hiatus. This enlargement of the levator opening was associated with descent or prolapse of the uterus (Figure 19-4). Moschowitz[50] had long recognized the importance of the levator hiatus in pelvic organ prolapse; in 1912, Moschowitz[50] published his theory on the pathophysiology of rectal prolapse as a pelvic floor hernia and described how the loss of fascial support of the rectum leads to a "hernia par glissement," meaning a sliding out of the rectum. He was able to prevent the rectum from prolapsing out by placing two fingers on the anterior rectal wall, while the same did not hold true when he placed his fingers on the posterior wall of the rectum. His findings
FIGURE 19-4. Illustration of the incline of the levator plate and enlargement of the levator hiatus resulting in pelvic organ prolapse. (With permission from Berglas B, Rubin IC. Study of the supportive structures of the uterus by levator myography. Surg Gynecol Obstet 1953;97:677–92).[38]

suggested that stabilization of the anterior rectal wall by his fingers restored a reanchoring of the rectum to some type of fascia, which he called "transversalis." He likely was referring to the rectovaginal septum, which is believed to play an important role in the anchoring of the rectum and vagina to the pelvic side wall and perineal body.[51–53] The importance of the ability of the anterior rectal wall was further confirmed in 1967 by Broden and Snellman,[54] who demonstrated with the use of cystodefecography that rectal prolapse begins with an anterior wall intussusception beginning about 6–8 cm up the rectum. DeLancey and Hurd[55] in 1998 reported that not only is the grade of prolapse associated with the increase in size of the levator hiatus, but that successful repair of prolapse correlated to a smaller levator hiatus.

The true incidence or prevalence of colorectal diseases associated with pelvic floor disorder is unknown. This is in part due to our failure to recognize the early signs of pelvic floor laxity and in part due to the poor correlation between the degree of pelvic organ prolapse and symptoms.[56–59] In an attempt to identify patients with pelvic organ prolapse by history, Barber et al. found that when patients with high probability of prolapse were asked, "Do you usually have a bulge or something falling out that you can see or feel in your vagina?" an affirmative answer had a 96% sensitivity (95% CI 92–100) and 79% specificity (95% CI 77–92) for stage III and IV vaginal prolapse defined by the Pelvic Organ Prolapse Quantification (POP-Q).[60,61] Interestingly, the degree of colorectal symptoms associated with vagina and bladder prolapse seems to be higher in early stages than in late. In a study of 322 women presenting for sacrocolpopexy who were assessed with the Colorectal-Anal Distress Inventory (CRADI), a questionnaire, which measured 17 symptom items divided into 4 subscales (obstructive, incontinence, pain/irritation, and rectal prolapse),[62] they found that although there were no correlations between stages of genital prolapse and bowel symptoms, there was a higher incidence of defecation complaints with early than with late stages of prolapse.[63] This may not be too surprising when one considers the role of the anal sphincter and anal canal resistance. As the resistance of the anal canal is overcome by the stretching of the anal sphincter by the prolapsed rectum, defecation may actually improve and the symptoms of rectal pressure, pain, tissue prolapse, and fecal incontinence become more dominant. Hence, the lack of correlation between the degree of prolapse and symptoms may be related to the spectrum of pelvic floor disorders and the failure of the questions to identify changes in symptoms.

The progression of enlargement of the levator hiatus appears to be in a ventral-caudal direction. This view is not only supported by cystodefecography and MRI studies, but by numerous clinical studies showing the higher incidence of urinary and vaginal prolapse over rectal prolapse in women with pelvic floor prolapse.[10,64,65] Furthermore, patients with rectal prolapse have on average 1.5–3.3 operations related to bladder and vaginal prolapse prior to their presentation with anorectal symptoms.[19,66] Peters et al.[66] studied 55 women with rectal prolapse; 95% had other pelvic floor defects. The five most common complaints were vaginal prolapse/pressure (92%), rectal prolapse/pressure (69%), constipation (71%), fecal incontinence (40%), and obstructive defecation (38%). Their study underscores the importance of colorectal evaluation in patients with vaginal prolapse/pressure. Although there are no longitudinal studies to validate the progression of pelvic floor prolapse resulting in rectal symptoms, the clinical studies along with the cystodefecography and MRI support the postulate that as the rectum descends and loses its anatomical alignment in the pelvis, a spectrum of colorectal symptoms will emerge. In the early phase, the symptoms of worsening "hemorrhoids" and mucous discharge may be related to rectal mucosal prolapse. As the rectum descends further from the pelvic floor, symptoms of incomplete evacuation of stool and needing to splint or use fingers to extract the stool are often associated with rectocele and internal rectal prolapse. In the advanced phase of rectal prolapse, symptoms of tissue protrusion out of the anus or vagina, along with pressure and pain in the local and regional areas of the pelvis, may represent the rectal and vaginal prolapse with

enterocele.[37] In the extreme form of pelvic floor prolapse, the rectum, vagina, uterus, and bladder are prolapsed out, as shown in Figure 19-5. Sullivan et al.[67] described this condition as The Tetralogy of Fallout.

The continuum of pelvic floor laxity leading to anorectal symptoms makes it difficult to evaluate the effectiveness of medical versus surgical management, but medical management becomes less effective than surgery when the patient's complaints and physical findings of rectal and other pelvic organ prolapse become evident. The medical management of symptoms not specific to pelvic floor prolapse, such as constipation, pruritus ani, hemorrhoids, and fecal incontinence, has been addressed elsewhere in this book and will not be repeated here. The presence of rectocele and multi-pelvic-organ prolapse is specific to pelvic floor disorders and manifests as complaints of rectal pressure, defecation difficulty,

FIGURE 19-5. Extreme form of multiorgan prolapse with rectum, uterus, vagina, and bladder prolapsed out of the levator hiatus.

incomplete emptying, fecal seepage, low back and pelvic pain, "hemorrhoids," and tissue "falling out" of the rectum and vagina.

The evaluation and determination of when a rectocele becomes significant for surgical intervention are hampered by the lack of a unified agreement on the pathogenesis and diagnostic evaluation of rectoceles.[68] They are usually described as herniation or defect of the rectovaginal septum,[69,70] but clinical findings of perineal laxity and cystodefecography findings of increased length between the pubis and anus during strain, as shown in Figure 19-6A and B, suggest that rectoceles also have a component of rectal descent in addition to rectovaginal defect. The evidence of rectal descent is even more compelling in men with rectocele. Chen et al.[71] evaluated 234 men with defecation complaints and found 40 men (17%) with rectocele; 40% had prostatectomies. Rectoceles were anterior in 48% and posterior in 52%, nonrelaxing or partially relaxing puborectalis muscle 66%, perineal descent 65%, intussusception 23%, and sigmoidocele 15%. Their findings support the view that rectoceles rarely occur in isolation. Furthermore, rectoceles are not all equal in their effect on defecation dysfunction. Pucciani et al.[72] described two types of rectocele in women, type I (distension) and type II (displacement), and found that type II was associated with higher incidence of vaginal prolapse, more frequent manual evacuation, lower anal pressure, and greater mucosal intussusception than type I. The displacement type of rectocele is likely a result of the descent of the rectum. Brubaker[73] described the displacement of the rectum as the "rectal width," and correlated this to stool entrapment. The loss of rectal alignment in the pelvis means that intraabdominal pressure is ineffectively transferred during defecation, leading to obstructive defecation complaints. Halligan et al.[74] showed that patients who
FIGURE 19-6. Cystodefecographies show the widening of the distance between the pubis and anal opening in patients on the *right* (**A**) compared to the normal on the *left* (**B**). Measurement of the distance can be made by drawing a perpendicular line from the pubococcygeal line to the anal opening during the defecation phase.

were able to expel a 10 cc pressure transduced balloon had higher intrarectal pressure than those who did not (median 208 versus 143 cm H$_2$O).[74] Evacuation ability of the rectal balloon correlated with defecography findings of prolonged and incomplete evacuation.[74] Interestingly, they found eight patients who had prolonged evacuation time, low intrarectal pressure, and very little change in pelvic floor descent, and concluded that these patients lacked the ability to generate intraabdominal pressure. It is unclear if these eight patients had extreme pelvic descent such that they could not have any further excursion of their pelvic floor during the evacuation phase of their defecography. Karlbom et al.[75] showed that successful improvement of rectal emptying after rectocele repair is associated with elevation of the pelvic floor.

Surgical repairs of rectoceles are generally divided into transanal and transvaginal approaches. Transabdominal approaches for rectocele are usually done in conjunction with other more severe pelvic organ prolapse findings. The most common transanal approach to rectocele repair is the modified Delorme procedure popularized by Sullivan et al.[76] in which the anterior rectal wall was plicated after the mucosa was lifted up from the muscularis propria. The recognition that up to 70% of rectal mucosal intussusceptions or internal rectal mucosal prolapses were associated with rectocele[77] led to the return of Delorme's original description of the repair, which involved the circumferential stripping of the rectal mucosa and plication of the rectal musculature.[78,79] Currently, the technique begins with the patient in a prone jackknife position with buttocks taped apart. The rectal mucosa about 1–2 cm proximal to the dentate line is infiltrated with a 1:1 mixture of 1% xylocaine with epinephrine and 0.5% bupivacaine, injected circumferentially. The rectal mucosa is then circumferentially divided with electrocautery and dissected free from the rectal musculature, resulting in a mucosal tube for a distance of about 10–15 cm, or corresponding to the proximal edge of the rectocele. A series of imbricating 2-0 polyglycolic acid sutures on a swagged needle is placed initially in four quadrants and is then further reinforced by additional sutures between the quadrants. This technique in essence corrects the rectal intussusceptions and rectocele and lifts up the rectum back into alignment in the pelvis. The effectiveness of transanal repair of rectocele in alleviating defecation dysfunction or outlet obstruction is usually 80–98%.[80–82] However, long-term outcomes of transanal rectocele repair are associated with 50% recurrence at 5.5 years.[83] It is unclear if recurrence means return of symptoms of obstructive defecation, or anatomical recurrence of rectocele, or both. Other techniques using a stapler to obliterate the rectocele and reduce intussusception, such as the single-stapled transanal prolapsectomy with perineal levatorplasty (STAPL) and double-stapled transanal rectal resection (STARR), had 76 and 88% improvement of obstructive defecation symptoms at 20 months, respectively.[84] Again, the lack of postsurgical defecography or MRI studies makes it difficult to explain why reduction of the rectocele results

in improvement of symptoms. Van Laarhoven et al.[85] showed that there is no correlation between patients' symptoms and size of rectocele reduction, suggesting that other factors may be at play for patients' improved symptoms.

Transvaginal techniques of rectocele repair or posterior colporrhaphy are primarily performed by gynecologists using one of the four techniques: (1) levator ani (puborectalis) or rectovaginal muscularis reapproximation,[86] (2) site-specific repair of the rectovaginal septum,[107] (3) reapproximation of the rectovaginal septum to the levator ani fascia,[87] (4) posterior repair of the rectovaginal defect with grafts or mesh.[88] All these techniques involve an incision in the posterior wall of the vagina and separating the plane between the rectum and vaginal wall. Once the exposure is complete, then various techniques of reinforcement of the septum are performed. In general, the approximation of the levator ani results in up to 50% incidence of dyspareunia.[70] This technique has been mostly abandoned and replaced with rectovaginal septal repair by reapproximating it either longitudinally or transversally, with or without grafts or mesh. The concept of site-specific repair of the rectovaginal septum is best described by Richardson,[70] who described "breaks" in the rectovaginal septum resulting in rectocele formation. Depending on the location and extent of the breaks, various types of rectocele emerge, and with higher "breaks" enteroceles may enter into the rectovaginal plane. The use of biologic grafts and synthetic mesh in rectocele repair is reserved for large rectoceles (with >4 cm depth), presence of vaginal prolapse, poor native tissue, and associated vagina and bladder prolapse.[90–93] In general, the use of grafts or mesh in the repair of rectocele is safe, but its superiority and efficacy over established repair remains inconclusive.

The best study on the benefits of transvaginal repair of rectocele was done by Mellgren et al.[94] who reported on 25 patients prospectively for a mean period of 1 year. Constipation was present in 88% preoperatively and relieved in 84% postoperatively. Paraiso et al.[95] reported their randomized trial evaluating three surgical techniques of posterior colporrhaphy (rectovaginal muscularis reapproximation, site-specific repair, and site-specific repair with a xenograft) and found all three methods had similar improvement in symptoms, quality of life, and sexual function. Interestingly, they found a 46% anatomical failure rate with the xenograft, but without any difference in outcome compared to the other two techniques.[95] No cystodefecography studies were performed before or after the repairs to document the effects of the surgical intervention, which makes it difficult to explain the unexpected outcomes of any pelvic floor repair. An attempt to compare transanal versus transvaginal repair of rectocele for symptoms of obstructive defecation by Nieminen et al.[96] on 30 patients suggests that at 1 year postoperative follow-up, more transvaginal repair patients remain asymptomatic compared to the transanal repair group (93% versus 73%; $p = 0.08$). Again, there were no postoperative studies to explain the discrepancy of their results.

Progression of pelvic floor laxity leads to complex, multi-pelvic-organ prolapse similar to what Sullivan et al.[67] described as the Tetralogy of Fallout. Central to the successful restoration of the pelvic organs to their anatomic position is stabilization of the perineal body and reinforcement of the rectovaginal septum or posterior vaginal fascia. In men this septum or fascia is known as Denonvilliers' fascia. Sears[53] in 1933 published anatomic findings of the rectovaginal septum and described it as a double-layer sheet of fascia arising from the levator ani and uterosacral ligament. One of the layers (lateral) forms the urogenital diaphragm, and the other (medial) fuses to the fibers of the posterior vagina and perineal body (Figure 19-7).[53] Milley and Nichols[97] provided further evidence of the relationship between the rectovaginal septum and perineal body in 143 specimens, whose ages ranged from 8 weeks fetus to 100 years. Lane in 1962[98] was the first to use mesh in the pelvis to reinforce the rectovaginal septum in the repair of vaginal vault prolapsed. Although there has been a plethora of mesh development, Lane's technique of the transabdominal sacrocolpopexy has undergone very little modification. Nygaard et al.[99] summarized the published data on abdominal sacrocolpopexy from 1966 to 2004
FIGURE 19-7. The endopelvic layer arising from the pelvic sidewall and fanning out between the rectum and vagina to form the rectovaginal septum and anchoring to the perineal body. (With permission from Sears NP. The fascia surrounding the vagina, its origin and arrangement. Am J Obstet Gynecol 1933;25:484–92).

and reported the range of success rates for apical prolapse was 78–100%, organ prolapse 58–100%, reoperation for prolapse median 4.4% (range 0–18.2%), and mesh erosion 3.4%. They concluded that sacrocolpopexy with mesh is an effective technique for vaginal apical prolapse, but reported an increase in constipation complaints from 29% to 52%. Pilsgaard and Mouritsen[100] reported their experience with 35 patients who underwent sacrocolpopexy with mesh with a mean follow-up period of 2 years (6 months to 4.5 years) and reported a 30% increase in the symptoms of defecation difficulty. The exact etiology of the increased defecation dysfunction or constipation is unclear. Addison et al.[101] reported on 3 cases of sacrocolpopexy with mesh failure and suggested mesh avulsion from the apex of the vagina or herniation below the mesh repair as a cause of recurrent symptoms of prolapse. They advocated placement of the mesh throughout the length of the vagina. Sullivan et al.[19] in 2001 published the largest long-term result on pelvic floor prolapse repair with their technique called total pelvic mesh repair (TPMR). Over a 10-year period, 236 women had TPMR, and 205 were available for a median follow-up of 5.3 years. They reported resolution of defecation difficulty in 76% and of fecal incontinence in 85%, and patient satisfaction of 74% at 6 years or greater. Their procedure incorporates the current understanding of perineal stabilization and reinforcement of the rectovaginal septum by placing a mesh for the full length of the vagina and anchoring it to the perineal body. The mesh is made of polypropylene, cut into the shape of a trapezoid, placed below the visceral peritoneum, to the left of the rectum, and anchored to the sacrum at the level of S1 and S2. Two additional strips of mesh are secured onto the lateral edges of the sacroperineal mesh, tunneled deep to the peritoneum lateral to the vagina and bladder, and secured to Cooper's ligament about two fingers' breadth from the pubic symphysis (Figure 19-8). Cundiff et al.[102] developed a similar technique of anchoring the perineal body to the sacrum with polyester mesh, called the abdominal sacral colpoperineopexy. The procedure combines a transvaginal and transabdominal approach of securing a polyester mesh to the perineal body and vagina, and tying it down to the sacrum. Nineteen patients had this procedure and were followed for a mean of 11 weeks. All the patients had improvement in their stage of prolapse by at least one level as determined by the POP-Q. Bowel symptoms of fecal incontinence and constipation improved in 8 of the 12 patients (66%).[102] These two studies highlight the importance of perineal body stabilization and rectovaginal septum reinforcement with mesh in the support of pelvic floor prolapse.

The use of mesh slings have proliferated beyond the initial use for urinary incontinence and have been advocated for the treatment of fecal incontinence and rectal prolapse. However, this is not a new concept, Nigro[103] borrowing urologic concepts of fascial sling in the urethral support of urinary incontinence, reported his technique of Teflon mesh via a transcoccygeal–suprapubic approach in five patients with

FIGURE 19-8. In the Total Pelvic Mesh Repair (TPMR), a Cobb-Ragde needle (V. Mueller, Deerfield, IL) is placed in back of the rectovaginal sulcus and pushed through into the introitus to secure the perineal body. A polypropylene suture is placed through the eye of the Cobb-Ragde needle and pulled into the pelvis to secure the mesh between the sacrum and the perineal body. Two additional strips of mesh are then placed on each side of the sacroperineal mesh, tunneled deep to the peritoneum, and secured lateral to the vagina and bladder to Cooper's ligament in the space of Retzius.

FIGURE 19-9. Transperineal trocar system to place a posterior rectal sling for fecal incontinence.

rectal prolapse. He reported no recurrence with follow-up of 2 months to 5 years. In 1970, Nigro[104] reported a transabdominal approach in 6 patients, and updated on 15 patients with the transcoccygeal–suprapubic approach and revealed 2 out of 15 failures. More recently, Yamana et al.[105] reported the use of a transperineal trocar system to place a posterior rectal sling for fecal incontinence (Figure 19-9) in 8 patients, 1 developed infection requiring the removal of the sling, and the remaining 7 had improvement of their Fecal Incontinence Severity Index from 27 to 9, Cleveland Clinic Florida Fecal Incontinence Score improved from 13 to 5, Fecal incontinence Quality of Life Scale was improved in all four categories.

Although mesh placement, regardless of whether it is a transabdominal, transvaginal, or transperineal approach, seems to offer a better outcome than non-mesh repairs, there are no conclusive evidence to suggest that patients with early symptoms and findings of pelvic floor laxity will require more advance repairs with mesh than those patients reported by Sullivan et al.[19] Cundiff et al.[102] and others.[40] The current techniques of local repair of the bladder, vagina, and rectum may be adequate, provided that clinical and radiologic findings show them to be truly isolated pelvic organ prolapse, but as discussed earlier such isolated prolapse is uncommon, and the failure to recognize and repair multiorgan prolapse is a primary source of patient dissatisfaction.[106]

Unlike diseases which are surgically addressed with one technique such as appendicitis, the pathogenesis of pelvic floor prolapse is chronic and result in progressive constellation of symptoms and findings. The global transformation of the pelvic floor may result in surgical treatments that are successful for a limited period of time and fail not because of the technique, but because of the progression of the pelvic floor prolapse. The exact etiology of pelvic floor prolapse remains unknown, and it is for this reason that dynamic imaging with cystodefecography, MRI, and other modalities are so important in documenting the disease process of pelvic floor disorders. Undoubtedly there will be new technologies and techniques that will evolve to replace the old, but as Moschowitz[50] most elegantly put it in his axiom, or generally accepted truth, about treatments of rectal prolapse, "the more remedies there are suggested for the cure of a malady, the less the likelihood of the efficacy of any particular one." A corollary to this axiom would be, "the more remedies there are for a disease, the more reflective of our lack of understanding of its pathogenesis."

Anal Cancer

Mark Lane Welton and Nalini Raju

Introduction

This chapter reviews the anatomy that defines anal and perianal squamous cell carcinomas (SCC), discusses the cancers and precursor lesions that are most commonly found in these regions, and concludes with brief discussions of the less common malignancies of the anus and perineum.

New Anatomic Considerations

Approximately 5,290 new cases of anal cancer were diagnosed in the USA in 2009 according to the American Cancer Society.[1] This number may actually somewhat overestimate the true incidence, as it is our impression that perianal or anal margin cancers are often classified as anal canal cancers due to proximity to the anus without actual involvement of the anal canal. While colorectal surgeons are quite familiar with the landmarks that define the anal canal and anal margin, other health care providers involved in the diagnosis and treatment of this disease are less familiar with these landmarks in that their primary practices are internal medicine, gastroenterology, radiation oncology, medical oncology, dermatology, HIV medicine, etc. Given these limitations, new terminology based on landmarks that all healthcare providers can easily visualize and understand was developed and published in the previous version of this text and largely adopted in the latest version of the American Joint Committee on Cancer (AJCC) Staging Manual.[2] The new terminology is necessary because true anal canal lesions may have a more aggressive biology requiring chemoradiotherapy while lesions of the perianal skin may simply be treated with local excision. Thus, if the two classes of lesions are unwittingly grouped together, the response rates of anal cancer to chemoradiation therapy may be overstated.

The classification system divides the region into three easily identifiable regions, anal canal, perianal, and skin (Figure 20-1A, B).[3] *Anal canal* lesions are lesions that cannot be visualized at all, or are incompletely visualized, with gentle traction placed on the buttocks. In contrast, *perianal lesions* are completely visible and fall within a 5 cm radius of the anal opening when gentle traction is placed on the buttocks. Finally, *skin lesions* fall outside of the 5 cm radius of the anal opening. A key component of this classification system is that all clinicians, including gastroenterologists, surgeons, nurse practitioners, and medical and radiation oncologists can perform this simple exam in their offices without the aid of an anoscope or a clear understanding of the anatomic landmarks (dentate line and anal verge) of the region.

Identification of a new zone, the *transformation zone*, was also proposed to help clinicians and pathologists understand how anal squamous cell carcinomas (SCC) may be found 6, 8, or even 10 cm proximal to the dentate line in the anatomic rectum. The transition zone is a well-known region. It is an area, zero to 12 mm in length beginning at the dentate line, where a "transitional urothelium-like" epithelium may be found in the rectal mucosa instead of the standard columnar mucosa of the rectum. The *transformation zone* of the rectum is a region in which squamous metaplasia may be found overlying the normal columnar mucosa. This immature metaplastic tissue may extend up the rectum in a fluid and dynamic fashion involving at times 10 cm or more of distal rectal mucosa. The *transformation zone* is an important region, where metaplastic tissue susceptible to human papiloma virus (HPV) infection, in particular HPV 16, may be found.

Locations of all lesions within the above referenced zones should be clearly reported. Frequently, accurate reconstruction of the exact location of a lesion removed by a referring caregiver is not possible. This may lead to overtreatment of perianal and even skin lesions. In the distal rectum, it may still be necessary to refer to one established anatomic landmark, the dentate line (mucocutaneous junction), to accurately reflect how far proximally in the rectum a lesion was found. In contrast to the dentate line, the anal verge is poorly understood, poorly visualized and often confused with anal margin, which represents a region, not an anatomic boundary.

A

B
FIGURE 20-1. **A** and **B**. Terminology for location of anal and perianal lesions. Tumors **A**, **B** and **C** represent **ANAL** lesions that are not visible or are incompletely visible while gentle traction is placed on the buttocks. Tumor **D** is a perianal tumor because it is completely visible with gentle traction on the buttocks and lesion **E** is a skin cancer.

Terminology

The terminology used by pathologists when reporting premalignant lesions of the anus and perineum is often confusing to the treating clinicians. The terms squamous cell carcinoma in situ (CIS), anal intraepithelial neoplasia (AIN), anal dysplasia, squamous intraepithelial lesion (SIL), and Bowen's disease may all be used to refer to the same histopathology. The training of the pathologist often dictates the terms chosen. An additional point of confusion is that AIN terminology derives from histologic exams (microscopic evaluation of thin slices of tissue) while SILs are cytologic diagnoses (microscopic evaluation of cell scrapings or needle aspiration). AIN and dysplasia have both historically been broken into AIN I, II, and III and low-, moderate-, and high-grade dysplasia. However, as with other pathologic staging systems, the

intra- and inter-observer variability is too high with this many categories. Therefore, when referring to anal canal, perianal, and skin lesions of the buttock the tissue should be classified as either normal, low-grade squamous intraepithelial lesions (LSIL), high-grade squamous intraepithelial lesions (HSIL), or invasive cancer as is done in the AJCC Staging Manual.[2]

Lymphatic Drainage

Lymphatic drainage above the dentate line occurs via the superior rectal lymphatics to the inferior mesenteric lymph nodes and laterally to the internal iliac nodes. Below the dentate line, drainage is not only primarily to the inguinal nodes, but may also involve the inferior or superior rectal lymph nodes.

Etiology and Pathogenesis of Anal Dysplasia and Anal Squamous Cell Carcinoma

The HPV is a necessary but not sufficient cause for the development of anal SCC and SIL.[4,5] HPV is a DNA papovavirus with an 8 kb genome and is the most common viral sexually transmitted infection.[6–8] Although most patients clear the virus with only 1% of the patients developing genital warts with low oncogenic potential (HPV serotypes 6 and 11),[9–11] an estimated 10–46% of patients develop subclinical infections that may harbor malignant potential (HPV serotypes 16, 18, 31, 33, 35).[12–15]

Transmission is not prevented by condoms as the virus pools at the base of the penis and scrotum. Thus, abstinence is the only effective means of prevention. In women, the virus may pool and extend from the vagina to the anus. Anoreceptive intercourse may be associated with the development of intra-anal disease but the presence of condylomata or dysplasia within the anus does not indicate that anoreceptive intercourse has occurred.[16]

In the rare patient who develops chronic infection, a variety of events must occur starting with the virus entering the basal and parabasal cells. This may occur through a disruption in the normal mucosal barrier that developed as a result of anoreceptive intercourse, other sexually transmitted diseases (ulcers from syphilis, gonorrhea), friable prolapsing hemorrhoidal tissues or a firm bowel movement. As noted above, the squamous metaplastic tissue above dentate line is a relatively "immature" incompletely developed squamous epithelium overlying the columnar epithelium and may not require trauma to disrupt an intact "barrier" making it particularly susceptible to HPV infection.[17] If high-risk viral DNA eludes immune surveillance and gains access to the nuclei of replicating cells (wound repair or metaplasia), the infection can become widespread and persistent lasting for decades resulting in an increased risk of cancer.

Cell-mediated immunity appears to be important to the cellular response prohibiting the virus from establishing a

prolonged presence. This hypothesis is supported by the observation that cervical dysplasia patients with established high-risk lesions had a decreased ability to mount a T helper cell type 1 (Th1 IL-2) response in contrast to those patients with low-risk lesions.[18] Further support comes from the increased anal cancer rates observed in kidney transplant and HIV (+) patients, both populations with blunted cell-mediated responses.[19–25]

Oncogenic viruses lead to cellular proliferation in the latency phase by interfering with cell cycle control mechanisms.[17,26] Two "early region" viral genes, E6 and E7, inhibit cell cycle control resulting in increased proliferation. E7 binds directly to the retinoblastoma (Rb) tumor suppressor protein products p105, p107, and p130 related proteins leading to a complicated cascade of events involving E2F transcriptions factors, cyclin complexes and other regulatory proteins allowing the cell to progress through G1 into S phase.[27] Cell cycle release by E7 allows for immortalization of the cells but is not sufficient for the transformation of the infected cell. Accumulation of genetic errors appears necessary for transformation, which is consistent with the clinical scenario of a long-standing low-grade infection preceding the development of malignancy.[28] The genetic errors may accumulate as a result of the E6 protein which binds to p53 with E6-associated protein (E6AP) leading to degradation of the complex through the ubiquitin pathway.[27,29] The unblocked p53 protein is an important cell cycle regulating protein that leads to cell cycle arrest and apoptosis when genetic errors have accumulated thus allowing for DNA repair and avoidance of replication of errors.

The E2 protein allows the HPV DNA to avoid intracellular detection by facilitating the attachment of the HPV DNA to the host chromatin. This also assures replication in a steady state with each cell division.[17,30–32] In uninfected epithelium, division occurs in the basal layers and maturation results in pyknotic condensed cells that slough from the tissue surface. In infected tissues, the viral DNA replication process is reactivated leading to the presence of specific proteins and viral particles that can be detected in the upper cell layers. In summary, through the combined effect of E7, E6, and E2, cells with genetic errors may proliferate, accumulate and involve the entire thickness of the epithelium.[17] This may result in carcinogenesis.

As the infection with oncogenic viruses persists the anal tissues may progress through low-grade to high-grade dysplasia and cancer. With this disease progression is an associated increased proliferation and angiogenesis, and decreased apoptosis.[33] In contrast to the mechanisms responsible for the increased proliferation and decreased apoptosis outlined in the above discussion, the mechanisms involved in increased angiogenesis are less well defined. However, in the cervix, angiogenic changes have long been recognized as an important and visible step in the progression of dysplasia to cancer. Colposcopy, a magnified view of the cervix with the aid of acetic acid and Lugol's solution, allows for direct visualization of characteristic vascular patterns seen with LSIL and HSIL. Gynecologists are trained to recognize these vascular patterns and target their therapeutic destruction in the cervix accordingly. This therapeutic intervention, in combination with screening Pap smears, has led to the belief that cervical cancer is a largely preventable cancer.

Fortunately, the angiogenic changes associated with the development of anal HSIL are also visible with the aid of acetic acid and Lugol's solution in the perianal skin, anus and distal rectum through an operative microscope, colposcope, or loupes in the office or operating room (Figure 20-2A–D).[15] Targeted destruction is safe and may result in the same decrease in anal cancer incidence as was seen with cervical cancer when cervical Pap smears and targeted destruction were introduced for cervical disease.[34,35]

The cost-effectiveness of such an anal cytology screening system to prevent anal cancer has been demonstrated using an economic model in both HIV-positive[36] and HIV-negative men who have sex with men (MSM).[37] These studies demonstrated that screening to identify patients with HSIL to be referred for treatment would be cost-effective if performed annually for HIV-positive MSM and every 2–3 years for HIV-negative MSM.

Although the association of MSM and anal cancer is clear[16,38,39], the association of HIV with the development and progression of anal cancer has been hard to separate from other confounding factors. Initial studies accumulating anal cancer rates from the pre HAART (highly active antiretroviral therapy) era failed to show a correlation presumably because patients succumbed to complications of the HIV.[40,41] HPV is an indolent infection that leads to cancer in a minority of patients who generally suffer from a long-term infection. Thus, as might be expected, more recent studies reporting anal cancer rates in patients who are now surviving longer with effective HAART suggest an association with HIV and anal cancer.[19,20,42–45] Supporting this association is the observed rise in anal cancer and dysplasia rates seen in HIV positive MSM, and HIV positive heterosexual men and women who do not report anoreceptive intercourse.[19–21] Further, HIV positive patients are more likely to have HSIL, are more likely to progress from LSIL to HSIL over a two-year time period, and both of these findings are increased in the patients with a lower CD4 count (<200 cells/mm).[42–44] Low CD4 counts are a surrogate measure for immunosuppression from the HIV infection, and it is therefore suggested that HIV infection is associated with an increased risk of progression of anal disease.

Although the above articles suggest a permissive role for HIV in the development of anal cancer in HIV positive men and women, one cancer registry report comparing anal cancer rates before and after the individual's AIDS diagnosis found no correlation.[46] Nonetheless, data is accumulating that suggests that as men and women live longer in the HAART era, the indolent HPV infection results in an increased risk for the development of anal cancer, and this effect is the most significant in the most immunocompromised patients.[45]
FIGURE 20-2. LSIL and HSIL visualized in the office with a colposcope after the application of acetic acid. The *arrows* in both images depict where the biopsy of the lesion was taken. **A** and **B** Anal LSIL in the distal rectal mucosa with subtle punctate vessel changes. The geography of the lesion in highlighted in the left frame. **C** and **D** Anal HSIL in the distal rectal mucosa with the left image highlighting serpiginous, cerebriform vessels and the outline of the entire lesion and the right image highlighting the mosaic pattern created by the vessels in the aceto-white background.

Epidemiology

The incidence of anal SCC has been increasing in frequency in over the last 30 years in the USA, Europe, and South America. This increase has been quite pronounced over the last 8 years, where there has been an increase from 3,900 new cases for 2002 to 5,290 new cases for 2009.[1,47] The California Cancer Registry found a statewide increase in anal cancers in non-Hispanic white men of approximately 2% per year between 1988 and 1999 with 1.0 case per 100,000 population in 1988 and 1.4 cases per 100,000 population in 1999.[22] There was not a comparable increase for women over the same time period. Most alarming was the increase in the age adjusted incidence for San Francisco white men age 40–64, where the rates rose from 3.7 per 100,000 for 1973–1978

to 8.6 per 100,000 in 1984–1990 and ultimately to 20.6 per 100,000 in 1996–1999. This is the first report ever of anal cancer rates higher among men under age 40 compared to women of the same age group.[22] Previous reports have consistently shown a higher rate in women in all age groups.[48]

In Denmark during the years 1943–1987, there was a 1.5-fold increase in men and a threefold increase in women.[49] A significant decrease in the mean age of men diagnosed with anal SCC from 68 to 63 years of age was also found. An even greater increase was found in city populations, where a threefold increase in the incidence of anal cancers in Copenhagen and its suburbs was observed. A significant rise in incidence for the entire male population was still seen with the incidence observed between the years 1983 and 1987 representing an increase of 30–40% of that seen

in the 5-year span of 1943–1947. The rates in Copenhagen and surrounding areas were equal to the national level in 1943–1947, but in 1983–1987 the incidence in the city was 2.5-fold higher than that seen in the rest of the country. The average age of women patients with SCC did not change, but the incidence did increase threefold over the entire country with a significantly greater increase in Copenhagen when compared to the entire country. Men with anal cancer were significantly less likely to have been married when compared to men with colon cancer and stomach cancer. The same was not true of women with anal cancer. Similar findings were reported from Sweden, where a dramatic increase in incidence of anal cancer was observed around 1960, with a greater change in women than men (2:1), and the steepest increase in the heavily populated cities.[48] A study from Vermont shows that the trend seen in the cities is also present in more rural settings.[50]

In another Copenhagen study, women with anal cancer were noted to have a higher risk of having had cervical neoplasia or cancer.[51] Risk factors for developing HSIL and anal cancer also included HIV seropositivity, low CD4 count, persistent infection with high-risk HPV genotypes (16, 18, 31, 33, 35), infection with multiple genotypes, cigarette smoking, anal receptive intercourse, and immunosuppression for organ allograft. Multiple partners was not a significant independent risk factor.[28,42,43,52–58]

Anal Canal and Perianal High-Grade Squamous Intraepithelial Lesions (Formerly Bowen's Disease)

As mentioned earlier in the chapter, the distinction between Bowen's disease and HSIL is unclear and appears to have more to do with the pathologist's training, histopathology versus cytopathology, than any biologic difference. Bowen's disease is anal SCC in situ, AIN II and III and HSIL. The term Bowen's disease is applied to SCC in situ in both keratinizing and nonkeratinizing tissues. Thus, we feel the term is archaic and confusing, and should be abandoned in favor of HSIL. Throughout this chapter, we use the term HSIL to refer to what has previously been termed Bowen's Disease.

HSIL is commonly found as an incidental histologic finding after surgery for an unrelated problem, often hemorrhoids. The lesion is clinically unapparent, but histologic assessment of the specimen reveals HSIL (Figure 20-3). Alternatively, patients may present with complaints of perianal burning, pruritis, or pain. Physical examination may reveal scaly, discrete, erythematous or pigmented lesions (Figure 20-4).

The natural history of HSIL is poorly defined. In the immunocompetent, fewer than 10% progress to cancer.[59] However, in immunocompromised patients, the progression rate appears greater as evidenced by the higher rates of anal cancers observed in the HIV (+) and immunosuppressed

transplant patients.[19–24] As we are as yet unable to identify those patients that progress, the authors favor treatment of HSIL. An exception to this recommendation would be patients with advanced AIDS with poor performance statuses despite maximal medical therapy. This was a common

problem in the early 1990s but since the advent of HAART, the vast majority of our AIDS patients are candidates for surgical intervention. The other exception might be the elderly patient with an asymptomatic lesion and a short life expectancy. Unlike perianal Paget's disease, there is no association with other visceral malignancies.[60]

The preferred treatment is fairly controversial and should be tailored to the given patient. An older recommendation for the unsuspected lesion found after hemorrhoidectomy is to return the patient to the operating for random biopsies taken at 1 cm intervals starting at the dentate line and around the anus in a clock-like fashion. Frozen sections establish the presence of HSIL and these areas are widely locally excised with 1 cm margins. Large defects are covered with flaps of gluteal and perianal skin. Although this technique has been shown to provide excellent local control, it does not prevent recurrences.[61] Recurrence rates in one series were as high as 23% despite this radical approach.[62] Although no cancers developed in this group, HIV status was not noted and complications, including incontinence, stenosis, and sexual function were not reported. In another study of wide local excision, the authors noted a 63% persistence rate at 1 year and a 13% recurrence rate at 3 years. Eleven percent of the patients developed incontinence or stenosis.[63] The unknown risk of disease progression, high recurrence rate, and the significant morbidity associated with extensive wide excisions have led many authorities (including the authors and a few editors) to rarely use or recommend this option.

A less radical approach involves taking patients to the operating room to perform High Resolution Anoscopy (HRA) with the aid of an operating microscope, acetic acid, and Lugol's solution. The lesions are visualized and targeted for electrocautery destruction. Like cervical disease, the HSIL is visible because of its characteristic vascular pattern identifying the at-risk tissue for selective destruction (Figure 20-2).[15] This technique minimizes the morbidity of the procedure and saves the normal anal mucosa and perianal skin that would otherwise be sacrificed. Postoperative pain is significant as with any perianal procedure. One author (MLW) reviewed 247 patients with HSIL treated with HRA.[35] The majority of these patients had extensive circumferential or near circumferential disease and were immunocompromised (HIV or other.) Although recurrent HSIL lesions occurred in 57% of patients, most were retreated with high-resolution directed office-based therapies. Initial extent of disease was the only factor that correlated with recurrence. During the 10-year study period, only 3 (1.2%) patients progressed to SCC. Patients were followed for an average of 19 months (range 3–92) and 78% had no evidence of HSIL at their last office visit.[35] HSIL identified with HRA may also simply be locally excised taking care to stay close to the lesion margin directly visualized with the operative microscope. The deep margin is kept equally close as wide local excision seems of limited benefit and increases morbidity. The resulting minimal defects heal in secondarily. High-risk patients, the

immunocompromised, and patients practicing anoreceptive intercourse should be followed with Pap smears at yearly and three yearly intervals for the immunocompromised and immunocompetent, respectively.[36,37]

Other therapeutic modalities include topical 5-Fluorouracil (5-FU) cream, Imiquimod, photodynamic therapy, radiation therapy, laser therapy, and combinations of the above. The reports are generally small series with limited follow-up, but there may be anecdotal success with each approach, and the options may be kept in mind for challenging cases. Initial reports of the use of 5-FU cream were generally disappointing.[64] However, two small subsequent studies have shown encouraging results.[65] One of these reports suggests that Erbium:YAG laser pretreatment may improve the response of HSIL.[66] Reports of the use of Vidarabine and cidofovir support their consideration but the series are small with limited follow-up.[67,68] Imiquimod has been reported to be of benefit alone[69] and in combination with 5% 5-FU therapy in the immunosuppressed transplant and HIV (+) patient population.[70,71] Radiotherapy with a special skin patch or conventional external beam has also been reported.[72,73] Photodynamic therapy has been tried with success[74,75] and compared favorably to topical 5-FU in a randomized comparison.[76]

Perianal Squamous Cell Carcinoma (Formerly Anal Margin)

SCC arises from both the perianal skin and the anal canal. The distinction between the two locations has become more important as they are increasingly considered different entities with separate treatments and prognosis. Immunohistochemical studies of squamous cell tumors from the anal margin and anal canal demonstrate differences in expression of cadherin, cytokeratins and p53 confirming that these tumors are of distinct histogenetic origin.[77] Perianal lesions are completely visible and fall within a 5 cm radius of the anal opening when gentle traction is placed on the buttocks.

Clinical Characteristics

Perianal tumors resemble SCC of other areas of skin and are therefore staged and often treated in a similar fashion.[78] They have rolled, everted edges with central ulceration, and may have a palpable component in the subcutaneous tissues although the sphincter complex is not usually involved. Patients present in the seventh decade of life with equal incidence in men and women.[79,80] Presenting symptoms include a painful lump, bleeding, pruritis, tenesmus, discharge or even fecal incontinence.[81] In general, perianal tumors are characterized by a delay in diagnosis due to their location and indistinct features, and SCC is no exception. Patients have been noted to have symptoms anywhere from 0 to 144 months prior to diagnosis (median of 3 months),[82] and almost a third are misdiagnosed at their first physician

TABLE 20-1. American Joint Committee on Cancer (AJCC) Staging of Squamous Cell Carcinoma (SCC)

Primary Tumor (T)

Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T*is*	Carcinoma in situ (Bowen's disease, high-grade squamous intraepithelial lesion (HSIL), anal itraepithelial neoplasia II-III (AIN II-III)
T1	Tumor less ≤2 cm in greatest dimension
T2	Tumor 2–5 cm in greatest dimension
T3	Tumor ≥5 cm in greatest dimension
T4	Tumor of any size invades adjacent organ(s), e.g., vagina, urethra, bladder*
	*Direct invasion of the rectal wall, perirectal skin, subcutaneous tissue, or the sphincter muscle(s) is not classified as T4.

Nodal Status (N)

Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in perirectal lymph node(s)
N2	Metastasis in unilateral internal iliac and/or inguinal lymph node(s)
N3	Metastasis in perirectal and inguinal lymph nodes and/or bilateral internal iliac and/or inguinal lymph nodes

Distant Metastasis (M)

M0	No distant metastasis
M1	Distant metastasis present

Stage IV	Any T	Any N	M1	

visit.[81] Patients were given erroneous diagnoses of hemorrhoids, anal fissures, fistulas, eczema, abscesses, or benign tumors. For perianal tumors, however, there was no significant difference in survival between correctly diagnosed and misdiagnosed patients.[81]

Staging

The staging of perianal SCC is based on the size of the tumor and lymph node involvement, both of which correlate with prognosis. Lymphatic drainage of the perianal skin extends to the femoral and inguinal nodes and then to the external and common iliac nodes. Venous drainage occurs through the inferior rectal vein. Lymph node involvement is associated with the size and differentiation of the tumor.[82–84] In one study, the incidence of inguinal lymph node metastasis was noted to be 0% for tumors <2 cm, 23% for tumors 2–5 cm in size, and 67% for tumors >5 cm.[84] Distant visceral metastasis at presentation is rare but should be evaluated with a CT scan of the abdomen and pelvis, to assess for liver metastases, as well as the presence of nodal disease. A chest X-ray or CT may be performed to evaluate for lung metastases. These tumors are generally slow growing and histologically are well differentiated with well-developed patterns of

keratinization.[79,85] The AJCC staging system is described in Table 20-1.[2]

Treatment Options

Treatment of perianal SCC traditionally consisted of surgical resection with wide local excision for smaller-sized tumors and abdominoperineal resection (APR) for larger, invasive tumors. However, it is well documented that wide local excision alone results in high locoregional recurrence rates (18–63%) (Table 20-2)[79,86–91] and should be reserved for those lesions that can be excised with a 1 cm margin, are T*is* or T1, and do not involve enough sphincter to compromise function.[80] A series of 27 patients with T*is* and T1 lesions treated with wide local excision had a 100% 5-year survival[91] and in

another study, all patients with small or superficial tumors locally excised had a survival of 100%, whereas those with deep invasion did not survive 5 years.[89] Since it was introduced in the early 1970s, radiation therapy has become the mainstay of therapy for SCC of the anal canal and its application to perianal tumors is increasing. In patients with T1 or early T2 lesions, local excision or radiation therapy provides similar local control rates (60–100%),[84,92,93] but for less favorable lesions, chemoradiation is now utilized as the first line therapy using perineal and inguinal fields, even without clinically detectable disease in the groin.[84,93] Pelvic lymph nodes are also treated for those patients with T3 and T4 tumors.[79,80,84,94] Local control rates for radiation therapy reported by T stage are as follows T1:50–100%, T2: 60–100%, T3:37–100% (Table 20-3).[84,92,93,95,96] In one study, the T3 lesions were separated into tumors 5–10 cm in size and those greater than 10 cm with local control rates of 70% versus 40%, respectively.[95] Patients with persistent tumor can be treated with local excision or APR with a 50% salvage rate.[86,97] Those with recurrence after successful radiation can also be salvaged for cure with surgery.[98–101] The absolute 5-year survival rate for patients treated with local excision or APR ranges from 60 to 100% but is lower in patients with larger tumors.[87,88,102] Similarly, absolute 5-year survival in patients treated with radiation ranges from 52 to 90% with sphincter preservation in about 80%.[80] The use of chemoradiation specifically pertaining to perianal SCC has not been well examined. However, one study did show an improvement in local control (64% vs. 88%) with the addition of 5-FU and mitomycin to radiation.[95] In extrapolation of data from a randomized, multicenter study, including early stage tumors, anal canal, and perianal cancers, it would be postulated that chemoradiation is superior.[101] More recently, Mendenhall et al.[80] report local control in 19 patients treated with radiotherapy alone or combined with adjuvant chemotherapy over a 21-year period. One patient with T1 disease died secondary to regional and distant disease. Four patients died of intercurrent disease and the remaining 14 patients were disease-free at 25, 29, 37, and 113 months following treatment. No patients required salvage APR or salvage surgical therapy.

In summary, the choice of treatment is dependent on the stage of tumor, the anticipated functional result as a result of therapy and the risk of complications. Although surgery may result in alteration of sphincter function, or a permanent colostomy, radiation therapy may also cause skin changes or proctitis that produces urgency, incontinence, or the need for diversion. For T1 and early T2 tumors, wide local excision may be less morbid and time consuming than radiation therapy and therefore a superior choice. However, if the excision will result in damage to the sphincters with impairment of sphincter function, radiation provides similar local control and survival. Larger T2 tumors should be treated with radiation therapy to the primary lesion and inguinal fields due to poor local control with excision and the significant risk of lymph node metastasis. This treatment modality is much less morbid than resection of the primary and bilateral lymph node dissection with similar control rates.[83] Those with T3, T4, or poorly differentiated tumors should receive radiation to the primary lesion and include inguinal and pelvic fields to treat regional nodes in these areas. APR should be reserved for those patients with persistent or recurrent disease after radiation therapy.[80,94]

Squamous Cell Carcinoma of the Anal Canal

SCC incorporates all large-cell keratinizing, large-cell nonkeratinizing (transitional) and basaloid histologies. The terms epidermoid, cloacogenic, and mucoepidermoid carcinoma are all encompassed in the squamous cell carcinoma group.[2,103] SCC of the anal canal is five times more common than perianal SCC, but its incidence is one-tenth that of rectal cancer. The incidence, epidemiology and etiology were described earlier in this chapter.

Clinical Characteristics

The most common presenting symptom is bleeding, which occurs in over 50% of patients with many complaining of anal pain. Other symptoms include palpable lump, pruritis, discharge, tenesmus, change in bowel habits, fecal incontinence, and rarely, inguinal lymphadenopathy.[81,104,105] A small number of patients are asymptomatic. Unfortunately, most patients are diagnosed late with up to 55% of patients being misdiagnosed at the time of presentation.[81] In another study of 172 patients with SCC, only 17 were diagnosed with tumors confined to the epithelium and subepithelial connective tissue.[106]

Evaluation

Physical examination should include a complete anorectal examination with external inspection of the anoderm, digital exam, anoscopy, proctoscopy, when necessary, and examination of inguinal nodes. Lesions are characteristically hard and ulcerated and, if large, may extend outside the anal canal (Figure 20-5). Careful notation should be made of the size, location, and mobility of the mass, associated perirectal lymphadenopathy, and in women, a pelvic examination should be performed to look for any associated lesions or invasion of tumor into the vagina. Complete examination and biopsy may require anesthesia for those patients with significant pain. Additional workup may include an endoanal/endorectal ultrasound to assess the depth of the tumor, presence of perirectal lymph nodes, and invasion of adjacent organs as an adjunct to the physical examination although this may be limited by pain.[107–110] Ultrasound has been found to be superior to physical exam in assessing the involvement of internal and external anal sphincter muscle and perirectal lymph nodes. This has an impact on staging as physical exam often under-stages tumors. One study demonstrated that endorectal ultrasound T and N stage were significant predictors of relapse, whereas the corresponding clinical staging was not.[109] A study of three-dimensional ultrasound has demonstrated improved accuracy in detecting perirectal lymph nodes and some suggestion of improved evaluation of tumor invasion.[111] Inguinal nodal involvement at the time of presentation can be difficult to determine. The sensitivity of radiologic imaging and clinical exam are poor.[112] Enlarged lymph nodes can be reactive to secondary inflammation in some cases and therefore should be biopsied with direct fine-needle aspiration (FNA) or ultrasound-guided FNA if detected by imaging. Excisional lymph node biopsy is rarely required but may be done if FNA is inconclusive. Studies of sentinel lymph node biopsy have demonstrated that the technique is safe and may result in more accurate staging[113], but the actual impact on initial and subsequent management remains unclear as long as inguinal fields are included during radiation therapy. CT scan or MRI of the abdomen and pelvis can add to locoregional staging as well as evaluating for liver metastasis. A chest CT or chest X-ray is used as a screening tool for lung lesions. PET scans are primarily useful for assessing persistent or residual disease after treatment. Sigmoidoscopy can exclude any associated lesions proximal to the anal canal. Lastly, a HIV test should be performed for those at higher risk. HIV positive patients with CD4 counts <200 need better monitoring of opportunistic infections, closer attention to toxic effects of chemoradiation with possible alterations in dosage, and management of antiretroviral therapy.[104,105,114,115]

Staging

The staging of anal canal SCC is based on the size of the tumor and lymph node metastasis. The TNM staging is listed in Table 20-1. The risk of nodal metastasis correlates with the size, depth of invasion, and the histologic grade of the tumor. In a series of 305 patients with SCC, lymph node metastasis was present in 16%. Nodal metastasis by T stage was as follows: T1 (0%), T2 (8.5%), T3 (29%), T4 (35%). Lymph node metastasis occurred in 47% of patients with T4 tumors greater than 5 cm in size.[116] Inguinal metastases have been detected in 10–30% of patients at the time of diagnosis[90,106,117,118] with an additional 5–22% of patients developing clinically apparent lymph node metastases over time.[118] Nodal metastasis was almost double (58% vs. 30%) in those tumors invading beyond the external sphincter compared to invasion of the internal sphincter.[119] Lymphatic drainage of the anal canal above the dentate line proceeds along the superior rectal vessels. At the dentate line, the drainage basin includes the internal pudendal, internal iliac, and obturator nodes. Below the dentate line, the lymphatic drainage is through the inguinal, femoral, and external iliac lymph nodes.[120] Mesenteric lymph nodes are more common in tumors of the proximal anal canal (50%) than the distal anal canal (14%).[104] An anatomic study of lymph node metastasis demonstrated that they most often occur above the peritoneal reflection and not in the perianal area. Additionally, almost half of the positive lymph nodes were less that 5 mm in size.[120] Distant visceral metastasis occurs in 10–17% of patients at presentation and can be found in the liver, lung, bone, and subcutaneous tissues.[100,101] Subsequent metastasis is more common and was the cause of 40% of cancer-specific deaths in one series.[101]

Treatment

Surgery

The treatment of anal canal SCC was historically operative with APR being the standard of care. Unfortunately, local recurrence rates ranged from 27 to 47% and 5-year survival was 40–70%.[89,90,103,104,106,112,121] The presence of pelvic lymph nodes decreased the 5-year survival to below 20%.[105] Local excision was performed in those patients who could not tolerate an abdominal operation, refused a permanent colostomy, or

FIGURE 20-5. Anal canal carcinoma.

had small, well-differentiated tumors. The recurrence rates and 5-year survival ranged from 20 to 80% and 45 to 85%, respectively.[85,86] However, in well-selected patients with early tumors, the 5-year survival was 100%.[89,90,106]

Radiation Therapy

Primary radiation therapy is quite effective in treating SCC as this tumor is extremely radiosensitive. It can be given as external beam radiation, brachytherapy or in combination. Response is dose-dependent with the best chance of tumor eradication occurring with at least 54 Gy of external beam radiation (Table 20-4).[122,123] However, this benefit is lost when radiation is administered in a split-course fashion.[124,125] Local control and cure can be achieved in 70–90 % of selected patients with 60–70% retaining sphincter function.[117,122] However, when tumors are larger than 5 cm or lymph nodes are involved the cure rate decreases to 50%.[78,100,117,122] Better results with higher doses of radiation must be exchanged with increased radiation-induced complications when more than 40 Gy is administered. Serious late complications include anal necrosis, stenosis, and ulcerations, diarrhea, urgency and fecal incontinence, cystitis, urethral stenosis, and small bowel obstruction. Significant impairment of bowel control due to anal complications can

lead to the placement of a colostomy. Studies have found a dose-dependent effect on morbidity with the requirement of a colostomy in 6–12% of patients.[117,126,127] However, one study examining risk factors predictive of requiring a colostomy for management of anal cancers found that tumor size was the only risk factor. Although radiation toxicities did occur, patients were not at an increased risk for requiring a stoma.[128] Brachytherapy used alone or in conjunction with external beam radiation is also effective with local control rates of 75–79% and 5-year survival of 61–65%, but 3–6% of patients had serious complications that required surgery. The high rate of anal necrosis seen when both modalities are used has dampened the enthusiasm for this approach.[129,130] At this time, radiation therapy alone is not commonly utilized but may have a role in treating T1 tumors.[126,131]

Chemoradiation Therapy

The introduction of chemoradiation therapy by Nigro in 1974 revolutionized the treatment of anal canal SCC by demonstrating equivalent local control and survival rates with the preservation of sphincter function and thus avoidance of a colostomy.[132–134] Since that time, multiple studies have confirmed these results and chemoradiation is the standard therapy for SCC of the anal canal. Nigro described using 30-Gy external beam radiation with 5-Fu and mitomycin C, and demonstrated a complete pathological response in 21 of 26 patients treated (81%). Since that time various radiation doses (30–60 Gy) and chemotherapeutic regimens have been used with similar complete pathologic responses (45–100%) and survival rates (70–90%) (Table 20-5). As a result, operative treatment for anal canal SCC was largely abandoned and reserved for those patients with persistent or recurrent disease

after chemoradiation. Although much controversy existed as to the benefit of chemoradiation therapy compared to primary radiation therapy, two randomized controlled studies have demonstrated the superiority of chemoradiation therapy with 5-FU and mitomycin C to radiation alone.[100,101] Using 45 Gy with a boost for good response, both studies exhibited better local control rates with chemoradiation (Table 20-6) but no significant difference in survival. However, one study noted a higher complete response rate (80% vs. 54%) and an improvement in colostomy-free survival (72% vs. 47% at 3 years) which is significant.[100] Chemotherapy-related deaths occurred in 5.4% of patients in one series leading to changes in the protocol which included a reduction of the dose for patients older than 70, bed-bound, frail, or with evidence of tumor-related sepsis.[101] The role of mitomycin C was also examined in a randomized trial which demonstrated better complete pathologic response rate (92% vs. 85%), local control rate (84% vs. 66%), colostomy-free survival rate (71% vs. 59%), and disease-free survival (73% vs. 51%) when mitomycin C was used in conjunction with 5-FU and radiation compared to 5FU and radiation alone.[135] However, treatment toxicity was increased in the mitomycin C group (23% vs. 7%) with a 4% chemotherapy-related mortality and overall survival was equivalent.

Although the use of mitomycin C has provided excellent results, cisplatin has gained favor as it is a radiation sensitizer, is less myelosuppressive than mitomycin C and has been used for those patients who failed to respond to mitomycin C. In series of patients treated with 45–55 Gy of radiation, 5-FU, and cisplatin, the reported rates of local control (80–83%), disease-free survival (77–90%), and colostomy-free survival (71–82%) were comparable to the best results obtained from mitomycin C regimens. Additionally, there were fewer severe toxicities reported.[136,137] A pilot study of the CALGB using cisplatin demonstrated a complete response rate of 80%, colostomy-free survival of 56% and overall survival of 78%.[105,115] Although the initial studies were encouraging, more recent data suggests that mitomycin C remains the mainstay of chemotherapy. The US Gastrointestinal Intergroup trial RTOG 98-11 was a randomized controlled trial conducted between October 1998 and June 2005 that compared treatment with cisplatin, 5-FU, and radiotherapy to mitomycin C, 5-FU, and radiotherapy.[101] A total of 682 patients with anal canal carcinoma were enrolled in the trial. The primary end point was defined as 4-year disease-free survival. Secondary endpoints were overall survival and time to relapse. Cisplatin-based therapy did not improve

disease-free survival compared with mitomycin-based therapy. Additionally, cisplatin-based therapy was associated with a higher rate of colostomy.

Although the presence of inguinal metastasis at presentation indicates a worse prognosis, the overall 5-year survival is 48% (range 30–66%). Those with lymph nodes greater than 2 cm in size, T3 or T4 tumors or anal margin involvement had a worse survival (29–32%).[118] For patients with obvious evidence of inguinal node metastasis, local control can be achieved in 90% of patients receiving chemoradiation compared to 65% receiving radiation alone. Surgical management with radical groin dissection can lead to significant complications and may be successful only 15% of the time.[112] The management of synchronous inguinal node metastasis is not standardized and different centers use primary radiation therapy (45–65 Gy), chemoradiation, and selective lymph node dissection followed by radiation which has been reported to maintain disease-free intervals in up to 60% of patients.[79] For those with subclinical lymph nodes in the groin, chemoradiation is advocated with doses as low as 30–34 Gy. This minimizes toxicity but is effective in treating small volume disease based on previous studies of small sized tumors.[105] Whether or not inguinal fields should always be included when treating patients for anal canal SCC remains controversial.

Follow-up

No consensus has been reached on appropriate follow-up after the treatment of SCC. It is generally agreed that early intervention for persistent disease and recurrent locoregional disease can lead to successful salvage therapy. Routine examination with digital rectal exam and anoscopy every 3 months in the first 2 years, and every 6 months until 5 years has been recommended. Ultrasound examination has also become popular in detecting recurrence although the literature is mixed on its benefit.[109,138] CT scan or MRI performed after the completion of chemoradiation may also be useful as a baseline for future comparison. MRI is useful for distinguishing surrounding tissues and detecting persistent or recurrent disease.

Treatment of Residual or Recurrent Disease

Persistent or recurrent disease localized to the pelvis after chemoradiation can be treated with salvage therapy. Patients need to be restaged with a CT of the chest, abdomen,

and pelvis. MRI may be useful to assess resectability of pelvic recurrence and PET scan may help to differentiate tumor from radiation-induced tissue changes or other undetectable metastases. APR can be performed for tumor localized to the pelvis with a 5-year survival of 24–47%.[139–144] Those with positive margins, nodal disease at salvage and persistent disease after chemoradiation have poorer outcomes.[144,145] Morbidity for APR in this setting is significant with an increased risk of perineal wound complications. This has prompted the use of plastic surgery reconstruction using rotational or advancement flaps or alternatively, use of the vacuum assisted closure (VAC) to promote healing. The benefit of adjuvant chemotherapy after APR is currently unknown. Symptomatic inguinal disease after chemoradiation of the primary tumor can be treated with radical groin dissection if radiation has already been administered. Additional radiotherapy can be considered if maximal doses of radiation were not delivered. Radical groin dissection in selected patients can result in a 5-year survival of 55%.[146] Distant metastasis have been found in 10–17% of patients treated with chemoradiation,[100,101] and are usually treated with systemic chemotherapy, such as cisplatin or 5-FU for palliation. If the metastases are isolated in the liver or lung and the primary disease is controlled, resection can be considered.

Uncommon Anal Canal Neoplasms

Adenocarcinoma

Anal canal adenocarcinomas are classified into three types. The first group may arise from the mucosa of the transitional zone in the upper canal and are indistinguishable from rectal adenocarcinoma. The second derives from the base of the anal glands, which are lined with mucin-secreting columnar epithelium. The last can develop in the setting of a chronic anorectal fistula.[85] Adenocarcinomas account for 5–19% of all anal cancers[147–149] and have a more aggressive natural history than SCC.[150] The average age at presentation ranges from 59 to 71 years with equal gender distribution.[148,151] Patients may present with pain, induration, abscess/fistula, or a palpable mass. Other symptoms include bleeding, pruritis, seepage, prolapse, and weight loss.[85]

Due to the rarity and heterogeneity of this tumor, the role of surgery and chemoradiation has been difficult to assess, thus making definitive recommendations for treatment impossible. Many patients present with advanced local or metastatic disease making curative treatment challenging. The local disease may tend to be more advanced in those that arise in glands and fistulous tracts because these locations are outside the bowel wall, and therefore the disease originates in a locally advanced location. Wide local excision may be feasible for those patients with a "rectal-type" tumor that is small, well differentiated, and does not invade

the sphincter complex. All other tumors require APR. Chemoradiation alone has not been shown to be as effective for adenocarcinoma compared to SCC due to high local recurrence rates (54% vs. 18%) and poor survival rates (64% vs. 85%).[150] However, in another study analyzing treatments for anal canal adenocarcinoma, including APR, surgery with radiation, and chemoradiation, similar locoregional recurrence rates (20%, 37%, 36%) and better overall survival was seen in the chemoradiation group (21%, 29%, 58%).[151] Other studies have suggested that a combined modality approach of surgery with chemoradiation does improve outcome with survival rates exceeding 60%.[147,148] Although no large series of patients has been treated in any uniform manner to substantiate the approach of chemoradiation therapy followed by surgery, the success of this approach for rectal adenocarcinoma would support its use.

Melanoma

Anorectal melanoma is characterized by lesions that are often difficult to differentiate from benign pathology. For this reason, and its rarity, many patients present with advanced stage disease. Although the anorectum is the most common site for primary melanoma of the gastrointestinal tract, it comprises only 0.5–5% of all malignancies there. Fewer than 500 cases have been reported in the literature.[152] Patients are frequently female, Caucasian and in their sixties. Isolated cases have been reported in African American and Asian populations.[78,153,154]

Anorectal bleeding is the most common symptom described. However, anal pain, change in bowel habits, or tenesmus may also be reported. Weight loss and malaise may be indicative of advanced disease. A mass in the anal canal is the most frequent sign with palpable inguinal lymph nodes common. These tumors arise from the transitional epithelium of the anal canal, the anoderm or the mucocutaneous junction. Although some lesions may seem to arise within the rectal mucosa, it is postulated that this is due to heterotopic epithelium within the rectum or mucosal spread from a primary foci within the anal canal.[153]

Most lesions are pigmented, with early lesions appearing polypoid and larger lesions having ulcerations, raised edges or significant growth into the rectal vault. An early lesion may be indistinguishable from a thrombosed hemorrhoid, and some cases have been incidentally diagnosed from a hemorrhoidectomy specimen. Approximately two-thirds of the lesions are grossly pigmented or show histological evidence of melanin.[155] Amelanotic lesions can be difficult to differentiate from undifferentiated squamous cell carcinoma.

Surgical management of anorectal melanoma provides the only chance for cure. However, the choice of operation continues to be controversial since the prognosis is so poor. Up to 35% of patients present with metastatic disease,[156,157] and those patients with tumors greater than 10 mm in thickness are not cured by any treatment.[157] Additionally, long-term

survival rates, which range from 0 to 29%,[152,155–159] do not seem to differ when wide local excision or APR is performed. However, some studies have shown fewer locoregional recurrences with a more radical operation,[155,156,160] thereby supporting the use of APR for earlier stage tumors. In a study of anorectal melanomas stratified by tumor thickness, tumors greater than 4 mm had inadequate local tumor control with wide local excision alone and APR was advocated.[157] Despite this, anorectal melanoma is largely a fatal disease and so the choice of treatment has little influence on the eventual outcome. Therefore, many authors advocate local excision to spare patients the morbidity of an APR and a colostomy. If the tumor is bulky and negative margins (1–2 cm) cannot be achieved, it involves the sphincter complex, or local resection will result in incontinence, then an APR is the recommended treatment option. If the patient already has signs of regional or systemic metastasis, radical excision should not be performed. The use of endoanal ultrasound and sentinel lymph node biopsies may further guide treatment for this disease.[152,158]

Adjuvant therapy for cutaneous melanoma has been studied extensively; however, the applicability of this data to anorectal melanoma remains uncertain. Many immunotherapeutic and chemotherapeutic agents such as dacarbazine, bacillus Calmette-Guerin, levamisole, and interferon-α have demonstrated no benefit.[158] Cytotoxic chemotherapy, including cisplatin, vinblastine, and dacarbazine, combined with interleukin-2 or interferon-α2b has shown some improvement in survival, however, patients suffered significant treatment-related toxicity.[161] Radiation therapy has also been utilized to improve local and regional control yet due to the small numbers of patients with anorectal melanoma, its efficacy is unknown. Due to its predilection for developing systemic metastasis, it is unclear whether efforts to achieve better local control are useful.

Gastrointestinal Stromal Tumors

Gastrointestinal stomal tumors (GIST) of the anus are extremely uncommon with only 17 cases reported in the literature up to 2003.[162] GISTs are tumors of mesenchymal origin that are not derived from smooth muscle or Schwann cells. They are identified by immunohistochemical studies that stain positive for CD34 and CD117 antigens. It is important to differentiate them from true smooth muscle tumors, with which they were previously combined, as they have a different pathogenesis and biological outcome. However, most series that have reported on leiomyomas and leiomyosarcomas in the past did not make this distinction, but in fact, reflect a large proportion of GISTs.[162,163] Due to the rarity of anal GISTs, they have only been studied with lesions of the rectum as a single entity.

Patients present in the fifth to seventh decade of life are more commonly men. Most patients are asymptomatic but bleeding, anal pain, change in bowel habits, or urinary symptoms can occur. Pathologic factors implicated in aggressive tumors with metastatic potential are size greater than 5 cm in diameter and high mitotic counts, pleomorphism, infiltration of muscularis propria, and coagulative necrosis. The presence of symptoms is also associated with a worse prognosis.

Treatment involves local excision for tumors less than 2 cm and APR for those with larger tumors or worse pathologic features.[162] In a study of anorectal stromal tumors, recurrence rates for local excision and radical resection were 60% and 0%, respectively.[164] The natural history of GISTs is indolent with a long latency period (greater than 4 years) to recurrence or metastasis, which is usually by a hematogenous route.[163] The role of adjuvant therapy in anal GIST is uncertain given the small numbers of patients affected. However, the success of Gleevec® (imitanib mesylate) in treating other GISTs would suggest it as a first line therapy for c-Kit (+) (CD117) GIST of the anus and rectum where compromised bowel control or permanent stoma is an issue.

Small-Cell Carcinoma/Neuroendocrine Tumors

Small cell or neuroendocrine tumors comprise less than 1% of all colorectal malignancies and are extremely rare in the anal canal. In a series of neuroendocrine carcinomas of the lower gastrointestinal tract, 16% were found in the anal canal.[165] Diagnosis involves identification of the classic histopathologic pattern. Hyperchromatic nuclei, pale nucleoli, high mitotic count, in addition to tumor growth in loose, noncohesive sheets are seen, similar to small cell or oat cell carcinoma of the lung. Sixty-five to 80% of patients with extrapulmonary small cell tumors present with metastatic disease. Therefore, it is important to stage them accurately. Those with disease limited to the anal canal are treated in a similar fashion to those with adenocarcinoma, including chemoradiation and radical surgery. Those with disseminated disease may benefit from combination chemotherapy regimens used for small cell lung cancer, such as cisplatin and etopside.[153,165]

Uncommon Perianal Neoplasms

Basal Cell Carcinoma

The incidence of basal cell carcinomas (BCC) of the anus, in comparison to sun-exposed areas of the body, is extremely low. It comprises about 0.1% of all BCC diagnosed and fewer than 200 cases of BCC have been reported on the perianal and genital area.[166] BCCs of the anal margin account for only 0.2% of all anorectal cancers. The largest series of perianal BCC thus far reported includes only 34 cases.[167]

The etiology of perianal BCC is likely different from BCC arising in sun-exposed skin. Although preexisting skin conditions, such as basal cell nevus syndrome and

xeroderma pigmentosum, immunodeficiency, and genetics, may contribute to both types, radiation, chronic irritation or infection, and history of trauma or burn have all been implicated in perianal lesions.[166,168] The majority of these carcinomas occur in men (60–80%) and the average age at presentation is 65–75 years. Approximately one-third have a previous or concomitant history of BCC at other skin sites.[166,167,169]

The average size at presentation is less than 2 cm, although they can be as large as 10 cm and extend into the anal canal.[167] The clinical appearance can range from erythematous papules to nodules, plaques, and ulcers.[166] They tend to be mobile and superficial with little invasive or metastatic potential. Histologically, they are similar to BCC of other areas of the body and do not contain HPV.[166] It is extremely important to differentiate BCC from basaloid carcinoma histologically as these entities behave in a different manner.

It was previously thought that anorectal BCC was more aggressive than other cutaneous BCC, but it is[169] likely that perianal BCC was not adequately differentiated from the more aggressive basaloid tumors thus suggesting a worse prognosis.

Treatment is wide local excision ensuring adequate margins, which is possible in lesions less than 2 cm. Larger lesions may require excision with skin grafting or use of Mohs micrographic surgery to preserve uninvolved tissue. Recurrence rates for local excision range from 0 to 29%.[167,169] Cancer specific survivals in both series were 100% at 5 years. Recurrences can be treated with re-excision. Large lesions extending into the anal canal may be better treated with radiation or APR.

Paget's Disease

Paget's disease can be divided into two groups, mammary and extra mammary. The former was identified on the nipple of the female breast with an underlying carcinoma by Sir James Paget in 1847.[170] The latter was described specifically in the perianal area by Darier and Couillaud in 1893[171] and comprises about 20% of the extramammary type.[153] Other sites of Paget's disease include the axilla, scrotum, penis, vulva, groin, thigh, and buttock where apocrine glands are found.

It is currently believed that Paget's cells represent an intraepithelial adenocarcinoma with a prolonged preinvasive phase that eventually develops into an adenocarcinoma of the underlying apocrine gland given enough time. The origin of these cells is not completely understood. One theory suggests that a pluripotent basal cell is the progenitor of the Paget's cell with the adenocarcinoma arising in the epidermis and extending into the dermis. The other theory supports the origin of Paget's cells from the apocrine glands that spreads into the overlying epidermis. The latter hypothesis may be more likely given the fact that the lesions tend to occur in areas of high density apocrine glands.[79,153,172]
FIGURE 20-6. Perianal Paget's Disease. With permission from Beck DE, Wexner SD. Anal neoplasms. In: Beck DE, Wexner SD, editors. Fundamentals of anorectal surgery. London: W. B. Saunders; 1998. p. 261–277.

This is a rare condition with fewer than 200 cases reported in the literature to date.[173] Patients present in the seventh decade of life with equal distribution among men and women. The most common presenting symptom is intractable itching followed by bleeding, palpable mass, inguinal lymphadenopathy, weight loss, anal discharge and constipation. The median duration of symptoms is 3 years.[174,175] The lesions themselves often have an erythematous, eczematous appearance with well-demarcated borders mimicking a rash (Figure 20-6). They may look ulcerated or plaque-like with oozing or scaling. A third of cases involve the entire anus.[176] These lesions are often misdiagnosed because of their similarity to other conditions. The differential includes HSIL, Crohn's disease, condyloma acuminatum, hidradentits suppurativa, pruritis ani, and squamous cell carcinoma. Biopsy is essential to confirm the diagnosis.

Histologically, Paget's cells have large, round, eccentric, hyperchromic nuclei with pale-staining, vacuolated cytoplasm (Figure 20-7). The cytoplasm stains positive with periodic acid-Schiff stain due to the abundance of mucin
FIGURE 20-7. Perianal Paget's Disease (Photomicrograph hematoxylin and eosin ×400). With permission from Beck DE, Wexner SD. Anal neoplasms. In: Beck DE, Wexner SD, editors. Fundamentals of anorectal surgery. London: W. B. Saunders; 1998. p. 261–277.

and also stains positive for mucicarmine, cytokeratin 7, and alcian blue, which stain mucoproteins, and differentiates it from HSIL. Both mammary and extramammary Paget's disease have similar histologic features but mammary Paget's consistently presents with an associated invasive carcinoma, whereas in perianal Paget's disease, less than half (30–44%) present with invasive adenocarcinoma.[172,176,177] However, the incidence of associated visceral malignancies in perianal Paget's disease is elevated with various series reporting rates of 30–50%. The most common sites include the gastrointestinal tract, anus, skin, prostate, neck, and nasopharynx.[172,176–178] There may also be synchronous lesions in the axillary or anogenital area in patients diagnosed with perianal disease, and therefore a careful survey of other sites for malignancy and secondary disease is necessary.[153]

The treatment for perianal Paget's disease depends on the presence of invasion and other associated anorectal malignancies. For noninvasive lesions, wide local excision is the procedure of choice. In addition to resecting the lesion with grossly negative margins, it is important to map the extent of involvement of the lesion microscopically. This can be performed either by taking random biopsies 1 cm from the edge of the lesion in all four quadrants, including the dentate line, anal verge, and perineum[173,178] or by using toluidine blue and acetic acid to stain the Paget's cells, thereby directing the site for biopsy.[79] The use of intraoperative frozen sections ensures that any disease that extends beyond the gross lesion is excised to reduce the chance of recurrence. Positive margins requiring re-excision are not uncommon when this technique is not utilized. In a series of 27 patients, nine had positive margins and 12 required further surgery. Of the five patients who had mapping with 1 cm biopsies, none developed recurrence.[172] Another study reported positive margins

in 53% of patients.[179] Preoperative mapping can also be performed using dermatologic punch biopsies. If the defect is small, the skin may be closed primarily. For larger lesions that require circumferential excision of the perianal skin, split-thickness skin grafts or sliding and rotational flaps may be required. Recurrence rates range from 37 to 100%.[172,177,180] Most recurrences were treated with wide re-excision with excellent results. For those who developed invasion, more radical surgery or adjuvant therapy was utilized.

Patients who have an invasive component or an associated anorectal malignancy should be considered for radical excision with APR. If positive inguinal lymph nodes are present, then an inguinal lymphadenectomy should be added. Unfortunately, patients with invasive disease present with metastasis 25% of the time and all patients who die of this disease have an invasive component.[79,172] Too few cases of perianal Paget's disease exist to allow for a comparison of invasive and noninvasive groups. Disease-specific survival for all perianal Paget's disease at 5 years ranges from 54 to 70%[172,176–178] and at 10 years decreases to 39–45%.[172,176]

The role of adjuvant chemoradiation therapy remains uncertain. It is currently used in some cases of invasive or aggressive recurrent disease. Concurrent anorectal malignancies may be another indication. Radiation has been associated with an increased rate of local complications when used for perianal Paget's disease[179] and is therefore reserved for patients who are not candidates for further surgical resection.[172]

Verrucous Carcinoma

The term verrucous carcinoma was initially coined in 1948 to describe a low-grade carcinoma of the oral mucosa that resembled viral warts. It has now been expanded to include those lesions described as giant condyloma acuminatum or Buschke-Lowenstein tumors. Abraham Buschke first described the latter in 1896 with respect to two invasive condylomata of the penis. Buschke and Lowenstein[181] then further delineated these lesions of the anus in 1925. Condylomatous features characterized these tumors with growth to a large size, local invasion and destruction of surrounding tissues, and the absence of metastases. Although it is a well-recognized entity, fewer than 60 cases have been reported in the literature to date.[182] HPV is frequently detected.

These tumors are more commonly found in men with a 2.7:1 male to female ratio. The average age of patients is 45 years and is slowly decreasing. Patients present most commonly with the complaint of an anal growth. Pain, perianal discharge/abscess, anorectal bleeding, pruritis, and a change in bowel habits may also occur.[182,183] The lesions themselves are generally slow growing with a soft, cauliflower like appearance that can become nodular as it penetrates the underlying tissues. One theory suggests that direct expansion of the tumor causes erosion and even necrosis of the surrounding tissues thereby predisposing to the development of fistulas that drain purulent fluid. Another suggests that

condylomatous disease complicates existing abscess fistulous disease leading to the appearance of tissue erosion, necrosis, and invasion. The tumors arise most commonly from the perianal skin but can also present in the anal canal and distal rectum. At presentation, they tend to be quite large measuring anywhere from 1.5 to 30 cm.[182] Regional lymphadenopathy may also occur secondary to infection.

The tumor, which is clinically difficult to distinguish from a malignancy, is histologically benign. Papillomatosis, acanthosis with hyperplasia of the prickle cell layer, variable hyperkeratosis, parakeratosis, and underlying inflammation are often found.[181] However, of all the cases of giant condyloma acuminatum reported, only 42% were histologically diagnosed as condyloma without any invasion. A malignant transformation was identified in 58% of the tumors; 8% had carcinoma-in situ, and 50% had invasion that was termed verrucous carcinoma, SCC or basaloid carcinoma.

The standard treatment for verrucous carcinoma is radical local excision. For those patients with extensive deep tissue involvement, multiple fistulas, or involvement of the anal sphincter, APR is indicated. Cure can be achieved only by radical excision. Neoadjuvant radiation therapy may be useful for those tumors with invasive carcinoma and to render a tumor resectable due to its large size; however, some controversy exists as to whether radiation promotes malignant transformation of the tumors. The most current studies do not support this concept, as the incidence of invasive lesions after radiation is extremely low.[183] It has been hypothesized that the high recurrence rates after radical excision may be attributable to spillage of residual tumor, which could potentially be prevented by reducing the tumor size with preoperative chemoradiation. Certainly, size and local extent of tumor invasion, not malignant histology, has the greatest impact on morbidity, recurrence, and mortality. The authors favor the hypothesis that local recurrence is related to transection of the complicated infected fistulous tracts commonly associated with this process. Unfortunately, the rarity of this condition makes it difficult to study this issue prospectively.

HIV-Related Anal Cancer

Kaposi's Sarcoma

Although Kaposi's sarcoma is the most common cutaneous malignancy in patients with AIDS,[184] the incidence of perianal lesions is quite small and decreasing with the increasingly effective antiretroviral therapy available today.[185] A study of 180 consecutive HIV-seropositive patients seen for anorectal symptoms revealed two perianal Kaposi's sarcomas. They were both small, round, purplish lesions that could easily have been mistaken for hemorrhoids. Both were treated with chemotherapy although radiation has been used for localized cutaneous lesions.[186]

Lymphoma

The incidence of non-Hodgkin's lymphoma (NHL) has been increasing in AIDS patients as treatment improves and life expectancy increases. NHL is the second most common AIDS-related neoplasm after Kaposi's sarcoma. Compared to lymphomas found in the general population, these tumors are characterized by B-cells of a higher histologic grade that originate from extranodal tissue. They are also more aggressive, prone to dissemination, and resistant to treatment. Most lymphomas are found in the central nervous system and the gastrointestinal tract. However, anorectal lymphomas are extremely rare, comprising less than 1% of all anorectal neoplasms in the general population.[187] Although the anorectal area is devoid of lymphoid tissue, it is postulated that the exposure to chronic infections from anal receptive intercourse or an immunocompromised state may result in an "acquired" mucosa-associated lymphoid tissue (MALT).

The most common presenting symptoms are pain, pruritis, drainage, or a palpable mass. Some patients may have more constitutional symptoms, such as fever, night sweats, or weight loss.[187] After appropriate staging, patients are treated with a standard regimen for NHL of chemotherapy and radiation therapy of the affected area.

There is no role for surgical treatment. Usual chemotherapeutic agents include cyclophosphamide, actinomycin, vincristine, and corticosteroids (CHOP). There are too few cases of anorectal lymphoma reported to discuss overall prognosis. However, younger patients without constitutional symptoms may fare better. Additionally, low CD4 counts and performance status may affect a patient's ability to endure aggressive therapy.[153] Isolated reports of immunocompetent patients with anorectal lymphoma have been reported with excellent response to treatment.[188]

Presacral Tumors

Eric J. Dozois and Maria Dolores Herreros Marcos

Introduction

The presacral or retrorectal space may be the site of a group of heterogeneous and rare tumors that display indolent growth and produce ill-defined symptoms. As detection is often difficult and delayed, patients frequently present with tumors that have reached considerable size and involve multiple organ systems, complicating their treatment. The diagnosis and management of these tumors has evolved in recent years due to improved imaging modalities, a better understanding of tumor biology, adjuvant chemoradiation therapy and a more aggressive surgical approach. Few surgeons have the opportunity to treat these complex lesions, and the care of these patients can be greatly optimized by an experienced, multidisciplinary team.

Anatomy and Neurophysiology

A thorough understanding of pelvic anatomy, including soft tissue, neurologic, and osseous structures is essential in the evaluation and management of presacral tumors. The boundaries of the retrorectal region include the posterior wall of the rectum anteriorly and the sacrum posteriorly (Figure 21-1). This space extends superiorly to the peritoneal reflection and inferiorly to the rectosacral fascia and the supralevator space. Laterally, the area is bordered by the ureters, the iliac vessels, and the sacral nerve roots (Figure 21-2A). Several important vascular and neural structures are located in this area and injury to them may have important physiologic rectoanal sequelae, as well as neurologic and musculoskeletal consequences. If all sacral roots on one side of the sacrum are sacrificed, the patient will continue to have normal anorectal function. Likewise, if the upper three sacral nerve roots are left intact on either side of the sacrum, the patient's ability to spontaneously defecate and to control anorectal contents will remain essentially intact. If, however, both S-3 nerve roots are sacrificed, the external anal sphincter will no longer contract in response to gradual balloon dilation of the rectum and this will translate clinically into variable degrees of anorectal incontinence and difficult defecation.[1] If sacrectomy is to be performed, the surgeon must be familiar with the relationship among thecal sac, sacral nerve roots, sciatic nerve, piriformis muscle thecal sac, and sacrotuberous and sacrospinous ligaments (Figure 21-2B). Structurally, the majority of the sacrum can be resected, if more than half of the S-1 vertebral body remains intact, pelvic stability will be maintained. However, preoperative radiation to the sacrum may ultimately lead to stress fractures if only S-1 remains. As such, spinopelvic stability may be augmented with fusion in select patients. Knowledge of anatomy of the thigh and lower extremity is also required in complex cases requiring muscle or other soft tissue flaps. It is important to discuss with patients preoperatively the potential neuromuscular and visceral losses that may occur during the operation and how this will influence their function and quality of life.

Classification

General Considerations

Presacral lesions are rare. Reports from various large referral centers have indicated that their incidence may be as low as 1 in 40,000 hospital admissions (0.014%).[2] Spencer and Jackman found precoccygeal cysts in only 3 of 20,851 proctologic exams.[3] While Jao et al.[4] reported 120 patients over a 19-year period.

Lesions found in the presacral space can be broadly classified as congenital or acquired, benign or malignant. Two-thirds of lesions are congenital, two-thirds of which are benign and one-third neoplastic. Overall, 45–50% of the presacral masses are malignant or have areas of malignant change within them.[4–6] The presacral space has a complex embryologic development, and this potential space is primarily composed of connective tissue, nerves, fat, and blood vessels. As this area contains totipotential cells that differentiate into three germ cell layers, a multitude of tumor types may be encountered.
FIGURE 21-1. Relationship of pelvic structures to presacral space.

The classification first described by Uhlig and Johnson[7] has been used for many years and divides tumors into broad categories; congenital, neurogenic, osseous, and miscellaneous. We have modified and updated this system to subcategorize tumors into malignant and benign entities, as this greatly impacts therapeutic approaches (Table 21-1).

Gross and Histologic Appearance

Epidermoid cysts result from defects during the closure of the ectodermal tube. They are histologically composed of stratified squamous cells, do not contain skin appendages, and are typically benign.

Dermoid cysts also arise from the ectoderm, but histologically they contain stratified squamous cells and skin appendages. These are also generally benign. Epidermoid and dermoid cysts tend to be well circumscribed, round and have a thin outer layer. Occasionally, they communicate with the skin surface producing a characteristic postanal dimple. They are most common in females and the infection rate may be high as they are often misdiagnosed as a perirectal abscess and operatively manipulated.

Enterogenous cysts are lesions thought to originate from sequestration of the developing hindgut, if related with the rectum they are called rectal duplication cysts. Because they originate from endodermal tissue, they can be lined with squamous, cuboidal, or columnar epithelium. Transitional epithelium may also be found. These lesions tend to be multilobular with one dominant lesion and smaller satellite cysts. Like dermoid and epidermoid cysts, they can
FIGURE 21-2. **A** Anterior view of pelvic anatomy. **B** Posterior view or pelvic anatomy with sacral elements removed.

become infected and are more common in women. These are generally benign, but case reports have described malignant transformation within rectal duplications.[8]

Tailgut cysts, which are sometimes referred to as cystic hamartomas, are congenital lesions arising from remnants of normally regressing postanal primitive gut. They are more common in females and can be seen as multiloculated or biloculated cysts on magnetic resonance imaging (MRI) (Figure 21-3).[9] These cysts are composed of squamous, columnar, or transitional epithelium that may have a morphologic appearance similar to that of the adult or fetal intestinal tract. The presence of glandular or transitional epithelium differentiates this lesion from an epidermoid or dermoid cyst. Malignant transformation has been reported in up to 13% in some series.[10,11]

Teratomas are true neoplasms derived from totipotential cells and include all three germ layers. They may undergo

malignant transformation to squamous cell carcinoma arising from the ectodermal tissue, or rhabdomyosarcoma arising from the mesenchymal cells. Anaplastic tumors are also seen in which the tissue of origin may not be distinguishable. Histologically, these tumors are referred to as either "mature" or "immature" reflecting the degree of cellular differentiation. Teratomas are more common in females and in the pediatric age group, and are often associated with other anomalies of the vertebra, urinary tract, or anorectum.[12] In adults, malignant degeneration can occur in 40–50%.[13] Incomplete or intralesional resection increases the likelihood of malignant degeneration.[14] These lesions can also become infected and be misdiagnosed as a perirectal abscess or fistula. Diagnosis is often delayed and these tumors may reach considerable size.

Sacrococcygeal chordoma is the most common malignancy in the presacral space. These tumors are believed to originate from the primitive notochord which embryologically extends from the base of the occiput to the caudal limit in the embryo. They can occur anywhere along the spinal column, but have a predilection for the pheno-occipital region at the base of the skull and for the sacrococcygeal region in the pelvis. Over half occur in the sacrum (Figure 21-4). They predominate in men and are rarely encountered in patients younger than 30 years of age.[15] These tumors may be soft,

gelatinous, or firm and may invade, distend, or destroy bone and soft tissue. The center of these tumors contains extracellular mucin. Hemorrhage and necrosis within tumors may lead to secondary calcification and pseudocapsule formation. Common symptoms include pelvic, buttock, and lower back pain aggravated by sitting and alleviated by standing or walking. Diagnosis is often delayed and these tumors may reach a considerable size. Although chordomas are low to intermediate-grade malignant lesions, a radical surgical approach that achieves negative margins greatly improves survival.[15]

Anterior sacral meningoceles are a result of a defect in the thecal sac and may be seen in combination with presacral cysts or lipomas. Typical symptoms include constipation, low back pain, and headache exacerbated by straining or coughing. Anterior sacral meningocele may be associated with other congenital anomalies, such as spina bifida, tethered spinal cord, uterine and vaginal duplication, or urinary tract or anal malformations. Surgical management consists of ligation of the dural defect.

Neurogenic tumors include neurilemmomas, ganglioneuromas, ganglioneuroblastomas, neurofibromas, neuroblastomas, ependymomas, and malignant peripheral nerve sheath tumors (neurofibrosarcoma, malignant schwannomas, and neurogenic sarcomas). In a Mayo Clinic series, schwannomas were the most common benign tumor and malignant peripheral nerve sheath tumors the most common malignant lesions.[16] Benign schwannomas are usually solitary, well circumscribed, encapsulated tumors.[17] Malignant transformation of benign schwannoma is very rare and only nine cases have been reported.[18] Although neurogenic tumors tend to slowly grow, they may eventually reach considerable size. Preoperative differentiation between benign and malignant pathology can be difficult without a tissue biopsy, but is of paramount importance to guide the operative approach.

Osseous tumors include chondrosarcoma, osteosarcoma, myeloma, and Ewing's sarcoma. These tumors arise from bone, cartilage, fibrous tissue, and marrow. Due to relatively rapid growth, these lesions often reach considerable size and pulmonary metastases are common. All osseous tumors of the presacral space are associated with sacral destruction. Although benign, giant cell tumors are locally destructive and can metastasize to the lungs ("benign metastasizing giant cell tumor").

Miscellaneous lesions in this region include metastatic deposits, inflammatory lesions related to Crohn's disease or diverticulitis, hematomas, and anomalous pelvic ectopic kidneys. Carcinoid tumors of the presacral space are unusual but have been reported.[19] Most represent direct extension or metastatic spread from rectal carcinoids. There is no gender predilection. Half of them are associated with development cyst, being malignant about 30% of the cases. Sigmoidoscopy and biopsy is required to differentiate a primary presacral carcinoid with a rectal lesion that has metastasized.

Overall, most presacral tumors occur in females and are cystic. Most solid tumors are chordomas and more commonly seen in males. Benign lesions are frequently asymptomatic and are incidentally discovered during routine gynecologic examination which may explain the greater incidence in females. By contrast, malignant tumors are more often symptomatic, but still commonly found late due to their vague symptomatology. Some presacral tumors present as part of a congenital syndrome, such as Currarino syndrome, which is a combination of presacral mass, anorectal malformations, and sacral anomalies.[20] In Currarino syndrome, the most frequent component of the presacral mass is meningocele, but teratomas have been identified in 20–40% of reported cases.[21]

Diagnosis and Management

History and Physical Examination

Due to their indolent course, presacral tumors are commonly found incidentally at the time of periodic pelvic or rectal examination. Symptomatic patients typically complain of vague, longstanding pain in the perineum or low back. Pain may be aggravated by sitting and improved by standing or walking. In a Mayo Clinic series, pain was more common when the tumor was malignant as compared to benign (88 vs. 39% repeatedly).[4] Occasionally, patients complain of longstanding perineal discharge and their symptoms may be confused with anal fistula or pilonidal disease.[22] Several clues may alert the clinician to the presence of a retrorectal cystic lesion, including repeated operations for anal fistula, the inability of the examiner to uncover the primary source of infection at the level of the dentate line, a postanal dimple, or fullness and fixation of the precoccygeal area. All patients in the Mayo series with osseous tumors complained of low back pain, perineal pain, or both.[4] Some patients may give a history of referral to a psychiatrist because of clinicians' inability to ascertain the origin of their chronic, ill-defined pain. Patients with larger tumors may complain of constipation and/or rectal and urinary incontinence, and sexual dysfunction due to the sacral nerve root involvement.

Patients should be carefully examined, focusing on the perineum, rectal examination and assessing for a postanal dimple. In a series from our institution, 97% of presacral tumors could be palpated on rectal exam.[4] Digital rectal exam (DRE) typically reveals the presence of an extrarectal mass displacing the rectum anteriorly with a smooth and intact overlying mucosa. Rectal examination is also critical in assessing the level of the uppermost portion of the lesion, degree and extent of fixation, and relationship to other pelvic organs, such as the prostate. Rigid or flexible sigmoidoscopy can be used to assess the overlying mucosa and rule out transmural penetration of the tumor. A careful neurologic exam

focusing on the sacral nerves and musculoskeletal reflexes is mandatory, and may also aid in the diagnosis of extensive local tumor invasion.

Diagnostic Tests

The presence of a presacral tumor can be confirmed with imaging modalities such as computerized tomography (CT), MRI, and endorectal ultrasound (ERUS). Simple anterior–posterior and lateral radiographs (AP/LAT) of the sacrum can identify osseous expansion, destruction, and/or calcification of soft tissue masses, but are typically not helpful in rendering a specific diagnosis. A chordoma is the most common tumor causing these findings, but sarcomas or benign, locally aggressive tumors, such as giant cell tumor, neurilemmoma (schwannoma) and aneurysmal bone cysts, may also cause extensive bony destruction. The characteristic "scimitar sign" on plain radiographs denotes the presence of an anterior sacral meningocele, a diagnosis that can be confirmed with conventional myelography or MRI with gadolinium.

In recent years, state-of-the-art imaging, such as CT, MRI, and positron emission tomography (PET) scan, has dramatically changed the way in which these tumors are evaluated. Computerized tomography and MRI complement each other and are the most important radiographic studies in evaluating a patient with a presacral lesion. Computerized tomography can determine whether a lesion is solid or cystic and whether adjacent structures, such as the bladder, ureters, and rectum, are involved (Figure 21-5A–C). CT is also the best study to evaluate cortical bone destruction. MRI is highly recommended because of its multiplanar capacity and improved soft tissue resolution that is essential for planning specific lines of resection (Figure 21-6A and B). Sagittal views assist in decision making in regards to need for and level of sacrectomy (Figure 21-6C). MRI is also more sensitive than is CT in spinal imaging, showing associated cord anomalies, such as a meningocele, nerve root, and foraminal encroachment by tumor, or thecal sac compression.[23] Angiography and venogram can be added to the MRI (MR angiogram, venography) to delineate vascular involvement and anatomy grossly distorted by tumor mass effect. This information is helpful to the vascular, plastic, and orthopedic surgeons for operative planning. Gadolinium-enhanced MRI imaging before, during, and/or after neoadjuvant therapy may also show the effectiveness of this treatment in terms of volume of tumor that appears vascularized and viable.

In patients with presacral cystic lesions thought to be the source of a chronically draining sinus, fistulogram may occasionally help clarify the diagnosis. ERUS has been used by some to characterize retrorectal tumors and its relationship to the muscularis propria of the rectum.[24]

Preoperative Biopsy

Historically, the role of preoperative biopsy of presacral tumors has been a controversial topic. Methodology, and even its very necessity, varies among authors. In the past, some authors have considered any presacral tumor deemed resectable as a contraindication to preoperative biopsy,[4,25–27] with only a minority of authors stating that all solid tumors should be preoperatively sampled by biopsy.[28] This recommendation in part, may have to do with the fact that the literature on this topic is sparse and outdated, especially when one considers the availability of modern imaging, better knowledge of tumor biology, and new opportunities for neoadjuvant therapy. Indeed, some patients substantially benefit from preoperative chemotherapy and radiation, especially in osseous tumors, such as Ewing's sarcoma, osteogenic sarcoma, and neurofibrosarcoma. Likewise, very large tumors, such as pelvic desmoids, can be more easily removed after reducing their size with radiation. Preoperative tissue diagnosis *is* essential to the management of solid and heterogeneously cystic presacral tumors.[11,16] For example, the surgical approach and necessary margins is dramatically different when faced with a neurofibroma as compared to a neurofibrosarcoma. When performed correctly, preoperative biopsy can only improve the overall management, rather than harm it.

What is clear about preoperative biopsies of presacral tumors is that they should never be transrectally or transvaginally performed. In the presence of a cystic lesion, such an approach is likely to result in infection rendering its future complete excision more difficult and increasing the likelihood of postoperative complications and recurrence. More importantly, inadvertent transrectal needling of a meningocele may lead to disastrous sequelae, such as meningitis and even subsequent death. Moreover, as the biopsy tract needs to be removed en bloc with the specimen, transrectal biopsy would mandate proctectomy in a patient whose rectum may otherwise have been spared.

There is rarely an indication to biopsy a purely cystic presacral lesion. From a technical standpoint, a presacral tumor biopsy should be done by a radiologist with experience in the evaluation and management of pelvic tumors. In planning the approach for a biopsy, the surgeon should always consider the resection margins so that the needle tract can be removed en bloc with the specimen. The transperineal or parasacral approach is usually ideal and falls within the field of the pending surgical resection (Figure 21-7A and B). Transperitoneal, transretroperitoneal, transvaginal, and transrectal biopsy should be avoided. Biopsy tracts should never traverse neurovascular planes. Normal coagulation studies are required prior to biopsy, as hematoma formation and/or bleeding potentially contaminate(s) involved areas. PET-CT scan can be useful to guide biopsy needles into small focal areas of high tumor density.

Role of Preoperative Neoadjuvant Therapy

Modern protocols and the wide availability of neoadjuvant tumor irradiation and systemic chemotherapy have

FIGURE 21-5. Massive cystic teratoma with sacral appendage. **A** CT image of teratoma, intrapelvic portion, **B** extrapelvic portion, **C** including fully developed phalanx.

revolutionized the management of patients with complex malignancies. It is in large part due to these new treatment modalities prior to surgery that a preoperative diagnosis is of paramount importance. Although some tumors, such as chondrosarcoma and chordoma, are poorly responsive to both chemotherapy and irradiation, there are a number of tumors seen in the presacral space whose rate of local recurrence can be markedly decreased with the addition of irradiation. Preoperative, as opposed to postoperative, irradiation can be extremely helpful in the face of large pelvic tumors.

One of the significant advantages of preoperative irradiation is that it allows treatment to a smaller radiation field. Postoperative irradiation for a pelvic tumor would require irradiation of the entire surgical bed, previous tumor site, all contaminated surgical planes and the sites of all skin incisions. This increased radiation exposure is associated with increased morbidity. Furthermore, should "spillage" occur during resection of a radiosensitive tumor, this contamination may be with previously irradiated necrotic, nonviable cells. A third, and perhaps most important, advantage of
FIGURE 21-6. MRI of pelvic neurofibroma displacing the rectum anterior and lateral. **A** T1 weighted coronal image, **B** T2 weighted coronal image, **C** sagittal view with tumor exiting the 3rd sacral foramen.

preoperative irradiation in sensitive tumors, is the fact that decreased tumor size is often observed. A decrease in tumor size in a pelvic tumor may allow the surgeon to spare vital structures, which would have had to be sacrificed in order for wide margins to be achieved without prior radiation. Additionally, a smaller tumor often means a surgery of a lesser magnitude and therefore less risk for intraoperative complications.

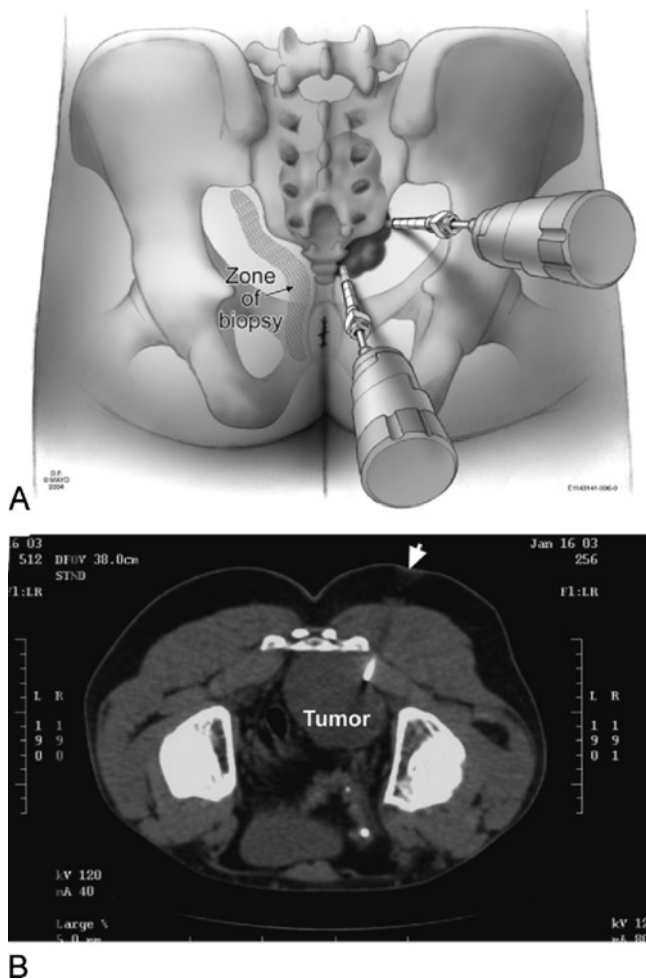
Large tumors in the presacral space, especially sarcomas, are notorious for systemic metastasis. Neoadjuvant chemotherapy is the cornerstone of treatment for diagnoses such as Ewing's sarcoma and osteogenic sarcoma. A wide resection of a pelvic tumor of this type, which would cause a delay in systemic chemotherapy treatment, is not in the patient's best interest. Micrometastatic disease must be treated in patients with diagnoses such as these preoperatively, unless the


FIGURE 21-7. **A** Preoperative biopsy technique using CT guidance, **B** Parasacral approach to presacral neurogenic tumor.

tumor has caused an immediate complication that requires emergent surgery. Furthermore, one could argue, that lymphoma or Ewing's sarcoma, can be completely treated with chemoradiation, and that surgery may not be necessary at all.

Most non-chordoma malignant presacral tumors are sarcomas. The use of adjuvant therapy for presacral sarcomas in our recent review followed protocols typically for other types of soft-tissue sarcomas (unpublished data).[29] Use of adjuvant radiation and chemotherapy in patients with pelvic sarcomas remains controversial due to small samples sizes, mixed pathology, and lack of randomized data. Radiation therapy has been shown to significantly decrease local relapse following surgery for both extremity and retroperitoneal sarcomas, and by extrapolation, would be expected to decrease local relapse in patients with pelvic sarcomas if adequate dose can be safely delivered.[30,31] Similar findings using chemotherapy alone, or in combination with radiation, have been seen for extremity and retroperitoneal sarcomas, resulting in decreased local and distant relapse with trends toward improved survival.[16,29,32,33] Due to the small sample sizes in most series, meaningful conclusions as to the utility

of adjuvant therapy in this surgical setting cannot be drawn. However, given that improved survival in patients with soft-tissue sarcomas, especially those with high-grade lesions, has been limited by high rates of local and distant relapse, an aggressive multimodality approach seems warranted.[16,29]

Regarding malignant neurogenic tumors, the use of adjuvant therapy has been recently reported by our institution.[16] Preoperative chemotherapy was given to 21% of patients, 33% of whom also had it in the postoperative period. The vast majority of patients had doxorubicin-, ifosfamide-, or doxorubicin/ifosfamide-based regimen. Radiation therapy, pre-, intra-, or postoperatively, was given to 72% of patients. The median preoperative radiation dose was 5,040 cGy (range 4,500–5,560 cGy) and the median postoperative dose was 3,000 cGy (range 1,402–6,400 cGy). For those patients who received intraoperative radiation with electrons, the median dose was 1,250 cGy (range 1,000–1,750 cGy).

Surgical Treatment

Rationale for Aggressive Approach

The rationale for an aggressive surgical approach for presacral tumors is based on several arguments. The lesion may already be malignant or transform into a malignant state if left in place. In patients with teratomas, especially those patients in the pediatric age group, the risk of malignant transformation is considerable and continues to dramatically increase if removal is delayed or incomplete.[13] Untreated anterior sacral meningoceles may become infected and lead to meningitis, which is associated with high mortality.[34] Cystic lesions may become infected making their excision difficult and increasing the possibility of postoperative infection and future recurrence. A presacral mass in a young woman may cause dystocia at the time of delivery. Lastly, benign and malignant tumors left untreated may grow to considerable size making surgical resection much more complicated.

In the past, many surgeons have adopted a rather defeatist attitude toward sacrococcygeal chordomas and other tumors in this area based on a number of erroneous misconceptions. Presacral tumors may produce vague symptoms, which leads to a delay in diagnosis for months or even years. Thus, patients may seek medical treatment late in the course of their disease and the presence of a large mass in this often unfamiliar and complex anatomic area makes some surgeons reluctant to consider aggressive surgical approach for fear of serious operative and postoperative complications.

Finally, and most importantly, tumors in this area have been inadequately treated in the past because of tumor violation, their large size and location, and fear of neurologic complication and/or musculoskeletal instability. Preoperative tumor violation can take place when such tumors are biopsied, or intraoperatively when margins of resection are inadequate or tumor cells are spilled in an effort to be too conservative. When a surgeon is attempting to avoid injury

to the rectal wall or important neurological structures, they may inappropriately restrict excision and compromise oncologic outcome. For malignant lesions wide, en bloc removal of adjacent organs, soft tissue, and bone (if locally adherent) is the goal of resection.

Role of Multidisciplinary Team

It is of great importance that an experienced team consisting of a colorectal surgeon, orthopedic oncologic surgeon, spine surgeon, urologist, plastic surgeon, vascular surgeon, musculoskeletal radiologist, medical oncologist, radiation oncologist, and specialized anesthesiologist evaluate and surgically treat tumors that are large and extend to or destroy the hemipelvis or the upper half of the sacrum. The importance of a multispecialty approach for presacral tumors was first described in 1953 by a Mayo Clinic team of surgeons. They found an improvement in outcome in this difficult to manage group of patients with the combined effort of multiple specialists.[35] This quote from their publication describes their convictions:

> The surgical management of presacral and sacral tumors has been in general unsatisfactory. We feel that progress in treating these lesions may have been impeded rather than enhanced by the individual surgical specialists who came into contact with these lesions. Consequently, we have united our efforts in solving the problem and thereby utilizing the special assets of the three surgical specialties – neurologic, orthopedic and general Surgery – in meeting this problem.

Surgical Approach

Careful surgical planning is important in deciding how to approach these tumors whether it be an anterior approach (abdominal), posterior approach (perineal), or a combined abdominoperineal approach. Computerized tomography and MRI help define the margins of resection and the relationship of the tumor to the sacral level (Figure 21-8). Small and low-lying lesions can be removed transperineally through a parasacral incision, whereas tumors extending above the S-3 level, especially if large, often require a combined anterior and posterior approach.

For large malignant lesions requiring extended resection, a plastic surgeon plays a significant role, as adequate soft tissue coverage can often be difficult. Most often, the authors use the transabdominal rectus abdominus myocutaneous (TRAM) flap, which fills dead space and can cover large cutaneous defects left by the resection. Healthy, well-vascularized tissue flaps, placed in the surgical bed, markedly decrease the incidence of wound-related complications.

Preoperative Considerations

Optimizing patients for surgery is of extreme importance in a majority of these cases. Adequate nutritional repletion with total parenteral nutrition or with a feeding tube may be necessary in patients who present severely debilitated.
FIGURE 21-8. Relationship of tumor to sacral level and proposed approach.

In technically complex cases, when we expect a long operative time and significant debilitation postoperatively, we consider placement of a temporary intravena caval filter, since the risk of deep venous thrombosis and pulmonary embolus is high and postoperative anticoagulation may be contraindicated. Preoperative selective coil embolization done by an interventional radiologist may be useful in patients with large, vascular tumors to decrease intraoperative bleeding.[36] A multidisciplinary team should preoperatively review films and plan surgical strategy avoids confusion during the day of surgery. An operating theater capable of managing massive transfusion requirements is mandatory, as is an anesthesiologist comfortable with the physiologic management needed during the procedure.

Posterior Approach

For low-lying tumors, the patient is placed in the prone jackknife position with the buttocks spread with tape (Figure 21-9A). An incision is made over the lower portion of the sacrum and coccyx down to the anus taking care to avoid damage to the external sphincter. Resection of the tumor may be facilitated by transection of the anococcygeal ligament and coccyx (Figure 21-9B). The lesion can then be dissected from the surrounding tissues, including the rectal wall, in a plane between the retrorectal fat and the tumor mass itself. In the case of very small lesions, the surgeon may double-glove the left hand and with the index finger in the anal canal and lower rectum, push the lesion outward, away from the depths of the wound (Figure 21-9C) facilitating dissection of the lesion off the wall of the rectum without injury. If necessary, the lower sacrum or coccyx or both can be excised en bloc with the lesion to facilitate excision.

An intersphincteric approach has been described for very low-lying tumors.[37] It is performed in a lithotomy position.
FIGURE 21-9. **A** Positioning for posterior approach. **B** Coccygectomy. **C** Index finger in anal canal to "push" tumor outward facilitating dissection.

Through a V-shaped, or radial incision posterior to the anus, the intersphincteric plane is opened and bluntly dissected. The anal canal and internal sphincter are separated from the external sphincter up to the level of the puborectalis sling. The dissection is continued upward in the retrorectal fatty space. The division of Waldeyer's fascia may be necessary to expose the upper surface of the levator ani muscles.

Combined Abdominal and Sacral–Perineal Approach

If the upper pole of the tumor extends clearly above the S-3 level, an anterior and posterior approach is usually indicated. Patients may be placed in the supine or lateral position, depending on the surgeon's preference and previous experience. A variety of techniques and positioning to the abdominal perineal approach have been described.[38] If an anterior–posterior approach is necessary, the patient can be
FIGURE 21-10. **A** Modified lateral position for anterior exposure via a midline (*large arrow*) or ileoinguinal (*smaller arrow*) incision. **B** Anterior exposure of vessels and tumor. **C** Posterior approach to sacrum.

placed in a "sloppy-lateral" position to facilitate a simultaneous two-team approach (Figure 21-10A–C). We always recommend cystoscopy and bilateral ureteral stent placement before laparotomy. Through a midline incision the abdomen should be carefully examined to rule out metastasis or other important pathology. After the lateral attachments to the sigmoid have been mobilized and the presacral space is entered just below the promontory, the posterior rectum can be dissected from the upper sacrum down to the upper extension of the tumor. The ureters and hypogastric nerves are identified and protected. The rectum can then be mobilized laterally, and if necessary, anteriorly.

If a malignant tumor can be safely separated from the posterior wall of the rectum without compromising a wide margin, the lesion can be dissected in a plane between its capsule and the mesorectal fat to preserve the rectum. If the tumor is extremely large, markedly compressing and displacing the rectum, making dissection between the rectal vault and the tumor hazardous, one should remove the rectum en bloc with the tumor and the involved segments of the sacrum. It is mandatory in malignant cases that no structures attached to the specimen should be separated with dissection, and that they are removed en bloc with the primary tumor mass. In this situation, the upper rectum is transected with a stapler at

the level of the promontory. Under these circumstances, it is imperative that the anterior wall of the rectum be completely freed from the seminal vesicles and prostate in men and the upper two-thirds of the vagina in women. The pelvic floor can then be reconstructed over the anal remnant and the sigmoid colostomy established in the left lower abdominal wall.

In the presence of very large tumors, blood loss during the procedure can be substantial. This potentially adverse sequelae may be minimized by ligating the middle and lateral sacral vessels and both internal iliac arteries and veins (Figure 21-11). When ligating the internal iliac artery, in order to reduce the risk of perineal necrosis it is best to preserve the anterior division from which the inferior gluteal artery arises. This maneuver is often performed in conjunction with permissive hypotension. A vascular surgeon can be helpful during this portion of the procedure especially in patients that have had prior irradiation or have distorted vascular anatomy. In a situation in which a large tissue defect is expected, one may elect to mobilize one rectus muscle on its vascular pedicle and place it in the presacral area for later use in the closure of the perineal wound when the patient is prone. In the anterior–posterior approach, when a flap is used, a thick piece of silastic mesh is placed posterior to the vital structures and anterior to the bony structures to protect vital structures from injury during bony resection while in the prone or lateral position. After the abdominal incision is closed and the colostomy is matured, the anesthetized patient can then be moved from the supine to the prone position. The perineal approach is similar to that used for benign low-lying cystic or solid tumors, except that wider and more proximal dissection is necessary. After an incision has been

made over the sacrum and coccyx down to the anus, the anococcygeal ligament is transected and the levator muscles are laterally retracted. If the rectum is to be preserved, the tumor can be separated from the rectum by careful dissection of the plane between the rectum and the tumor. The orthopedic surgeon can then proceed with the separation of gluteus maximus muscles on both sides, detachment of the sacrospinous and sacrotuberous ligaments, and division of the piriformis muscles bilaterally to protect the sciatic nerves (Figure 21-12A). A posterior laminectomy may be required to expose and ligate nerve roots (Figure 21-12B) to be sacrificed and/or the thecal sac (Figure 21-12C). In this manner, the lesion can be removed en bloc with the lower sacrum and coccyx and involved sacral roots. If the surgeon previously elected to excise the rectum en bloc, it is preferable to remove the anus and anal canal with the rectal specimen. The wound is then closed in layers over suction silastic drain, or a rectus abdominus myocutaneous flap is inserted and sewn

FIGURE 21-12. **A** Posterior approach and exposure of sciatic nerves, **B** sacral nerve roots, **C** and ligation of the thecal sac.

FIGURE 21-11. Ligation of middle sacral and internal iliac vessel.

into place by the plastic surgeon. More complex soft tissue procedures may be required if the tumor involves the posterior soft tissue elements.

Recently, there have been reports using minimally invasive laparoscopic techniques as an approach for presacral tumor resection, both for anterior-only and for anterior–posterior approaches.[39–42] If the anterior portion of a combined anterior–posterior approach can be done laparoscopically (rectum divided, colostomy made, tumor partially mobilized, vasculature ligated), it should decrease the morbidity of the overall operation significantly. Leygyel et al.[42] described a laparoscopic approach to treat advanced rectal cancer with similar surgical steps to the malignant presacral tumor laparoscopic resection. The operation was performed in two phases: a laparoscopic abdominal phase with the patient in the modified Lloyd-Davies position, followed by a transsacral phase with the patient in the prone jackknife position. The key features of the abdominal (laparoscopic) component were lateral-to-medial mobilization of the rectum, ligation of the inferior mesenteric vessels, careful identification and preservation of the pelvic nerves and sacral nerve roots, and division of the colon with construction of the colostomy and completion of the proctectomy.

Follow-Up Considerations

The authors recommend an annual visit, including a digital rectal examination, to assess for recurrence of a benign lesion. If digital rectal examination reveals a mass, a CT scan is done. We recommend a baseline CT at 1 year following surgery and then repeated at every 5 years, even if examination is normal.[11]

In the case of malignant tumors, the patients are closely followed with particular attention to local recurrence and pulmonary metastasis. An annual pelvic MRI and chest CT-scan is performed for the first 5 years. If the patient rectum was left in place, annual DRE with possible anoscopy is performed by the colorectal surgeon. Patients are offered repeat resection for locally advanced tumors and for pulmonary metastasis if all disease can be removed operatively.

Results of Treatment

Malignant Lesions

Results of surgical treatment of presacral lesions depend on both the natural behavior of the tumor and the adequacy of resection. If wide margins were not achieved during resection of a malignant lesion or if the tumor is violated, one can expect a high local recurrence rate and a poor overall outcome. In general, most malignant tumors reported in the literature have had a rather poor prognosis, but many such tumors had been incompletely resected or excised

piecemeal, breaking oncologic principles.[4,16] Kaiser et al.[43] found that local recurrence rate increased from 28 to 64% if chordomas are perioperatively violated in patients.

Fuchs et al.[15] reported one of the largest series of sacral chordoma. Fifty-two patients underwent surgical treatment for sacrococcygeal chordoma in a 21-year period. Posterior approach was performed in 22 patients while a combined anteroposterior approach was used in 30. A wide surgical margin was achieved in 21 patients, it was defined as a cuff or normal tissue at least 1–2 cm except anteriorly. At an average of 7.8 years of follow-up, 23 patients were alive with no evidence of disease. Twenty-three patients (44%) had local recurrence. The rate of recurrence-free survival was 59% at 5 years and 46% at 10 years. The overall survival rates were 74, 52, and 47% at 5, 10, and 15 years, respectively. The most important predictor of survival was a wide margin. All patients with a wide margin survived, and this survival rate was significantly different from that for patients who had either marginal or intralesional excision ($p = 0.0001$). Of the 21 patients with a wide margin, 17 (81%) had undergone a combined anteroposterior approach and only four had been treated with a posterior approach. Overall, lung metastasis developed in 16 (31%) of the 52 patients, and all but three of those patients also had a local recurrence.

On the contrary, surgical management of non-chordoma malignant retrorectal tumors has only been reported in small series or single case reports, and therefore limited data exist on the long-term oncologic outcomes.[4,44] In a recent analysis of presacral sarcomas at the authors' institution (unpublished data), 37 patients underwent resection, with an R0 margin in 84% and R1 in 16%. Overall, 76% of the patients required en bloc resection of adjacent pelvic organs and bony structures. The most frequent sarcomas found were malignant peripheral nerve sheath tumors and chondrosarcomas. Postoperative chemotherapy was given to 70% of the patients, and IORT was administered to 22% of the patients. Thirty-day mortality occurred in one patient and overall survival at 2, 5, and 10 years was 75, 55, and 47%, respectively. Disease-free survival at 5 years was 51%.

Cody et al.[44] reported their experience with malignant presacral tumors, nine (38%) of which had chordomas. Excision of these tumors was described as "en bloc" or "in fragments." Forty-eight percent developed local recurrence; 60% of patients underwent open biopsy. For all treated patients, survival at 5, 10, 15, and 20 years was 69, 50, 37, and 20%, respectively.

Lev-Chelouche et al.[25] reported on 21 patients with malignant presacral tumors, nine of which were chordomas. No patients underwent preoperative biopsy; nearly all patients had a palpable lesion on rectal exam. Fifteen of 21 malignant lesions were completely excised. Most recurrences were seen in patients with incomplete resection and 50% of these patients died of disease.

Wang et al.[5] reported their series of 22 patients with malignant presacral tumors, five of which were chordomas, and seven of which were leiomyosarcomas, tumor size ranged from 1.5 to 40 cm. The average size of malignant tumors was 17 cm, 96% were palpable by rectal exam. Computerized tomography was felt to be the best test to identify the lesions and define extent and degree of tumor invasion, but the diagnosis remained nonspecific. No patients underwent preoperative biopsy. Five patients had complete resection and 17 had incomplete resection. The overall 5-year survival rate for malignant tumors was 41%. No patients underwent preoperative adjuvant therapy. Postoperative chemotherapy and radiotherapy was used in selected patients with malignant tumors.

Bohm et al.[27] reported their series of 24 patients with congenital presacral tumors. They had four patients with chordomas and 20 with developmental cysts. All patients with chordoma underwent excision. Three of four chordoma patients had recurrence at 25, 32, and 55 months. Patients with recurrence presented with pain and neurologic disturbance. Complete local re-excision was done in the three patients with recurrence. Only 3/20 patients with developmental cysts developed recurrence, all of which underwent successful re-excision.

Few data exist regarding the outcomes in patients undergoing surgery for presacral tumors of neurogenic origin. The largest surgical series reported to date of pelvic neurogenic tumors included several in the presacral space.[16] In that series, 89 patients were identified, of whom 44 were male. Median age was 38 years. Malignant lesions were found in 43 patients (48%). Schwannomas were the most common benign tumor (61%) and malignant peripheral nerve sheath tumors the most common malignant lesion (81%). Malignant tumors had histopathologic evidence of infiltration of surrounding structures in 49% of cases. Intralesional resection was the most common surgical technique for both benign and malignant tumors. Five-year local recurrence rates for benign and malignant lesions were 35.9 and 35.0%, respectively. Survival in those with malignant lesions at 1, 5, and 10 years was 79.5, 47.9, and 29.6%, respectively. For all patients, the overall probability of being disease free at 1, 5, and 10 years was 72.6, 40.0, and 30.0%, respectively. Five-year disease-free survival for malignant tumors was 25.9%.

Congenital Cystic Lesions

In general, cystic lesions can be treated adequately by complete excision via a posterior approach. Large cystic lesions such as teratomas extending high into the pelvis can be excised via a combined abdominal–perineal approach. There continues to be some debate as to whether or not a coccygectomy needs to be done for all resections of congenital cystic lesions.[22] Several authors advocate coccygectomy stating that this approach improves surgical exposure and decreases the risk of recurrence as the coccyx may harbor a nidus of totipotential cellular remnants that may later evolve into a recurrent cyst.[6,12,45] The concern of increased recurrence though is not supported by any published data. In fact, some authors state that if the cyst is not adherent to the coccyx, and can be removed entirely without coccygectomy, the coccyx should be left in place.[27] Likely the cyst itself, and not the coccyx per se, harbors the aberrant remnants of the postanal gut leading to the formation of the cyst, and if the cyst is not adherent to the coccyx, there would be no advantage to a coccygectomy. It is clear from our recent series that our approach followed this perspective, and most surgeons elected to preserve the coccyx unless en bloc resection was required for malignancy or if the cyst was densely adhered to the coccyx.[11]

In a Mayo Clinic series, 49 congenital cystic lesions were described, including 15 epidermoid cysts, 16 mucus-secreting cysts, 15 teratomas, and 2 meningoceles.[4] Three teratocarcinomas were seen. Most lesions were in females with only three in males. Average size of cysts was 4–7 cm. Almost all cystic lesions were treated with a posterior approach. Of 66 patients with benign tumors, ten had recurrence (four had giant cell tumors, six had congenital benign cysts), most of which were treated successfully with re-excision.

Presacral tailgut cyst surgical outcomes at Mayo Clinic have been recently reported.[11] Thirty-one patients were identified and complete cyst excision was achieved in all patients, using a posterior (20/31), anterior (9/31), or combined (2/31) approach. Coccygectomy or distal sacrectomy was performed in 26% of the patients. Malignant transformation was present in four patients (13%), adenocarcinoma in three and carcinoid in one. A fistula to the rectum was found in four patients (13%). One benign recurrence was detected during follow-up and there has no mortality. Long-term complications were noted in five patients and included: delayed wound healing ($n=2$), pelvic floor dysfunction ($n=2$) and sexual dysfunction ($n=1$) in a male reoperated for recurrence.

Lev-Chelouche et al.[25] reported 21 benign presacral lesions. Complete excision of benign lesions was possible in all cases with no recurrences during the 10 year follow-up. Singer et al.[22] reported on seven patients with presacral cysts (six females, one male). All patients had previously been misdiagnosed and treated for pilonidal cysts, perirectal abscesses, fistula in ano, psychogenic disorder, proctalgia fugax and posttraumatic or postpartum pain before the correct diagnosis was made. Patients underwent an average of 4.1 prior operative procedures. All patients were successfully treated with resection through a parasacrococcygeal approach after the correct diagnosis was made with CT fistulogram.

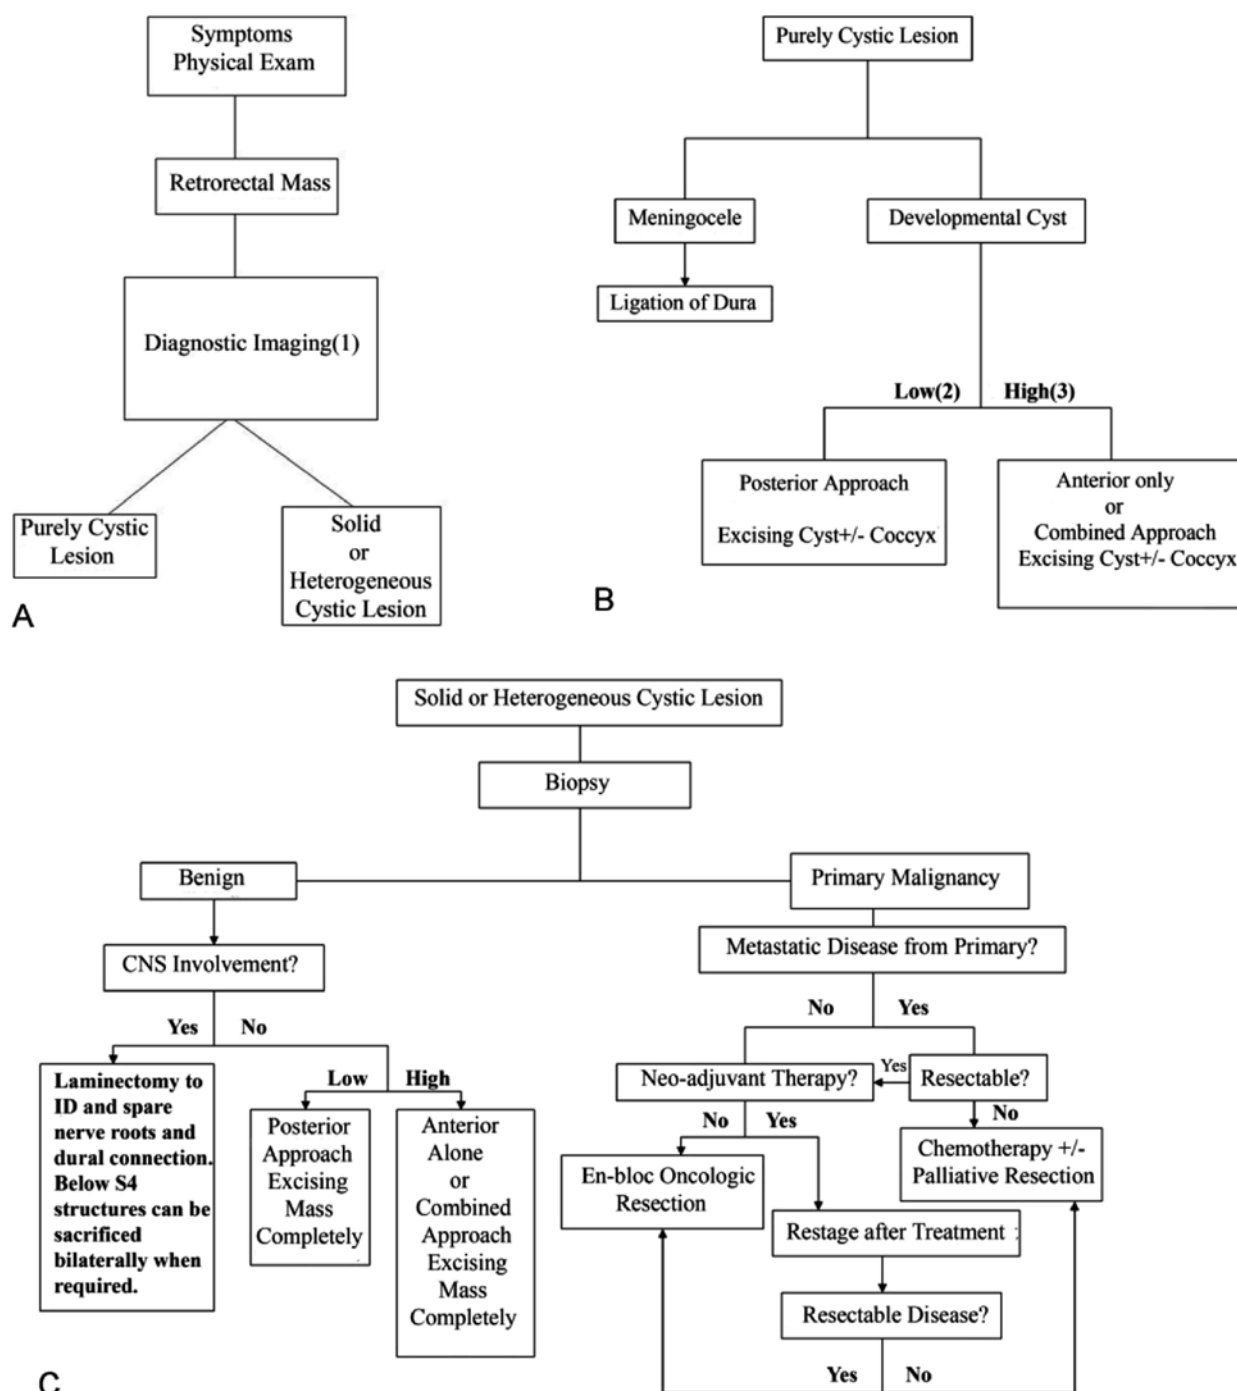
Based on the experience at our institution, we have established a decision-making algorithm to guide the management of presacral tumors (Figure 21-13).


FIGURE 21-13. Proposed treatment algorithm.

Conclusion

Presacral tumors are rare, the differential diagnosis extensive, and their discovery is notoriously difficult and late. A high index of suspicion is needed to identify these patients. Once a benign or malignant presacral lesion is discovered and histologically diagnosed, it should be treated, even if the patient is asymptomatic. CT and MRI imaging can help differentiate between benign and malignant, cystic and solid and accurately define the extent of adjacent organ and bony involvement to guide operative planning. Completely cystic lesions, in general, do not require preoperative biopsy unless malignancy is suspected. All solid tumors and heterogeneous cysts should be considered for biopsy to rule out malignancy, guide neoadjuvant therapy, and plan the extent of resection.

An aggressive approach, by an experienced, multidisciplinary team, that can achieve a tumor-free, en bloc resection, avoid tumor violation, restore spinopelvic stability, and minimize intraoperative and postoperative complications, should decrease the risk of local recurrence and improve survival. Minimally invasive approaches may improve overall recovery and the quality of life in selected patients in the future.

Diverticular Disease

Alan G. Thorson and Jennifer S. Beaty

The term "diverticular disease" of the colon represents a continuum of anatomic and pathophysiologic changes within the colon related to the presence of diverticula. These changes most commonly occur in the sigmoid colon but may involve the entire colon. The continuum can range from the presence of a single diverticulum (a sac or pouch in the wall of an organ) to many diverticula (which may be too numerous to count). It can refer to an asymptomatic state (diverticulosis) or to any one of a number of combinations of inflammatory symptoms, changes, and complications (diverticulitis).

Symptoms may result from: simple physiologic changes in colonic motility related to altered neuromuscular activity in the sigmoid colon, varying degrees of localized inflammatory response, or complex inflammatory interactions leading to diffuse peritonitis and septic shock. These more complex symptoms and resulting complications arise from breaches in the integrity of the wall of one or more diverticula.

This chapter will deal with inflammatory diverticular disease and its associated complications. Bleeding diverticular disease is discussed in Chap. 24.

Incidence

Diverticulosis was first described in the mid nineteenth century as more of a curiosity than a significant disease entity. However, since the early twentieth century, an increasing prevalence of the disease has been recognized in industrialized countries. The incidence increases with age and with the adoption of a diet high in red meat, refined sugars, and milled flour but low in whole grains, fruits, and vegetables. Although the exact incidence is not well established, numerous autopsy, radiographic and endoscopic series have shown that the incidence has increased dramatically over the past 75 years,[1–4] from around 5% near the turn of the century to 50% or more by 1975.[2,3] It is now estimated that the risk of developing diverticular disease in the USA approximates 5% by age 40 and may rise to over 80% by age 80.[5]

This increase in observed incidence was originally attributed to new imaging techniques (the introduction of the barium enema in the early twentieth century) and bias inherent to estimates based on a population presenting with symptoms requiring an investigation.[6] It is now clear that not only is the incidence of diverticulosis increasing but also the incidence of related complications is increasing as well. This is exemplified by increasing costs in the treatment of diverticular disease which accounts for nearly 450,000 hospital admissions, two million office visits, 112,000 disability cases, and 3,000 fatalities each year in the USA.[7] It is estimated that costs will continue to increase as the population continues to age over the next several decades.

Proportionately, few people become symptomatic from the presence of diverticula. Roughly 10–20% of people with diverticula develop symptoms of diverticulitis. Only 10–20% of these will require hospitalization. Of those that require hospitalization, 20–50% will require operative intervention. The percentage of hospitalized patients requiring operation has been increasing as outpatient management becomes more common and those admitted as inpatients are more seriously ill.[8] Overall, less than 1% of patients with diverticula will ultimately require surgical management.[9]

National Census data estimates that as of July 2006, there would be 89,327,640 adults aged 50 or greater.[10] That would mean that approximately 15 million people would develop diverticulitis and of those, 2.5 million would be admitted. If the 1% average is correct and taking into account the percentage of patients with diverticulosis based on age, approximately 539,015 people will ultimately require an operation for diverticular disease.

There is some evidence that males are more frequently affected at a younger age compared to females; however, significant bias may influence this impression. Young females may frequently be under diagnosed due to confusion with gynecologic diseases in women who are of child-bearing age. Older females may be over diagnosed due to confusion with irritable bowel syndrome (IBS). There also appears to be a dichotomy in age and sex with regard to complications of

diverticular disease, particularly perforation. The incidence of perforation is higher in males under age 50. In contrast, the incidence of perforation is higher in females over age 50.[11]

Pathophysiology

Diverticulosis is associated with high intraluminal pressures. Pressures in patients with diverticular disease have been found to be as high as 90 mmHg during peak contraction. This represents a value nearly nine times higher than seen in patients with normal colons.[12] It has been theorized that abnormally high pressures lead to segmentation. Segmentation refers to a process whereby the colon effectively functions as a series of separate compartments rather than as one continuous tube.

The high pressures that each compartment is capable of producing are directed toward the colonic wall rather than as propulsive waves. These pressures predispose to herniation of mucosa through the muscular defects that occur where blood vessels penetrate to reach the submucosa and mucosa (vasa recta brevia). Most of these penetrations occur between the mesenteric and anti-mesenteric tinea where, coincidentally, most diverticula are found. As the mucosa herniates, it does so without dragging the muscular layer along, leaving the diverticula denuded of muscle, which is consistent with the definition of an acquired process. Diverticula may be true, containing all layers of the bowel wall (congenital), or false, lacking the muscular layer (acquired or pulsion diverticula). Thus, the most common diverticula are acquired or pulsion diverticula.

These high pressures are consistent with the sigmoid colon being the most common site of involvement. This can be explained by the Law of Laplace which states that the tension in the wall of a hollow cylinder is proportional to its radius multiplied by the pressure within the cylinder. As the narrowest segment of colon, the sigmoid has the highest pressures and, consequently, the highest risk of diverticulum formation. It is hypothesized that at least a part of the protective effect of dietary fiber is stool bulking, which maintains a larger lumen within the bowel. The stool bulking and larger lumen prevent segmenting contractions and, therefore, decrease high pressures.

Complementary to these theories of pathogenesis is the consistent muscle abnormality associated with sigmoid diverticular disease. Both the circular and longitudinal muscle walls are typically thickened resulting in a reduction in the size of the lumen and a shortening of the sigmoid colon. The reduced lumen size may be further enhanced by secondary pericolic fibrosis.

The source of this muscular thickening is not clear. It has been observed that in the normal process of left colon peristalsis, smooth muscle in the rectosigmoid will relax in response to a stimulus, causing contractions in the colon above and in the rectum below. A combination of poor diet, aging, and constipation could lead to malfunction of this relaxation response leading to a functional obstruction and the hypertrophy seen in the muscle.[13] Cellular hypertrophy, cellular hyperplasia, and elastosis have all been described. Elastosis appears to precede the development of diverticulosis. It is not found in any other inflammatory conditions of the colon.

Several alternative concepts have been advanced to explain the differences in presentation of diverticular disease. Although the most common finding in diverticular disease is the muscular changes already discussed, some patients fail to demonstrate this characteristic. These patients are more likely to have diffuse diverticula throughout the colon. There is a higher incidence of bleeding with diffuse involvement. There may be an underlying connective tissue abnormality, which could explain the development of diverticula in the absence of high intraluminal pressures. The high incidence of bleeding in these patients could be related to an associated inadequate vascular support in the diverticular wall.

Pain associated with diverticular disease may be related to muscle spasm as well as inflammation. Perforation can occur in the absence of inflammation and may be secondary to the extremely high intraluminal pressure.[14]

Etiology

The etiology of diverticular disease remains complex and relatively poorly understood. Pathophysiologic studies reveal that complications do not occur until there is microperforation through the wall of a diverticulum into the pericolic tissue. A single diverticulum experiences a change in the permeability of its isolated mucosa from physical, biochemical, or physiologic means. It is postulated that perforation then occurs leading to a characteristic response which results in varying degrees of inflammation. The perforation might cause microabscess, phlegmon, large abscess, fistulas, or even free perforation. Free perforations occur rarely, while fistulas are more likely, with the bladder being the most common site of fistula formation.[15]

The original communication between the diverticular perforation with the lumen of the bowel, is usually rapidly obliterated by the inflammatory process. Occasionally, failure of the diverticular neck to obliterate may lead to a free communication between the bowel and the peritoneal cavity with resultant fecal peritonitis. Rupture of a noncommunicating abscess may lead to purulent peritonitis.[16]

Low-grade inflammation of colonic mucosa, induced by changes in bacterial microflora, can affect the enteric nervous system and alter gut function, leading to symptom development. This explanation for symptoms in IBS can be easily extrapolated to diverticular disease since some patients with diverticular disease demonstrate bacterial overgrowth.[17]

Recent clinical investigations have shown that disturbances in cholinergic activity may contribute to diverticular disease. Cholinergic stimulation in patients with diverticular disease leads to unsynchronized slow waves of relatively low frequency as opposed to bursts of action potentials normally associated with peristalsis.[18,19] This suggests a possible role for cholinergic denervation hypersensitivity in colonic smooth muscle with upregulation of smooth muscle muscarinic receptors.[20]

A colon with diverticular disease has more cholinergic innervation than a normal colon. In addition, there is less noncholinergic, nonadrenergic inhibitory nerve activity. This increased cholinergic activity and the relative paucity of inhibitory activity may contribute to the high intraluminal pressures and segmentation seen in colonic diverticular disease.[21]

Epidemiology

Diet

Large cohort and case–control studies in the USA and Greece have shown that diets high in red meat and low in fruit and vegetable fiber increase diverticular symptoms by as much as threefold.[22,23] Vegetables and brown grains have been shown to be protective.[23] Fiber may be protective by increasing stool weight and water content which decreases colonic segmentation pressures and transit times.[24] Fiber, through the process of fermentation, also provides short chain fatty acids to the colonic epithelial cells, an important source of fuel and mucosal health.[25–27]

Patients with diverticulosis were often told to avoid seeds, nuts, and popcorn. A large cohort study of US health-care professionals evaluated 47,228 men between the ages of 40–75 who were free of diverticulosis at baseline, and they were followed for 18 years.[28] There were inverse correlations between nut and popcorn consumption and the risk of diverticulitis.[28] The consumption of nuts, corn, and popcorn did not increase the risk of diverticulosis or diverticular complications and therefore the recommendation to avoid these foods to prevent diverticular complications should be reconsidered.[28]

Red meat has been associated with heterocyclic amines, a factor in colon mucosal apoptosis.[29] Dietary heme has been shown to be highly cytotoxic to rat colons.[30]

Age and Gender

Female patients present with complications requiring surgery an average of 5 years later than male patients. Men have a higher incidence of bleeding than women; however, women have a higher incidence of fistula formation compared to men. Younger men present with fistula more frequently, while older men present more frequently with bleeding.

Young females are more likely to present with perforation while older females are more likely to present with chronic disease and stricture. Overall, patients younger than 50 present more often with chronic or recurrent diverticulitis.[31,32]

Nonsteroidal Anti-inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) have been linked to increased rates of complications related to diverticular disease. The plausible mechanism of action is indirect through known inhibition of cyclo-oxygenase and resultant decreased prostaglandin synthesis in the gut. Prostaglandins are important in the maintenance of mucosal blood flow and in providing an effective colonic mucosal barrier. A direct mechanism also exists through mucosal damage caused by NSAIDs which leads to increased translocation of toxins and bacteria.[33,34]

Immune Status

The use of corticosteroids is associated with a higher risk of perforation and more severe inflammatory complications. The postulated mechanism is immunosuppressive and anti-inflammatory effects hinder confinement of perforation in its early stages, resulting in more serious sequelae. The use of other immunosuppressive drugs has also been associated with such increased risks. The main risk appears to be more virulent complications once complications occur.[35]

Opiates

The use of opiate pain medications has been shown to raise intracolonic pressure and slow intestinal transit, both of which increase the risk of complications from diverticular disease. Case series have shown a higher percentage of perforation in patients who were taking opiate analgesics.[32,36] Although, patients who require narcotic pain medication may be at higher risk of perforation based on severity of abdominal symptoms.

Smoking

A recent large case–control study demonstrated that smokers had three times the risk of developing complications from diverticular disease than did nonsmokers.[37] However, a large cohort study involving over 46,000 men in the USA did not find this same association.[38]

Alcohol

A Danish cohort study showed the risk of diverticulitis was three times higher in female alcoholics compared to the general population and two times higher in male alcoholics. However, the data may be biased due to dietary and smoking habits associated with alcoholics.[39]

Clinical Manifestations

Clinical Patterns

Diverticular disease may be classified into diverticulosis (asymptomatic) and diverticulitis (symptomatic) (Table 22-1). Diverticulosis refers to the presence of diverticula with no related symptoms. This applies to the vast majority (80–90%) of patients with diverticular disease. Diverticulitis can be subclassified into noninflammatory, acute (simple or complicated), chronic (atypical or recurring/persistent), or complex disease. The term "malignant diverticulitis" has been used to describe a particularly severe form of fibrosing disease with phlegmonous inflammation extending below the peritoneal reflection. This is associated with frequent fistula formation, obstruction, and high postoperative morbidity and mortality.[40] Many consider this form to be misdiagnosed Crohn's disease.

Noninflammatory Diverticular Disease

Noninflammatory diverticular disease describes those patients with symptoms of diverticulitis but without associated inflammation.[41] The diagnosis is made at the time of elective operation when no inflammatory changes are found in the specimen. This has been reported in 15–35% of resections.[41] Some would consider this a missed diagnosis (IBS). However, if that were always the case, then one would expect a very low resolution of symptoms following resection. In fact, although a lack of inflammatory changes in the resected specimen has been associated with lesser degrees of symptom relief, the success rate is not zero.[41–44] One could conclude that resections are being performed for the right indication but the wrong pathology.

The term "atypical" has been applied to patients with chronic symptoms who never develop the necessary clinical and laboratory criteria to be judged as having acute diverticulitis. Up to 24% of these patients are found to lack inflammatory changes in the resected specimen thus fulfilling the criteria for noninflammatory diverticular disease. The remaining members of this group could be considered as having had acute diverticulitis based on histologic findings of inflammation. A high percentage of atypical patients (88%) became pain free after resection on short term (12 months) follow-up.[44]

Acute Diverticulitis

Acute diverticulitis is represented by signs and symptoms of acute inflammation and may be simple (limited to the colonic wall and adjacent tissues) or complicated (with perforation or fistula). Simple acute disease is usually accompanied by systemic signs of fever and leukocytosis while complicated acute disease may have the added signs of tachycardia and hypotension.

Complicated acute diverticulitis can be classified according to the extent of spread of the inflammatory process. A common classification for diverticulitis with perforation was first described in 1963 by Hughes et al.[45] and slightly revised and popularized by Hinchey et al.[16] in 1978. Stage I diverticulitis is a localized pericolic or mesenteric abscess, Stage II is a confined pelvic abscess, Stage III is generalized purulent peritonitis, and Stage IV is generalized fecal peritonitis (Table 22-2).

Chronic Diverticulitis

Patients with chronic diverticulitis remain symptomatic (left lower quadrant pain) despite standard treatment. It is considered atypical if systemic signs never develop. With systemic signs, chronic disease may manifest as recurring, intermittent episodes of acute disease or as persistent, symptomatic low-grade disease. This is frequently associated with the presence of a phlegmon. If resection is performed, there will be evidence of inflammatory changes within the specimen.

Complex Diverticular Disease

Complex diverticulitis refers to disease in those patients who manifest sequelae of chronic inflammation including fistula, stricture, and obstruction. Each of these complications will be addressed later in this chapter.

Presenting Symptoms

Patients with acute diverticulitis typically complain of left lower quadrant abdominal pain. However, in a patient with a redundant sigmoid colon an inflamed segment might present with pain in the right lower quadrant, thus complicating the differential diagnosis with appendicitis. The pain is generally

TABLE 22-1. The classification of diverticular disease

Diverticulosis	Asymptomatic
Diverticulitis	
Noninflammatory	Symptoms without inflammation
Acute	Symptoms with inflammation
Simple	Localized
Complicated	With perforation
Chronic	Persistent, low grade
Atypical	Symptoms without systemic signs
Recurring, persistent	Symptoms with systemic signs (may be intermittent)
Complex	With fistula, stricture, obstruction
Malignant	Severe, fibrosing

TABLE 22-2. The Hinchey classification (proposed by Hinchey et al. in 1978)[16]

Hinchey I	Localized abscess (para-colonic)
Hinchey II	Pelvic abscess
Hinchey III	Purulent peritonitis (the presence of pus in the abdominal cavity)
Hinchey IV	Feculent peritonitis

constant in nature, not colicky. Radiation may occur to the back, ipsilateral flank, groin, and even the leg. The pain may be preceded or accompanied by episodes of constipation or diarrhea. It commonly is progressive in nature if appropriate treatment is not instituted.

Historically, age was used as a primary determinant in distinguishing the most likely etiology of such pain. However, as increasing numbers of young people are found to have diverticular disease, the overlap between age groups has broadened and the need for diagnostic acumen has significantly sharpened.

Nausea and vomiting are unusual in the absence of obstruction. Bleeding is not an associated finding. Symptoms of dysuria or urgency suggest possible bladder involvement due to an adjacent inflammatory mass or a colovesical fistula. Pneumaturia, fecaluria, or passage gas and stool through the vagina suggest a colovesical or colovaginal fistula, respectively. Fever is common and proportional to the amount of inflammatory response present. A high fever suggests a perforation with abscess or peritonitis.

Occasionally, diverticular disease will present in unusual ways. These include lower extremity joint infections of a chronic nature that culture positive for enteric bacteria. Other unusual presentations include female adnexal masses on the left, inflammation/necrosis of the perineum and genitalia including Fournier's gangrene, subcutaneous emphysema of the lower extremities, neck and abdominal wall, isolated hepatic abscess due to enteric organisms, brain abscess due to enteric organisms, and cutaneous lesions mimicking pyoderma gangrenosum.[46,47]

Physical Findings

Patients presenting with acute diverticulitis will be tender to palpation in the left lower quadrant and left iliac region. There may be limited rigidity or localized guarding to deeper palpation. With resolution of the acute phase, palpation may reveal a mass in the left lower quadrant. Classically, there is no prodromal epigastric pain with diverticulitis as one might expect to see with appendicitis.

In the event of a perforation with development of fecal or purulent peritonitis, the area of pain will spread throughout the abdomen. Guarding will become prominent and the abdominal wall will become rigid.

Diagnostic Evaluation

Abdominal X-Rays

The primary value of abdominal X-rays is to rule out pneumoperitoneum or to assess for a possible obstruction, therefore plain films of the abdomen should include supine and upright or left lateral decubitus views. Computed tomography (CT) scan is often the evaluation of choice in the

FIGURE 22-1. CT scan reveals uncomplicated diverticulitis with bowel wall thickening and streaky fat in the mesentery.

face of acute abdominal pain, so in many centers, the plain abdominal film is rarely used.

Contrast Studies

Barium or water soluble contrast studies have their proponents for utilization; however, CT scans provide a significantly more thorough evaluation, making it the preferred imaging study in many centers (Figure 22-1). Nonetheless, due to costs, some clinicians will utilize CT scan only if there is clinical suspicion of an abscess or other complicating feature for which an alternative to standard bowel rest and antibiotics might be applied. A water soluble contrast study can evaluate the lumen of the bowel if there is concern about distal bowel obstruction. It may be an important part of the assessment for the possible use of a colonic stent if malignant disease is suspected.

Contrast studies have been shown to identify fistulas, most commonly colovaginal or coloenteric. Some clinicians prefer the anatomic view of the entire colon provided by barium enema since it distinguishes the extent of diverticulosis throughout the colon and can assess for stricture and colonic length. In most centers, contrast studies, if used at all, are used in a limited fashion to evaluate the anatomy of the colon prior to an operation.

CT Scan

An important advantage of a CT scan is the ability to document diverticulitis, even if uncomplicated, when the diagnosis is in doubt. Studies utilizing CT scan as the initial diagnostic test have shown that up to 5% of patients admitted

for acute diverticulitis have been hospitalized for the incorrect clinical diagnosis.[48]

It has been demonstrated that CT can recognize and stratify patients according to the severity of their disease. It can distinguish uncomplicated disease with a predictably short length of hospital stay from complicated disease as defined by abscess, fistula, peritonitis or obstruction and a predictably long length of stay. It also provides information about extracolonic pathology and anatomic variation which is useful for surgical planning. Early CT guided drainage of abscesses allows down-staging of complicated diverticulitis, converting an otherwise urgent or emergent operation with its attendant increases in morbidity and mortality to the safety of an elective operation.[48] In some selected cases there may be no need for elective resection.

Colonography

Preliminary studies utilizing magnetic resonance imaging (MRI) colonography have shown a high correlation with CT findings in patients with diverticular disease without exposure to ionizing radiation. Three-dimensional rendered models and virtual colonoscopy can be performed only in the nonacute setting. These comprehensive 3-D models, rather than barium enema, may have a role in presurgical planning with concurrent assessment of the residual colon.[49]

Ultrasonography

Transrectal ultrasound (TRUS) has been utilized in the evaluation of diverticular disease in conjunction with transabdominal ultrasound (TAUS). Combining TRUS with TAUS reveals complications not visualized on TAUS alone including inflamed diverticula. TRUS may be an accurate adjunct for confirming clinically suspected acute colonic diverticulitis when the rectosigmoid or perirectal tissues are affected as one might see in the case of malignant diverticulitis. It helps avoid false-negative results and defines the severity of disease in the lower sigmoid colon better than TAUS alone. TRUS may prove to be a useful adjunct in selected cases of rectosigmoid diverticulitis and perirectal involvement by diverticular disease in centers where CT scanning is not readily available.[50]

Endoscopy

Endoscopy in the face of acute diverticulitis must be undertaken with extreme caution due to risk of perforation and decreased chance of successful cecal intubation. It can provide important information prior to operation but will change acute management in less than 1% of cases.[51] Generally, in the absence of an urgent indication, colonoscopy should be delayed until resolution of the acute episode is complete.

In the case of elective colonoscopy, the unexpected finding of acute diverticulitis (manifested as erythema, edema, pus,

or granulation tissue at a diverticula opening) is distinctly unusual, occurring in just 0.8% of patients. Treatment with antibiotic therapy for such findings is generally unnecessary as follow-up has shown that symptoms of diverticulitis do not develop following the colonoscopy.[52]

Differential Diagnosis

The differential diagnosis for diverticular disease includes IBS, carcinoma, inflammatory bowel disease (IBD), appendicitis, bowel obstruction, ischemic colitis, gynecologic disease, and urologic disease. Of these, IBS is perhaps the most difficult to differentiate in many patients.

Irritable Bowel Syndrome

In many ways, the distinction between chronic diverticulitis and noninflammatory diverticular disease relies upon the pathologist while the distinction between noninflammatory diverticular disease and IBS relies on the diagnostic acumen of the clinician and the long-term outcomes of resection. Due to the prevalence of diverticular disease many patients with IBS will have concomitant diverticular disease. However, due to the fact that diverticular disease is most commonly asymptomatic, the presence of diverticulosis in these patients will often not be the source of their symptoms but rather just a source of confusion in the differential. It is helpful to be familiar with the Rome II criteria (Table 22-3) for the diagnosis of IBS in order to sort through this differential.

Colonic Neoplasia

Distinguishing diverticular disease from cancer can be difficult. Imaging techniques can provide significant diagnostic

TABLE 22-3. The Rome II criteria for irritable bowel syndrome

Irritable Bowel Syndrome can be diagnosed based on at least 12 weeks (which need not be consecutive), in the preceding 12 months, of *abdominal discomfort or pain that has two of three of these features*:
1. Relieved with defecation, and/or
2. Onset associated with a change in frequency of stool, and/or
3. Onset associated with a change in form (appearance) of stool
Symptoms that cumulatively support the diagnosis of IBS:
1. Abnormal stool frequency (>3 stools per day or <3 stools per week)
2. Abnormal stool form (lumpy/hard or loose/watery stool)
3. Abnormal stool passage (straining, urgency, or feeling of incomplete evacuation)
4. Passage of mucus
5. Bloating or feeling of abdominal distension.
Red Flag symptoms which are NOT typical of IBS:
Pain that often awakens/interferes with sleep
Diarrhea that often awakens/interferes with sleep
Blood in stool (visible or occult)
Weight loss
Fever
Abnormal physical examination

assistance but occasionally a resection is necessary. Several features of barium enema (BE) support a diagnosis of diverticular disease including preservation of the mucosa, long strictures, and the presence of diverticula. A BE is preferred by some clinicians to assess the extent of the diverticulosis and evaluate the length of the colon prior to resection. Although colonoscopy can frequently resolve this issue, it is not always possible due to acute angulations or narrowing of the lumen. CT evaluates the entire abdomen, which can identify concurrent disease and may give clues to underlying colonic pathology.

The increasing incidence of colonic neoplasia with increasing age parallels that of diverticular disease. Polyps and cancer must be considered whenever a diagnostic workup for diverticular disease is begun. Although unusual, cases of adenocarcinoma arising within a diverticulum have been reported.[53] Since colonic diverticula are thin walled, containing only mucosa and serosa, early penetration by cancer is likely, leading to advanced stages with small primary lesions.

Although historically diverticular disease was not felt to have an etiologic link to colon cancer, a causal association has been identified between left-sided colon cancer and diverticulitis. In a review of 7,159 patients from the Swedish Cancer Registry, patients with diverticulitis had a long-term increased risk of left-sided colon cancer compared to patients with asymptomatic diverticulosis (odd's ratio = 4.2).[54–56]

Inflammatory Bowel Disease

Crohn's disease can be a particularly difficult diagnosis to make. Both Crohn's and diverticular disease may present with similar complications including fistulas, phlegmons, and abscesses. Rectal involvement, anal disease, extracolonic signs, and bleeding suggest Crohn's disease. Recurrent "diverticulitis" requiring a repeat resection should always raise the question of possible Crohn's disease.[57] Ulcerative colitis is rarely a significant differential diagnostic dilemma since bleeding is not a prominent symptom of diverticulitis and a simple endoscopic exam showing inflammation within the rectum should suffice to rule out diverticular disease. In the unusual circumstance where diverticulitis and ulcerative colitis both exist, treatment should be targeted toward both entities simultaneously.

Other Colitides, Appendicitis, Gynecologic, and Urologic Disease

Endoscopy can be an important adjunct in differentiating IBD, ischemic colitis, and other forms of colitis although caution must be used in the acute setting. A major advantage of the CT scan is the ability to evaluate for many of the other potential differentials including appendicitis, gynecologic, and urologic disease.

Special Considerations

Diverticulitis in Young Patients

There continues to be some debate as to the issue of recurrence in patients younger than 50 years old. It does appear that there is an increased incidence in younger patients presenting with diverticulitis. In a recent study by Etzioni et al.[58] evaluating the nationwide inpatient sample data for changing patterns of diverticular disease and treatment, a 73% increase in the rate of admission for patients aged 18–44 years with diverticulitis was found between 1998 and 2005. While an increase was also found in patients aged 45–74 year, the increase was only 29%.

Historically, diverticular disease in patients less than age 50 has been described as more virulent and with more serious complications.[59–63] Despite the increased number of younger patients with the disease, its virulence does not appear to be any different compared to older counterparts.[64] It is now doubtful that age itself should be a primary consideration in the decision to operate. The literature is mixed with proponents of a more aggressive approach to the disease in young patients[59–66] and those that feel age alone does not significantly increase risk.[67–74] Other factors apply, most of which are not age related.

Young patients with diverticular disease are more commonly male,[59,66] obese[60,74] and have a higher incidence of right-sided diverticulitis.[69,70] Young patients undergoing operation are frequently misdiagnosed preoperatively[60,68,70] with appendicitis being the most common misdiagnosis.[70] Many recommend that patients less than age 50 have an elective resection after a single episode of acute disease. Recent evidence is mixed.

In some series, young people present with more severe disease at first presentation[61–63,65] but less frequently have a resection at that time. Reasons for this include missed diagnoses and rapid response to therapy. With fewer resections for more complex disease, a higher percentage of young patients return with delayed complications and the appearance of more aggressive disease. Elective resection following the first episode of diverticulitis is thus advised.[61–63]

Others have recommended elective resections at a younger age to avoid the increased morbidity and mortality associated with urgent or emergent surgery in the elderly (0% vs. 34.9%).[71] Some recommendations for elective resection in the young patient are based on cost savings related to definitive surgical management vs. the higher costs of ongoing medical treatment for recurring disease.[66] These types of recommendations assume a high risk of recurrent disease.

There is evidence that diverticular disease in young patients is changing. It is not as rare as in the past[62,72,73] and continues to become more prevalent.[73] And recent evidence suggests there is no increased risk of complications from diverticular disease in the young.[68–73] Based on these findings, resection following a single episode of diverticulitis is not recommended.

Data is difficult to interpret because the presentations of diverticular disease are so varied and most studies are small and retrospective with risks of unrecognized selection bias. However, it does appear that diverticular disease is more common in young patients than generally recognized. Obesity may be a risk factor related to diet. Diets high in fiber are less likely to result in obesity compared to diets associated with diverticular disease.

The issue of male predominance could be a result of missed diagnoses in females. Young females frequently have a gynecologic focus of attention placed on causes of abdominal pain other than diverticular disease. This is further compounded by the general poor recognition of the prevalence of diverticular disease in younger patients.

Current recommendations for resection are based on the predicted risk of developing a serious complication that would lead to emergency surgery with increased morbidity and mortality. To improve management we must become better at predicting who is at risk for recurrent disease. Age alone does not appear to be a reliable factor. The use of CT to identify "severe" or "complex" diverticular disease seems most promising.

In a recent study, the incidence of remote complications was the highest (54% at 5 years) for young patients with severe diverticulitis on CT and the lowest (19% at 5 years) for older patients with mild disease. Young age and severe diverticulitis taken separately were both statistically significant factors for poor outcome ($P = 0.007$ and 0.003, respectively), although age was no longer significant after stratification for disease severity on CT ($P = 0.07$).[75] Other studies have shown similar risks associated with complex disease on CT.[76,77]

Giant Colonic Diverticulum

Giant diverticula of the colon are rare entities associated with sigmoid diverticular disease. They are generally pseudo-diverticula with inflammatory rather than colonic mucosal walls. They usually arise off of the antimesenteric border of the sigmoid colon. The mechanism of formation is unknown but they have been reported to be as large as 30–40 cm[78,79]; 12% occur in patients under the age of 50.

Diagnosis is by plain film of the abdomen which demonstrates a large, solitary, gas-filled cavity. Communication with the colon can be demonstrated with contrast enema. The differential diagnosis includes congenital duplication of the colon, cholecystenteric fistula, colonic volvulus, emphysematous cholecystitis, infected pancreatic pseudocyst, pneumatosis cystoides intestinalis, Meckel's diverticulum, intra-abdominal abscess, giant duodenal diverticulum, dilated intestinal loop, gastric dilatation, tubo-ovarian abscess, and mesenteric cyst.[80]

Most patients will present with vague symptoms of abdominal discomfort or pain and a soft, mobile abdominal mass. A few patients will present with one of the known complications which include perforation, sepsis, intestinal obstruction, or volvulus. The natural history is slow enlargement over time. The treatment of choice is resection of the diverticulum and adjacent colon at time of diagnosis if the patient is symptomatic.

Rectal Diverticula

Rectal diverticula are rare. They are typically true diverticula since they include the muscular layer of the rectum in their wall. They are frequently solitary. Inflammation can generally be managed with antibiotics, rarely surgical resection is required.

Cecal and Right-Sided Diverticulitis

Right-sided diverticular disease is much more common in the Far East than in the west, representing 35–84% of diverticula in that region. Patients present an average of 20 years younger than with sigmoid diverticulitis. Classically, cecal diverticula are described as true diverticula containing all layers of the bowel wall. However, most cecal diverticula actually are false and frequently not solitary.

It is estimated that 13% of patients with cecal diverticulosis develop diverticular inflammation. Cecal diverticulitis can be graded according to the extent of the inflammation. Grade I disease refers to an easily recognizable projecting inflamed cecal diverticulum. Grade II is an inflamed cecal mass. Grade III encompasses a localized abscess or fistula. Grade IV is a free perforation or ruptured abscess with diffuse peritonitis. Cecal diverticulitis is correctly diagnosed preoperatively only 5% of the time. Appendicitis is the preoperative diagnosis in more than two-thirds of cases.[81]

Intraoperative diagnosis is relatively easy with Grade I and to a lesser extent with Grade II disease. Most episodes of cecal diverticulitis presenting with Grade III or Grade IV disease are misdiagnosed intraoperatively as perforated carcinoma.

If a correct diagnosis of uncomplicated cecal diverticulitis can be made preoperatively, then antibiotics and treatment similar to left-sided disease are appropriate. However, this is rare. Intraoperatively, the options for treatment include (1) appendectomy, nonresection of the diverticulum and postoperative antibiotic therapy; (2) appendectomy with diverticulectomy for Grade I and identifiable Grade II disease; or (3) right hemicolectomy is the procedure of choice for not readily identifiable Grade II, Grade III, and Grade IV disease, failed treatment or possible cancer. Appendectomy should always accompany nonresection or diverticulectomy whenever the base of the appendix is not inflamed to avoid confusion at a later date.[81–83]

Diverticular Disease of the Transverse Colon

This is an exceedingly rare condition. Clinical presentation most often mimics appendicitis, cholecystitis or, less frequently,

ischemic or Crohn's colitis. It is reported to occur in a younger age group than sigmoid disease and is more common in females. Treatment parallels that of sigmoid diverticulitis; however, resection is more commonly performed since a pre-operative diagnosis is more difficult to make and a carcinoma frequently cannot be ruled out.

Saint's Triad

Saint's triad is a described association of diverticulosis, chole-lithiasis and hiatal hernia. Although it has been suggested that the triad occurs in 3–6% of the general population,[82] it is of unknown clinical significance and likely represents the normal concomitant distribution of these common maladies.

Polycystic Kidney Disease

There is a such a high incidence of diverticulosis among patients with autosomal dominant polycystic kidney disease that some consider it an extra-renal manifestation.[84] These patients undergoing renal transplantation are at particularly high risk for devastating infectious complications due to their immunocompromised state. Many transplant centers recommend prophylactic sigmoid resection in those poly-cystic kidney patients scheduled for transplantation with a documented history of diverticulitis.[84–86]

Treatment of Acute Diverticulitis

Dietary Management

The primary management of asymptomatic diverticular dis-ease is diet. The goal of dietary manipulation is to increase the bulkiness of stool thus increasing lumen size, decreas-ing transit time, and decreasing intraluminal pressures. This decreases segmentation which has been described as a significant factor in the development of diverticular dis-ease. The ideal amount of fiber is not known; however, the recommended daily amount is 20–30 gm. In general, fiber can be obtained by consuming foods high in fiber or through supplementation with one or more of a large variety of bulk laxatives. Epidemiologic evidence strongly suggests a diet high in fiber can reduce the risk of developing diverticulosis. What is less clear is whether a high fiber diet can prevent diverticulitis and its complications in patients who already have diverticulosis. Recent evidence is building in support of this concept.[87–90]

Medical Management

In the absence of systemic signs and symptoms (high fever, marked leukocytosis, tachycardia, and hypotension), most patients experiencing symptoms of diverticulitis will respond to a regimen of bowel rest and antibiotics as outpatients. Diet is usually restricted to low residue or clear liquids during the acute illness but with resolution of the acute symptoms, a high fiber diet should be instituted. There is no need to restrict the ingestion of seeds or hulls since there is no data to substantiate this practice.

Appropriate antibiotics should be instituted. The most pre-dominant organisms cultured from acute diverticular abscess and peritonitis include the aerobic and facultative bacteria *Escherichia coli* and *Streptococcus* spp. The most frequently isolated anaerobes include *Bacteroides* spp. (*B. fragilis* group), *Peptostreptococcus*, *Clostridium,* and *Fusobacterium* spp.[91]

The use of anticholinergics as adjunctive therapy is based on theoretically reducing pain related to spasm and hyper-motility in the sigmoid colon. Efficacy has not been proven.

Signs of more advanced disease including marked leu-kocytosis, high fever, tachycardia, or hypotension as well as a physical examination demonstrating more advanced intra-abdominal pathology, dictate a need for inpatient man-agement. Patients admitted for inpatient care will usually undergo a baseline CT scan which can confirm the diagno-sis, rule out potential alternative diagnoses, and evaluate for complicated disease that would require a change in initial management.[48]

Antibiotics should be administered via an intravenous route. Generally the patient will be placed nil per os (NPO) until there is evidence of clinical improvement making surgical intervention less likely. The diet is then gradu-ally advanced from clear liquids to a low residue diet for a variable period of time before reinstituting a high fiber diet. Symptoms should improve within 24–48 h. Failure to improve requires further diagnostic workup including repeat CT and re-evaluation of the need for surgery.

Surgical Management

The surgical management of acute diverticular disease is replete with varied options that allow for customizing an operation to meet the needs of the individual patient. A thorough knowledge of these options and the indications for each is necessary for the surgeon managing these cases. The goal should always be to manage a complex patient in a way which will maximize the opportunity to avoid an emer-gency operation in favor of an elective resection.

Surgical options include primary resection with anasto-mosis with or without proximal diversion, resection with proximal colostomy and oversewing of the rectal remnant (Hartmann's procedure) or mucous fistula (Mikulicz opera-tion), simple diversion with drainage of the affected segment, diversion with oversewing of the perforation site and, rarely, subtotal colectomy. Adjunctive measures include on-table lavage and the option of a laparoscopic approach.

The historical discussion of these options would include the use of a three-stage approach with diversion and drain-age followed by a second operation for resection and a third operation for reestablishment of intestinal continuity.

A modification of this approach includes oversewing of a visible site of perforation with an omental patch as a part of the initial operation.[92] Alternatives include a two-stage approach consisting of a Hartmann's or Mikulicz procedure followed by a second operation for re-establishment of intestinal continuity and resection with primary anastomosis, with or without proximal diversion, as a single operation. For the most part, current discussions revolve around the relative merits of a single stage vs. a two-stage approach in acute cases requiring urgent or emergent surgery.[93–95] The three-stage approach is unlikely to be used except in the most extreme cases of medical instability.[96,97]

The following sections will discuss the applications of these approaches to the various presentations of diverticular disease including both chronic and acute forms. Special consideration will be given to the management of intra-abdominal abscesses.

Intra-abdominal Abscess

For a patient found to have an abscess, there is a large volume of clinical evidence supporting the advantages of percutaneous drainage and the conversion of an emergent operation with its attendant increased morbidity and mortality to the relative safety of an elective operation.[48,98] An abscess not responding to medical management should be drained percutaneously or transrectally as appropriate to its location (Figure 22-2).

If drainage cannot be accomplished nonoperatively, or if drainage is performed but fails to resolve systemic signs and symptoms, operation is indicated. Generally, the clinical scenario in this situation would be that of an advanced Hinchey Class II. Although it is possible that intraoperative findings would support a resection with primary anastomosis with or without proximal diversion, it is more likely that a Hartmann's resection will be required.

In a recent study of 511 patients diagnosed with complicated diverticulitis, 99 were diagnosed by CT scan with abscess, and 16 of these underwent percutaneous drainage.[99] Of these patients with continued nonoperative treatment, even after percutaneous drainage a recurrence rate of 42% was noted with an associated increased probability of emergent procedure. Based on these findings it is recommended that all patients with complicated findings undergo at best an elective operation.[99]

This therapy of treating patients with percutaneous drainage and medical management until it was feasible to perform an elective operation has also been evaluated. Salem reviewed all hospitalized patients for the state of Washington and found after evaluating over 25,000 patients that percutaneous drainage was associated with a decrease in emergency operative interventions.

Ricciardi et al.[100] evaluated the nationwide inpatient sample data from 1991 to 2005 analyzing the incidence of complicated diverticulitis admissions. Despite a significant decline in surgical treatment for diverticulitis during this time period, there was no change in the proportion of patients discharged with complicated diverticulitis.

Indications for Surgery for Acute Disease

The indications for surgery of acute disease include (1) failure of phlegmon or abscess to respond to nonoperative management with clinical deterioration (increasing fever, leukocytosis, tachycardia, hypotension, signs of sepsis, or a worsening physical examination), (2) free perforation with peritonitis, and (3) obstruction. Perforation without peritonitis may not require operation (Figure 22-3).
FIGURE 22-3. 3-Diverticulitis with localized perforation. The patient was treated with antibiotics and improved without the need for emergency surgery.

FIGURE 22-2. CT reveals pericolic abscess (Hinchey Stage I).

Surgical Procedures

For acute disease, the choice of operation is highly dependent upon the degree of inflammatory response encountered at the time of operation. Since most acute diseases can be managed nonoperatively (including the percutaneous drainage of most abscesses), the fact that an operation has become necessary suggests rather advanced pathology and the need to be conservative. In general, most Hinchey Class I and some Class II disease can be managed with a one-stage procedure (resection and anastomosis) if the patient is stable, the extent of contamination is limited and adequate bowel preparation is possible[93,101] recognizing, however, the necessity of mechanical bowel preparation in colon resections has been questioned.[102] Proximal diversion may be necessary. Most cases of Hinchey Class III and IV disease will require a two-stage approach. Some recent evidence suggests a possible role for resection with primary anastomosis and proximal diversion in highly selected cases without gross fecal contamination.[100–106]

In a recent review by Salem and Flum,[106] who reviewed 98 articles on the outcome of complicated diverticulitis based on the type of operation performed, 1,051 patients were identified who had a Hartmann procedure from 54 studies, and 569 patients who had a primary anastamosis from 50 studies. Of the 569 cases, 16% had covering stomas and 10% underwent on-table lavage. The mortality rates were higher in the Hartmann group, 19.6% vs. 9.9% for primary anastamosis. Anastomotic leak rate ranged from 6.3 to 19.3% in patients undergoing a primary anastamosis. When primary anastomosis was performed with a covering stoma, the lowest rate of leak rate (6.3%) and the lowest wound infection rate (4%) was demonstrated. Wound infections were also more frequently seen in the Hartman group 24.2% vs. 9.6%. Hartmann patients also required a larger second operation than those who had a primary anastamosis with or without a covering stoma. The conclusion was the primary anastomosis is no worse than a Hartmann and has several advantages including higher restoration of continuity rate, less hospitalization, and fewer infectious complications (Table 22-4).

A major disadvantage of a two-stage procedure is that 35–45% of patients never have their colostomy closed.[103] However, in patients with preexisting incontinence, a Hartman's pouch should be the procedure of choice. Women are more likely than men to not have closure.[103,104] For patients who do not undergo closure of their stoma, it is critical that their rectal stump undergo scheduled surveillance for neoplasia as the remaining rectum maintains at the same risk for neoplasia as other patients of equal age.[105]

Hartmann Reversal

Reversal of a Hartmann's colostomy carries significant risks that must be entertained when considering this operation for patients who will desire continuity in the future. Failure to reverse the colostomy has been reported in 20–50%[106] of

TABLE 22-4. Outcomes of primary anastomosis and Hartmann's procedure

	Patients	Mortality (%)	Wound infection (%)	Leaks (%)
Hartmann procedure	1,051	18.8	24.2	NA
Primary anastomosis	295	8.1	16.4	19.3
Primary anastomosis with stoma	<109	9.2	4	9.6

Modified from: Salem L, Flum DR. Primary anastomosis or Hartmann's procedure for patients with diverticular peritonitis. A systemic review. Dis Colon Rectum. 2004;47:1953–64.[106]

patients and leak rates on reversal range from 2 to 30%.[106,107] Mortality has been reported anywhere from 0 to 10% and wound infection rates range from 12 to 50%.

Maggard et al.[108] reviewed 1,176 patients who had a Hartmann's procedure for diverticular disease, only 65% had a reversal at a mean of 143 days. Younger men were more likely to have their ostomy reversed as opposed to older patients and women. Patients with more comorbidities also had fewer reversals. When evaluating all patients, 35% never had their ostomy reversed during the 4-year study. The complication rate following Hartmann reversal was 57.4%, including infection (9.1%), aspiration pneumonia (8.7%), pulmonary edema (6%), and acute renal failure (4.9%).[108]

Complications from Surgical Resection

Predictors of complications after resection for diverticular disease include advanced age (greater than 70–75 years), two or more co-morbid conditions, obstipation at initial examination, the use of steroids, sepsis, and obesity.[96,109,110] Complications of resection include anastomotic leak and hemorrhage.[111] The prevalence of leak from a low intraperitoneal anastomosis is generally considered to be between 2 and 5%.[112] Anastomotic leaks may lead to localized abscess, stricture, peritonitis and sepsis. The diagnosis is dependent upon a high index of suspicion on the part of the surgeon and quick response to any unusual signs of sepsis. Fever, vague abdominal pain, diarrhea, obstruction and sepsis all should raise the question of a leak. The diagnosis is most commonly confirmed by water soluble contrast enema or by CT scan with intravenous, oral and rectal contrast.

An anastomotic leak without an abscess can usually be managed with intravenous antibiotics and response assessed. Failure to respond to treatment within 24–48 h or initial severe sepsis or peritonitis requires exploration with resection of the anastomosis and proximal diversion. Repair of the anastomosis with proximal diversion is usually unsatisfactory because of the high risk for recurrent leak in this inflammatory setting. An exception would be a "pin-hole" leak with limited inflammatory response which may be managed with repair, colonic lavage, and proximal diversion.

An anastomotic leak resulting in an abscess can generally be managed with percutaneous or transrectal drainage. Again, failure to respond will require laparotomy, take down of the anastomosis and proximal diversion.

A colocutaneous fistula related to a diverticular resection will usually respond to nonoperative measures. Provided there is no distal obstruction, no foreign body, and no underlying Crohn's disease, spontaneous closure should be anticipated. Important steps to facilitate closure of colocutaneous fistulas include draining any undrained abscess; maximizing nutrition; and delivering appropriate wound care, which may require the help of enterostomal therapy nurses.

Strictures are an unusual complication related to diverticular resection, unless the underlying process is Crohn's disease. In the rare instance when stricture does occur, the most likely etiologies include ischemia or localized sepsis due to confined leak. Such strictures can most commonly be managed by dilatation with a balloon or rigid proctoscopy but occasionally will require a formal resection with recreation of anastomosis.

Ureteral injuries are reported to occur in 1–10% of abdominal surgeries.[112] Early identification of any injury is the key to preventing significant morbidity. Although ureteral stents have not been shown to decrease the rate of injury, they do improve intraoperative identification of the ureters and the early identification of any ureteral injury.[113] The decision to place ureteral stents prior to operation should be a function of clinical suspicion and the extent of inflammation on CT scan.

General postoperative complications related to colon and rectal surgery and specifics related to the recognition and management of the specific complications mentioned above are discussed more thoroughly in Chap. 10.

Recurrence After Resection

Recurrence of diverticulitis or its symptoms following resection has been reported in 3–13% of elective cases.[114] Factors contributing to recurrence of diverticulitis include shorter resection length and anastomosis to sigmoid colon rather than to rectum.[114,115] Thaler et al.[116] demonstrated that the level of the anastomosis is the only significant determinant of recurrence after laparoscopic resection for diverticular disease.

Treatment of Chronic and Recurrent Diverticulitis

Most patients who develop a first episode of symptomatic diverticulitis have been asymptomatic until 1 month prior to presentation. Most will respond to bowel rest and antibiotics as an outpatient. It is difficult to reliably estimate how many outpatients will have recurrence because outpatient data is generally not reflective of a primary care population. However, it has been reported that up to 10% of patients with a first episode who have responded to outpatient management will develop recurrent or persistent symptoms which will require hospitalization.[59]

Data is more readily available on recurrence for patients who were initially treated as inpatients. But our understanding of the natural history continues to evolve as antibiotics become more effective and inpatient status reflects increasingly severe disease. This makes historical data regarding these issues of less value. Presently, inpatients might be expected to be at a greater risk for recurrence. In fact, 20% or more of these patients will develop a recurrence.[59] Some, but not all, will require a second hospitalization. The interval between acute events may be prolonged (median 5 years).[117] Following a second hospital admission, up to 70% will continue with symptoms and over half of those that require another admission will do so within 1 year. The more complicated the attack, the higher the risk of recurrence.[4,15,118–121]

It has been estimated that up to 1% of all patients with diverticulosis will eventually require operative intervention.[9] However, with an increasing denominator in the number of individuals affected with diverticulosis and better antibiotics for managing infections, this estimate may now be too high.

The risk of recurrence following an attack of uncomplicated diverticulitis has been shown to be quite low. The range of recurrence following an attack is 1.4–18%.[122–124] It has been estimated that only 1 in 2,000 patient/years of follow-up will require an urgent Hartmann's procedure after resolution of diverticulitis.[125] In the 1950s, it was reported that morbidity and mortality were higher with recurrent attacks of acute inflammation, and early interval resection was a means of avoiding those problems.[75,126–128] Recent studies have shown repeatedly that prophylactic operation to prevent the need of a colostomy is unfounded. In patients with uncomplicated diverticulitis, Chautems et al.[75] followed 118 patients after a first uncomplicated attack of diverticulitis for 9.5 years. Of these patients, 71% had no recurrent episodes and of those who did, none required emergent surgery. More recently, Anaya and Flum[129] with a large population-based study of over 20,000 patients admitted with nonoperatively managed diverticulitis, found that only 5.5% progressed to require an emergent colectomy or colostomy. Younger patients in this study were found to be at higher risk than their older counterparts.[129]

Anaya and Flum[129] published a review of 25,058 patients hospitalized for an initial episode of diverticulitis. Of the 20,136 patients treated nonoperatively, 19% developed a recurrence, with those less than 50 years of age having a slightly higher incidence (27% vs. 17% $P<0.001$). These numbers are significantly lower than previous estimations of recurrence rates greater than 30%.

Very few patients presenting and requiring an emergent operation had been previously diagnosed with diverticulitis. An estimated 75–96% of patients presenting with peritonitis requiring an emergent operation had never been diagnosed with diverticulitis. This supports the notion that operating to prevent complications of diverticulitis is ineffective at achieving the goal.[8,130–132] Patients with multiple, recurrent episodes

of acute diverticulitis documented by CT scan should be considered for resection. Traditional teaching with respect to diverticulitis dictated elective sigmoid resection for patients suffering more than one episode of uncomplicated diverticulitis. In fact, most of the consensus data on elective resection after two documented episodes comes from literature that was published prior to the use of CT scanning and modern day antibiotic therapy. Because of these and other studies, the American Society of Colon and Rectal Surgeons (ASCRS) revised its previous recommendations for resection of diverticular disease. The 2006 revised practice parameters now reads as follows: "The decision to recommend surgery should be influenced by the age and medical condition of the patient, the frequency and severity of the attacks, and whether there are persistent symptoms after the acute episode."[133]

Recent data has suggested that the recommendation for resection following two episodes of diverticulitis treated as an inpatient may result in too many patients undergoing resection, thereby increasing the total cost of health care. Performing resection after the third episode of diverticulitis results in significant cost savings.[134] Performing resection following four documented episodes rather than after two results in fewer deaths, fewer colostomies, and an additional cost savings of over $5,000 per patient in those less than 50 years of age.[135] Others question the role of elective resection at all due to the high success rate of nonoperative management and the large percentage of patients presenting with urgent surgical disease that have no previous history of diverticulitis.[130,136]

The ultimate goal is to perform an operation electively rather than as an emergency. This requires correctly predicting those patients who are most likely to have serious complications as a result of their disease. CT evidence of complicated or "severe" disease has shown some promise in predicting risk. The risk of complications within 5 years of a first attack of diverticulitis exceeds 50% if CT shows severe diverticulitis at the initial episode.[75] Mild findings on CT can be defined as localized thickening of colonic wall and inflammation of pericolic fat. Severe findings are defined as abscess and/or extraluminal air and/or extraluminal gastrograffin. Abscess, extraluminal air, and extraluminal gastrograffin have been associated with an increased risk of poor outcome from medical management regardless of age.[76,77]

Another approach is to identify specific groups of patients (other than age) who are at increased risk. Immunocompromised patients are at particular risk for a poor outcome.[35] The risk is due to a higher incidence of perforation and more severe inflammatory complications when perforation does occur.

Surgical Procedures

Patients undergoing resection for chronic disease will almost always be candidates for single stage resection with primary anastomosis. This includes patients returning for closure of a colostomy following initial diversion and drainage, diversion with oversewing of perforation or diversion with resection via either Hartmann's or a Mikulicz procedure.

Techniques for Appropriate Resection

The practice parameters of the ASCRS set out several general recommendations regarding resection of diverticular disease. For elective resections, all thickened, diseased colon but not necessarily the entire proximal diverticula-bearing colon should be removed. It may be acceptable to retain proximal diverticular colon as long as the remaining bowel is not hypertrophied. All of the sigmoid colon should be removed. When anastomosis is elected it should be made to normal rectum and must be free of tension and well vascularized.[133] The single most important predictor of recurrence following sigmoid resection for uncomplicated diverticulitis is an anastomosis to the sigmoid colon rather than to the rectum.[137] In urgent or emergent cases, resection and diversion are generally required. In selected cases where sepsis can be removed, definitive resection with anastomosis (with or without proximal stoma) may be appropriate. On-table colonic lavage may be a useful adjunct to resection and anastomosis.[116]

Laparoscopic Surgery

The role of laparoscopy in the management of diverticular disease is evolving. Recent data suggest decreased overall costs associated with laparoscopic resections when compared to open resections.[137,138] Patients who are converted from laparoscopic to open procedures are a concern with regard to added costs but conversion rates are below 20%,[137–142] predictable[141,143], and thus probably avoidable in many instances.[140] Higher conversion rates are associated with more complex disease.[144] Recurrence rates match those for open procedures.[140,143,144] Laparoscopic resection results in a shorter length of stay[137,138] and fewer complications.[138] Hand-assisted laparoscopic colectomy has also been compared against straight laparoscopic colectomy and has been found to be equivalent in patient outcomes.[145,146] Marcello et al.[147] in a multicenter prospective randomized trial found the benefit of hand-assisted laparoscopic sigmoid resection compared to laparoscopic resection includes shorter operating time with similar length of hospital stay (Table 22-5).[147]

TABLE 22-5. Results of a multicenter prospective randomized trial of hand-assisted laparoscopic sigmoid resection compared to laparoscopic resection in diverticular disease

	HA ($n=33$)	LAP ($n=33$)	P value
Operative time (min)	175 ± 58	208 ± 55	0.021
Estimated blood loss (mL)	211 ± 160	198 ± 175	0.074

Adapted from Marcello PW, Fleshman JW, Milsom JW. Hand-assisted laparoscopic vs. laparoscopic colorectal surgery: a multicenter, prospective, randomized trial. Dis Colon Rectum. 2008;51:818–28.[147]

Despite the recent eruption of literature and discussion of laparoscopic colectomies, only 5–10% of all colectomies are currently performed using a laparoscopic technique.[145] As data continues to accumulate, it appears that laparoscopic surgery is set to play a significant role in the management of diverticular disease.

A therapy unique to laparoscopic surgery is the use of laparoscopic lavage. A new approach has been described by Myers et al.[148] from Ireland as an alternative to resection and Hartman's pouch in perforated diverticular disease. They describe using laparoscopic peritoneal lavage for generalized peritonitis for perforated diverticulitis in 100 patients prospectively. They converted 8 patients to a Hartmann's procedure who had feculent peritonitis, the remaining 92 were followed with only a 4% morbidity and 3% mortality. Only two patients required additional procedures for pelvic abscesses and two patients had recurrent diverticulitis, one at 12 months and the other at 84 months postprocedure. Additional studies are needed to determine what role this management option may play in acute diverticular disease.

Complications of Diverticular Disease

Bleeding

Bleeding is not recognized as a feature of diverticulitis. Bleeding related to diverticulosis is discussed in Chap. 24.

Perforation

Perforation can occur at two levels. If an abscess forms and then ruptures, purulent peritonitis is the result. If a large perforation occurs through the diverticulum directly into the peritoneum, fecal peritonitis is the result. Mixed fecal and purulent peritonitis may result from the rupture of an abscess which has an ongoing communication with the bowel lumen and then perforates. Clinically, the presentation is that of either abrupt onset of abdominal pain for a free perforation or an abrupt exacerbation of progressive localized pain in the case of a ruptured abscess. A pneumoperitoneum is seen on abdominal films or CT scan. Rapid progression to diffuse abdominal pain and rigidity can be expected.

Abscess

An abscess most commonly results from the mechanism described above. Small abscesses less than 1 cm in diameter will frequently resolve with antibiotic therapy. Larger abscesses may require drainage. CT-guided percutaneous drainage is the preferred approach when possible as it can convert the high risks of an urgent operation to a much safer elective operation.

Fistula

The incidence of fistulization reported in the literature ranges from 5 to 33% depending largely upon the type of referral center making the report.[47] Colovesical fistula is the most common fistula associated with diverticular disease and diverticular disease is the most common cause of colovesical fistula (Figure 22-4A and B). Other relatively common fistulas associated with diverticular disease include colocutaneous, colovaginal, and coloenteric. Most patients who develop a colovaginal fistula have had a previous

A   B
FIGURE 22-4. **A/B** CT scan reveals air in the bladder consistent with a colovesical fistula.
FIGURE 22-5. Colovaginal fistula occur almost exclusively in patient who have undergone prior hysterectomy.

hysterectomy (Figure 22-5). Other fistulas have rarely been described and include colocolic, ureterocolic, colouterine, colosaphingeal, coloperineal, sigmoido-appendiceal, colovenous, and even fistulas to the thigh (a variant of a colocutaneous fistula).

The diagnosis of diverticular fistula is generally clinical. Many fistulas will not be identifiable by imaging studies. Thus, excess efforts should not be undertaken to try to radiographically demonstrate a fistula. The primary aim of a diagnostic workup is not to see the fistula but to determine the etiology (diverticulitis, cancer, IBD, etc.) so that appropriate therapy can be initiated. The general principle of management is resection of the colon, usually with primary anastomosis, with varying treatment for the organ involved. For the bladder, simple drainage of the bladder for 7 days is advised. No treatment of the vagina is required in most circumstances. Cutaneous fistulas will usually require cutaneous closure by delay or secondary intention. Enteric fistulas require closure or resection of the involved small bowel or colon. Ureteral drainage for fistulas to the ureter, observation or hysterectomy for uterine fistulas, salpingo-oophorectomy for fistulas to the fallopian tubes, and appendectomy for appendiceal fistulas are the most common treatments for uncomplicated fistulas of the other named varieties. If there is any question of cancer, an en-bloc resection of a portion of the involved organ must accompany the resection.

Occasionally, nonoperative management is appropriate when symptoms are minor or when the patient is at otherwise too great a risk for other health reasons. The use of long-term suppressive antibiotic therapy in selected patients with colovesical fistula has been shown to eliminate symptoms and prevent complications related to the fistula until death from other causes.[149]

Stricture

The development of a phlegmon with repeated attacks of acute disease or long-term persistent disease may result in a stricture. Although a relatively uncommon complication, patients will present with constipation, abdominal pain, and bloating. It is necessary to rule out carcinoma as the true cause of the stricture. Colonoscopy is the first choice to help make this distinction; however, it is not uncommon for associated bowel angulation and fixation to prevent endoscopic visualization. Contrast studies may assist in the evaluation in such instances, but resection may be necessary to make a diagnosis.

Obstruction

On rare occasions complete obstruction may occur. If this is due to diverticular disease, most patients will respond to initial medical management allowing for an elective resection at a later date. Persistence of an obstruction may require a Hartmann's procedure or primary anastomosis with proximal diversion for management. The successful use of colonic stents to relieve obstruction secondary to diverticulitis has been described. [150,151] In this setting, the colonic stent is used as a bridge to surgery with later elective resection. However, the use of stents in benign disease is not an indicated use. There is a high incidence of complications leading to emergency surgery for removal of the stent and management of complications.[152]

Ureteral Obstruction

The ureter is infrequently involved with diverticular disease. When involved, it is most frequently the left ureter. Rarely, diverticular disease has been reported as fistulizing to the ureter. A stricture may occur but compression is more common. This can result from retroperitoneal fibrosis secondary to diverticular inflammation. Most commonly this resolves as the underlying diverticular disease process resolves, although occasionally ureterolysis has been advised.[153]

Phlegmon

A phlegmon represents an inflammatory mass without a surrounding central abscess. A phlegmon can significantly complicate the technical aspects of surgical resection. Many phlegmons will resolve with antibiotic therapy. If resection is planned due to recurrent episodes of disease, it is best to treat the acute phlegmon to resolution if possible, prior to resection. Occasionally, operation may become necessary in the face of an acute phlegmon. This situation may be the source of some descriptions of "malignant" diverticulitis as earlier described.

Colonic Volvulus

Jan Rakinic

Introduction

Volvulus, from the Latin *volvere*, means "to twist." Volvulus may occur in any part of the gastrointestinal tract where there is sufficient length of gut to twist about a fixed point. Colonic volvulus is the cause of 10–15% of colon obstruction in USA.[1,2] Colonic volvulus occurs when a mobile portion of the colon has a mesentery with a narrow, fixed base. The colonic segment twists around this fixed point, producing a closed loop obstruction. The mesenteric narrowing may be congenital or acquired, often by surgical scarring near the mesenteric root. As may be anticipated, the most common sites of colonic volvulus are the sigmoid colon and cecum, which are the most mobile parts of the colon. In a series of 546 cases of colonic volvulus in USA, the site-specific incidence was found to be cecum, 34.5%; transverse colon, 3.6%; splenic flexure, 1%; and sigmoid colon, 60.9%.[3] A more recent Australian study had incidence as follows: cecum, 39%; transverse colon, 2%; and sigmoid colon, 59%.[4] Factors that place patients at elevated risk for colonic volvulus include chronic constipation, previous abdominal surgery, and megacolon.

More than half of the patients with colonic volvulus present acutely with crampy abdominal pain, marked tympanitic abdominal distention, and absence of flatus or stool. Some institutionalized patients may not complain of pain; rather, a caregiver may notice an unusually long interval between bowel movements associated with significant abdominal distention. There may not be a preceding history of worsening constipation or thinner stools, as can be seen with progressive mechanical obstruction, since volvulus is a more acute process. Vomiting is an uncommon early symptom. Pain becomes more constant when ischemia worsens due to compression of the vessels within the twisted mesentery. There is a group of patients who have recurring subacute episodes of volvulus, with often painless abdominal distention and tympany. These episodes resolve spontaneously with passage of copious amounts of liquid stool and gas, described as "explosive." These patients should be evaluated for colonic dysmotility and megacolon, as these findings alter the surgical therapy. Total abdominal colectomy is the procedure of choice if megacolon is found, due to the high risk of recurrent volvulus if abnormal colon is retained.[5–8]

In children, colonic volvulus is rare, with a male predominance. Recurrent subacute episodes are most common. Mortality varies, but is higher when gangrenous bowel is present. Many of the children who develop colonic volvulus have medical comorbidities or developmental abnormalities. A report from Turkey described 19 pediatric patients treated for sigmoid volvulus over a 36-year period. The mean age was 10 years; 90% were male; two (10.5%) had volvulized previously. Gangrenous bowel was found in 15 patients (79%). Mortality was 21% (4/19).[9] A retrospective study from Texas over a 60-year span found 63 cases of colonic volvulus in children, with a median age of 7 years and a male:female ratio of 3.5:1. Of the 63 patients, 11 (17.5%) had Hirschsprung's disease. A number of the children had recurrent preoperative symptoms consistent with repeated episodes of volvulus. Overall mortality was 6%; operative mortality was 8.1%.[10] A series from England reported seven cases of pediatric colonic volvulus over a 6-year period; five of the children had cerebral palsy, and one had moyamoya disease with spastic paraplegia. Mean age was 8.3 years; six were female. Segmental resection was done in all cases; there was no mortality.[11]

Volvulus in the pregnant patient merits special consideration. While intestinal obstruction is rare in pregnancy, nearly 45% is caused by sigmoid volvulus, and it is estimated that 10% of patients with reports of cecal volvulus are pregnant at presentation. It has been postulated that the enlarging uterus lifts the sigmoid colon and cecum out of the pelvis, and that these segments become more prone to torsion about the pelvic sidewall attachments.[12,13] Volvulus in pregnancy carries a high mortality rate, often because diagnosis is delayed due to avoidance of radiography and because of similarity of symptoms to other clinical entities. A high index of suspicion for volvulus must be maintained when a pregnant patient presents with symptoms of "constipation" and abdominal pain.

Urgent intervention is often required in the setting of volvulus due to the risk to both mother and fetus.

Sigmoid Volvulus

Epidemiology/Pathogenesis

The sigmoid colon is the most common site for colonic volvulus in USA. American patients with sigmoid volvulus are generally elderly, institutionalized patients on psychoactive medications with chronic constipation, and approximately 80% are male.[14] In regions where a high fiber diet is the norm, including Africa, India, Pakistan, and the Middle East, the incidence of sigmoid volvulus is much higher than in the West, and patients are several decades younger, with persistence of male preponderance.[15–18] An anatomic study of the sigmoid mesocolon showed the female mesosigmoid to be wider than long, or brachymesocolic, whereas the male mesosigmoid was more likely to be dolichomesocolic, or longer than wide. This finding may explain the male predominance seen in sigmoid volvulus.[19]

The geographic variation in the incidence of sigmoid volvulus is believed to be linked to the ingestion of a high fiber diet, which lengthens the sigmoid colon and its mesentery, fostering an anatomic predisposition to volvulize.[20] Perry observed that while the bowel elongates as it distends, the antimesenteric border of the bowel elongates by 30%, whereas the mesenteric border elongates only by 10%.[21] In the setting of a long, narrow mesentery, distention of the bowel induces it to twist about the mesenteric axis. Several authors have described patients with other colonic disorders such as constipation and pseudo-obstruction developing sigmoid volvulus.[6,8] One researcher has suggested that sigmoid volvulus may itself be a variant of Hirschsprung's disease, which is marked by the absence of parasympathetic ganglion cells in the intramural and submucosal plexuses.[22] A VA study from 1996 investigated the density of ganglion cells in the Auerbach's plexus in dilated and nondilated segments of colons resected for volvulus. Fewer ganglion cells per highpowered field were found in the dilated portions. However, no correction was made for the acutely enlarged diameter of the affected colon segments.[23] Furuya et al. studied ganglion cell density comparing volvulized and non-volvulized sigmoid colons, and found no difference after correcting for the acute dilation. There was also no difference in ganglion cell density comparing sigmoid colons resected at the first instance of volvulus, and those re-resected ($N = 2$) for recurrent volvulus after what was thought to be an adequate initial volvulus resection.[24] This would seem to imply that there is no absolute loss of ganglion cells in sigmoid volvulus unaccompanied by megacolon.

The twist of the sigmoid volvulus is most commonly counterclockwise around the mesocolic axis. Torsion must be at least 180° to produce clinically significant obstruction. The sigmoid colon can tolerate more intraluminal pressure than other parts of the colon, and so the bowel wall can remain viable for a few days; however, strangulation will eventually occur, first with venous occlusion and then, followed by arterial occlusion, thrombosis, and necrosis. Gangrene may occur much more quickly due to a sudden, tight compression of the mesenteric vessels caused by rapid distention of the colon lumen.

Diagnosis

Exploratory laparotomy is mandatory if peritonitis is present. However, in the more usual presentation, the diagnosis is strongly suspected by history and physical examination. A plain abdominal film often confirms the clinical diagnosis, displaying the "bent inner-tube" or "omega loop" appearance of a massively distended bowel loop, with both ends closely adjacent in the pelvis (Figure 23-1). In up to 40% of cases, the plain film can be equivocal: there may be superimposition of distended transverse colon or small bowel; the sigmoid loop may be transversely oriented; or a massively dilated small bowel may mimic a sigmoid loop.
FIGURE 23-1. Plain abdominal X-ray of sigmoid volvulus indicating the "bent inner tube" sign.

FIGURE 23-2. Barium enema study of a sigmoid volvulus indicating the bird's beak deformity and complete obstruction to retrograde flow of contrast.

In these situations, a contrast enema or CT scan may clarify the diagnosis.

If a contrast enema is desired, it should be done with water-soluble contrast material, as the mortality with barium is very high if a perforation is encountered. A water-soluble contrast enema classically shows the contrast column ending sharply in a "bird's beak" shape at the site of torsion (Figure 23-2). The major differential diagnoses that must be considered are obstruction due to colonic neoplasm and colonic ileus, or Ogilvie's syndrome, both of which can present in a similar way. The contrast study is helpful in diagnosis clarification. In the case of neoplasm, there may be a wisp of contrast through the lesion; if the obstruction is complete, the appearance is distinctly different from the classic "bird's beak" appearance. In Ogilvie's syndrome, the water-soluble contrast enema will show that there is no obstruction, and may also be therapeutic.

Abdominal CT scan can be quite helpful in the identification of colonic volvulus. Much information has been written on the "whirl sign" indicating twisted mesentery and intestinal volvulus,[25,26] although most reports refer to small bowel volvulus. More recent reports have noted that the "whirl sign" can be observed in settings other than intestinal volvulus[27,28] and so may not be pathognomonic for intestinal volvulus.

In the pregnant patient, the diagnosis of sigmoid volvulus is usually made clinically, with subsequent endoscopic confirmation, or intraoperatively due to patient deterioration. The size of the uterus presents a challenge for operating in the pelvis; this makes simple detorsion or sigmoidopexy appear more attractive when the sigmoid colon is viable, but exposes the patient to a high risk of recurrence and need for another, definitive operative procedure.

Treatment and Outcome

The first volvulus-specific maneuver in the stable patient with a sigmoid volvulus is attempted endoscopic detorsion. Successful detorsion converts a surgical emergency into an elective situation. If the patient is febrile or has localized tenderness over the distended loop, nonviable colon should be strongly suspected, and attempted detorsion should be abandoned. Attempted detorsion of nonviable bowel risks perforation and peritonitis, with the attendant complications thereof. While detorsion was historically done with the rigid proctoscope, the flexible sigmoidoscope or colonoscope has replaced it as the instrument of choice. Detorsion has also been described using a column of barium or a blindly passed rectal tube. Due to concern that the sigmoid could be gangrenous, only detorsion techniques that visualize the mucosa should be used. When decompression is successful, as it is in 60–80% of attempts,[4,15,20,29,30] there is evacuation of significant flatus and stool with visible lessening of abdominal distention. A decompressing tube should be placed into the detorsed loop to allow continued decompression and to prevent retorsion. A plain abdominal film should then be obtained to confirm relief of volvulus and absence of intraperitoneal free air.

Decompression alone as a management choice bears the risks of recurrent volvulus and death, which are not always mutually exclusive. A large study from the VA reported that of 50 patients managed with endoscopic decompression alone, six (12%) died during the index admission, and ten of the remaining 44 (23%) developed recurrent volvulus requiring treatment; two of those ten (20%) subsequently died.[20] Lau et al. reported 49 patients from Brisbane, Queensland, of whom 12 were treated initially with endoscopic decompression alone. Six of these patients suffered seven recurrences within 32 days (one patient recurred twice), and 4 (33.3%) required emergency operation.[4] A study from Finland reported results of endoscopic decompression as the initial therapy for 17 of 58 patients with sigmoid volvulus: mortality was 12% and recurrence rate was 29%.[29] A Taiwanese study showed recurrence of sigmoid volvulus in 12 of 14 patients (86%) who refused operation after successful endoscopic decompression.[5] A study from Greece reported on 15 of 33 patients with sigmoid volvulus who were treated with endoscopic decompression and discharged. Five of these patients (33.3%) suffered recurrent volvulus requiring emergency operation; of these patients, three (60%) died.[30]

A study from Riyadh, Saudi Arabia, reported that of seven patients with sigmoid volvulus who were initially decompressed endoscopically and then refused elective surgery, three recurred (43%); these underwent repeat decompression followed by elective resection.[15] A recent study from Ireland reported a recurrent volvulus rate of 86.6% (13 of 15) in sigmoid volvulus patients initially managed with endoscopic decompression alone who survived the initial hospitalization.[31]

The high rate of revolvulus after detorsion alone, coupled with a mortality rate over 20% for emergent surgery compared to 6% or less with elective resection,[4,17,20,30] has prompted most surgeons to proceed with elective sigmoid resection during the same hospitalization for most patients. Complete colonoscopy should be performed prior to operation to rule out synchronous lesions that would alter management. The standard elective surgical procedure is sigmoid resection with primary anastomosis, which may be accomplished with open technique, or laparoscopic technique if the colon is sufficiently decompressed.[32,33] Patients successfully endoscopically decompressed prior to definitive resection have an incidence of recurrent volvulus close to zero.[4,17,20,30] However, in the setting of megacolon, total abdominal colectomy is the recommended procedure; otherwise, the patient is at very high risk of recurrent volvulus. Ryan reported 66 consecutive patients with sigmoid volvulus from Melbourne, six of whom had megacolon. He noted that in the non-megacolon group, flatus tube decompression was usually successful, and sigmoid resection was curative of the volvulus. In the megacolon group, patients had recurrent episodes of volvulus, tube decompression was less successful, and symptoms including revolvulus occurred after sigmoidectomy.[7] Morrissey reported on the postoperative course of 29 patients after surgery for sigmoid volvulus. There was an overall recurrence rate of 36%. In patients who had an otherwise normal colon, the recurrence rate was 6%, but in those with megacolon who had undergone resection of only the sigmoid colon, recurrence was 82%. Morrissey noted that no recurrence occurred in those with megacolon who had undergone subtotal colectomy.[6] Chung et al. reported on 35 patients from Singapore with sigmoid volvulus. Of patients who underwent sigmoid resection, six had recurrent volvulus. Chung found that concomitant megacolon and megarectum were significant predictors of recurrence.[5] Strom et al. reported a 30-year experience with 129 patients suffering 163 episodes of sigmoid volvulus, noting that sigmoidectomy resolved volvulus "only if bowel atony was limited to the segment removed." Megacolon required subtotal colectomy to avoid volvulus recurrence.[8]

A number of non-resectional techniques have also been described for the treatment of sigmoid volvulus. These include surgical detorsion without resection or fixation, or detorsion with methods of either sigmoid or mesenteric fixation. The described techniques of sigmoid fixation include extraperitoneal sigmoidopexy[16]; nonsurgical endoscopic sigmoidopexy with or without tube fixation[34,35]; parallel
FIGURE 23-3. Parallel colopexy as described by Mortensen.[36]

colopexy to the transverse colon (Figure 23-3);[36] laparoscopic fixation;[37] fixation of the sigmoid colon to the abdominal wall with bands of prosthetic with or without percutaneous colon deflation;[38] and percutaneous endoscopic colostomy.[39] Mesenteric fixation techniques include mesosigmoplasty and mesenteric fixation (Figure 23-4A and B).[40,41]

All nonresectional techniques are associated with high morbidity and/or high recurrence rate. Hiltunen reported on 58 patients from Finland with sigmoid volvulus, of which 21 were treated with detorsion with or without fixation.[29] This group had 24% recurrence, compared to 5% recurrence after sigmoidectomy. A 2007 report from Turkey cited 36% of recurrent volvulus after surgical detorsion as the only treatment.[18] Remes-Troche et al. reported 25 cases of sigmoid volvulus, of which 12 were treated with surgical fixation only. Recurrence after fixation was 38% at 12 months and 69% at 24 months, with associated 50% mortality.[42] In a large series from Turkey, 31 patients treated with mesosigmoidopexy had a recurrence rate of 16.1%.[18] A retrospective review from Varanasi, India, showed a recurrence rate of 38.5% (5/13) after colopexy alone.[43] In a recent report of 27 patients who underwent percutaneous endoscopic colostomy (PEC) for a number of indications, no recurrence of sigmoid colon volvulus occurred in eight cases with a PEC tube in place. However, mortality was 26% in the overall group; two deaths were from fecal peritonitis. Morbidity was also
FIGURE 23-4. Mesosigmoidoplasty. **A** A longitudinal peritoneal incision made in the elongated, narrow mesentery. **B** The incision is then closed transversely, broadening the mesenteric base and shortening the height of the sigmoid loop.

significant; 77% had episodes of infection which led to tube removal in 44%.[39] The only prospective randomized trial in the literature comparing mesosigmoidopexy with resection and primary anastomosis in sigmoid volvulus without gangrene indicates that sigmoid resection bears the lowest risk of recurrence of sigmoid volvulus.[44]

It is important to understand that the search for alternatives to resection for sigmoid volvulus was based on *historical* rates of morbidity and mortality. Considering that modern surgical and anesthetic techniques have significantly reduced surgical complication rates, it seems clear that resection after decompression provides near-zero risk of recurrence with acceptable morbidity and mortality rates.[17,20,30]

If endoscopic decompression is unsuccessful or visualizes gangrenous mucosa, the situation is a surgical emergency and efforts at detorsion should be halted and preparation of the patient for surgery should be expeditiously done. Exploration should be done via a midline laparotomy incision, or potentially by laparoscopy if the patient is hemodynamically stable. If the bowel appears viable or possibly viable, the twist should be reduced. While some surgeons advocate sigmoidopexy for a viable sigmoid, the recurrence rate is high and so most surgeons favor sigmoid resection. The decision for anastomosis versus Hartmann's procedure should be based on standard surgical criteria: the presence of good blood supply, absence of (or minimal) peritoneal soilage, reasonable nutritional status, and absence of shock would suggest that anastomosis is reasonable. When considering stoma formation, it should be remembered that many of the stomas formed in this setting will be permanent, as infirm patients with other medical comorbidities will rarely become candidates for stoma closure. The usual maneuvers used for selecting stoma location are often difficult to employ preoperatively, given the abdominal contour and urgency of the patient's situation. The bowel is often quite dilated, and a large opening in the abdominal wall may be required for a colostomy. This leads to a higher incidence of parastomal hernia.

Both morbidity and mortality are higher for emergent operations for sigmoid volvulus, compared to those for the elective or semi-elective setting. Deaths and complications increase further if gangrenous colon is encountered. A study of volvulus in urban Australia showed a mortality of 36% in patients operated emergently for sigmoid volvulus.[4] Grossman's study of sigmoid volvulus in VA medical centers showed 24% mortality for emergency operations, compared to 6% for elective operations after decompression. Mortality was positively correlated with emergency surgery ($p < 0.01$) and necrotic colon ($p < 0.05$).[20] In a report on 33 sigmoid volvulus patients from Greece, mortality after emergency operations was 40% and that after elective operations was 5.9%. However, if the sigmoid colon is found to be viable, sigmoidectomy and primary anastomosis have a good outcome and avoid the morbidity of a second surgery for stoma closure.[30] A study from Guinea showed that emergency sigmoid resection with primary anastomosis was well tolerated in the absence of gangrenous sigmoid, with mortality of 12.5%; however, in the presence of gangrene, the mortality rose to 33.3%.[44] In a 2009 study from Ireland, six of ten patients undergoing emergency surgery for sigmoid volvulus without decompression had sigmoidectomy with primary anastomosis. There were no deaths, wound infections, or anastomotic leaks in this group.[31] Oren's study of sigmoid volvulus includes patients treated over a 38-year span. In this large group, 36 patients with gangrenous sigmoid colon had sigmoidectomy with primary anastomosis. While mortality in this group was 21.6%, Oren notes that all deaths occurred in the earliest years of the series.[18] Kuzu et al. reported 106 patients from Ankara, Turkey, who underwent emergency sigmoidectomy for volvulus without preoperative decompression; 57 patients had a primary anastomosis performed. Mortality was 6.6%, but rose to 11% if the bowel was gangrenous. A higher rate of wound infection and intra-abdominal abscess was also seen in the group with gangrenous bowel.[45] These studies support that good outcomes can be achieved with primary anastomosis at the time of emergent sigmoidectomy for sigmoid volvulus with careful patient selection.

Caring for the pregnant patient with sigmoid volvulus presents the challenge of managing two patients at once. An argument can be made for endoscopic detorsion in the first trimester if mucosa is viable, with an attempt to delay definitive management until the second trimester, when the risk to the fetus is less. In the case of sigmoid volvulus in the third trimester, nonoperative therapy should be pursued when possible until fetal maturity; then delivery and definitive volvulus management can be undertaken.[12] Ischemic sigmoid colon is managed with Hartmann's procedure.

Ileosigmoid Knotting

Epidemiology/Pathogenesis

Ileosigmoid knotting, also called "compound volvulus" or "double volvulus," although these are now considered misnomers, is unusual in the West. It is more common in certain areas of Africa, Asia, and the Middle East, although still quite rare. Patients with ileosigmoid knotting are younger than those with sigmoid volvulus, and the condition is more common in males.[46–48] In this condition, loops of ileum and sigmoid colon wrap about one another, causing a double obstruction of both the ileum and the sigmoid. Four patterns of ileosigmoid knot formation have been described, which differentiate between an active or passive segment of bowel and the direction of rotation (Figure 23-5A–D).[49,50] The ileum is most commonly the active component and wraps around the sigmoid.[49,51] Less commonly, the sigmoid wraps around the ileum. In either instance, the direction of the wrap may be clockwise or counterclockwise. Endoscopic reduction attempts are always unsuccessful, and the diagnosis of ileosigmoid knot should be considered when endoscopic reduction has failed. Theories of pathogenesis center on the typical diet of the regions where ileosigmoid knotting is most common: a large volume diet high in bulk and carbohydrates, associated with large volumes of concomitant liquid ingestion. It is postulated that as the stomach contents empty into the jejunum, the weight pulls the bowel into the left paracolic gutter. Empty distal loops of small bowel are then displaced around a narrow based sigmoid. Continued peristalsis leads to further rotation of the loop, internal herniation, and knot formation. Another theory suggests that relatively rapid ingestion of large amounts of food and liquid, as in regions where a single daily meal is the norm, allows the sigmoid colon to volvulize due to the abruptly increased weight of luminal contents.[49,52]

Diagnosis

Presentation is acute, with distention, nausea and vomiting, and severe abdominal pain which may be colicky in nature. In contrast to other forms of volvulus, there is an absence of previous similar episodes. Patients often present in shock with signs of an intra-abdominal catastrophe, including acidosis, hypotension, and tachycardia. Preoperative diagnosis is difficult due to the rarity and complexity of the problem. Characteristic radiographic features have been described, consisting of a double obstruction with a distended obstructed sigmoid loop pulled toward the right and a proximal small bowel obstruction on the left.[53] In practice, X-rays are often atypical and difficult to interpret. Only one of 15 patients in an Ethiopian review had radiologic findings
FIGURE 23-5. Ileosigmoid knotting: these schematic illustrations indicate the four terms of knotting. The active ileum may rotate around the sigmoid colon in either a clockwise **A** or a counterclockwise **B** direction. Much more frequently, the sigmoid colon may act as the active loop and rotate in either a clockwise **C** or a counterclockwise **D** direction around the ileum.

of combined small and large bowel obstruction,[47] and only three of seven in an Indian series.[54] A diagnostic triad has been proposed, consisting of a clinical small bowel obstruction, a radiographic colon obstruction, and the inability to pass a sigmoidoscope to decompress a suspected sigmoid volvulus.[48] In practice, the diagnosis is made correctly in fewer than 20% of patients, and over 70% have gangrenous bowel at surgery.[46–51]

Treatment and Outcome

Patients who present in this manner should be urgently resuscitated and taken for exploration. Treatment recommendations range from simple double detorsion to double resection. Advocates of enbloc resection without detorsion reason that attempts to untie the knot are time consuming and difficult, may contribute to systemic release of endotoxin with worsening of shock, and increase the risk of bowel perforation and peritoneal contamination. However, others have recommended detorsion if one or both segments are felt to be viable. Deflation of the involved segments has been shown to assist in detorsion and diminish the risk of perforation.[47,48,55] The data on recurrence after detorsion alone are conflicting. Some authors advocate sigmoid resection in all cases, even if the sigmoid is viable, to eliminate the risk of recurrent knot or simple sigmoid volvulus in future.[46,48,56]

Primary small bowel or ileocolic anastomosis is performed in nearly all patients with gangrenous ileum. Historically, Hartmann's procedure has been the most commonly performed operation when nonviable sigmoid colon is found,[47,51,55] although more surgeons are now performing primary colonic anastomoses in this setting.[48,50] There appears to be a risk of thrombosis of the superior rectal artery or inferior mesenteric artery, prompting some authors to recommend resection of the sigmoid well beyond the areas of twisting or gangrene to ensure adequate vascular supply.[46,48,49,54]

Overall surgical mortality ranges from 30 to 50%.[49,50,55] However, when the colon is not gangrenous, the mortality is lower, approximately 10–30%. Several older studies have showed an inverse relationship between duration of symptoms and mortality,[49,52] although a smaller, more recent study from India did not bear that out.[48] In general, outcome is poorer when gangrenous colon is present. Finally, if extensive gangrenous small bowel is found, leaving less than 60 cm of viable small bowel, the mortality rate was 100%.[49]

Cecal Volvulus

Epidemiology/Pathogenesis

Cecal volvulus is the second most common site of colonic volvulus, and technically consists of volvulus of the terminal ileum, cecum, and proximal right colon. Two variants exist: a true axial rotation of the terminal ileum, cecum, and proximal right colon around its mesentery (Figure 23-6A),
FIGURE 23-6. **A** Schematic illustration of a cecal volvulus; **B** Schematic illustration of a cecal bascule.

and cecal bascule, which is an anteriosuperior folding of a mobile cecum over the proximal right colon without axial rotation (Figure 23-6B). The rotation of a cecal volvulus is most commonly clockwise around the mesenteric axis.

Cecal bascule accounts for approximately 10% of cases of cecal volvulus[2] and is less likely to present with vascular compromise. Individuals with cecal volvulus are several decades younger than patients with sigmoid volvulus, with a female:male ratio of 1.4:1.[57] While the gender ratio seems unchanged, more recent series have described a patient population that is increasing in age. The mean age in a 1984 series was 46.7 years,[58] whereas a 1990 series from Israel included patients of a mean age of 53 years.[57] While the seven patients in a 2000 Taiwanese report had a mean age of 63.4 + 17.3 years,[59] more recently a series from France reported a mean age of 64 years in their 45 patients[60] and a Spanish series of 18 cases reported a mean age of 63.3 years.[61]

Mobility of the cecum is required, but that feature alone is not sufficient to cause a clinically apparent volvulus: a cadaver study revealed an 11% incidence of freely mobile right colons and a 26% incidence of cecal mobility sufficient to allow anterior folding.[2] Previous abdominal surgery is felt to be a major risk factor for cecal volvulus: in published reports of cecal volvulus, 30–70% of patients had a history of abdominal surgery. Other risk factors include chronic constipation, obstructing colon lesions, and malrotation. Upward displacement of the cecum by an enlarged uterus or other pelvic mass may also promote cecal volvulus. Several series have reported that 10% of patients with cecal volvulus are pregnant at presentation.

FIGURE 23-7. Plain abdominal X-ray of a cecal volvulus with "coffee bean" deformity evident in the *left upper quadrant*.

Diagnosis

As with sigmoid volvulus, presentation may be that of an acute obstruction or one of an intermittent, recurrent pattern. Abdominal distention is generally less marked than that with volvulus of more distal colonic segments. The acute presentation is of a closed loop obstruction with vascular compromise. Abdominal pain, distention, obstipation, nausea, and vomiting are common signs. If intervention is not timely, ischemia may progress to gangrene. With the intermittent pattern, duration of symptoms may be relatively brief, and diagnosis may, therefore, be difficult to gain.

Diagnosis is most often made on the basis of clinical presentation and plain films. Plain abdominal radiographs may identify the classic "coffee bean" deformity directed toward the left upper quadrant (Figure 23-7). While nearly half of the plain films suggest the diagnosis,[58,62] fewer than 20% are clearly diagnostic.[57,60] Contrast enema increases the preoperative diagnostic rate, showing a "bird's beak" type cutoff in the right colon (Figure 23-8), and may be employed in stable patients when the diagnosis is in question. CT scan has become much more common in the setting of nonspecific abdominal pain and distention (Figure 23-9). CT scan findings in cecal volvulus include the location of the cecum within the abdomen, the "bird's beak" cutoff, and the "whirl sign" of mesenteric torsion.[63] However, about half of the patients with cecal volvulus have the diagnosis made in the operating room.

FIGURE 23-8. Barium enema study of a cecal volvulus revealing a bird's beak deformity.

FIGURE 23-9. Typical CT findings in cecal volvulus include bird's beak cutoff and location of the cecum on the left side.

Diagnosis of cecal volvulus in the pregnant patient is most often made in the operating room after clinical deterioration. Radiologic studies normally performed in the evaluation of most patients with abdominal pain are often deferred. A case can be made for judicious use of radiologic evaluation of the pregnant abdomen when trying to diagnose the cause of abdominal pain and vomiting in the pregnant patient.[64,65] Diagnostic laparoscopy is also a viable alternative when the pregnant patient has an acute abdomen.[64]

Treatment and Outcome

While less efficacious than endoscopic detorsion of more distal colonic volvulus, colonoscopic reduction of cecal volvulus has been reported with some success. Reasons cited for limited use of this approach include difficulty in traversing the unprepared bowel to reach the right colon, difficulty in performing the detorsion, lack of clear diagnosis, and a higher rate of ischemia in cecal volvulus.[2,42,66] Some authors feel that this approach simply delays definitive surgical management and places the patient at higher risk for perforation. Proponents feel that when successfully employed, there may be a relatively low rate of recurrence, and the subsequent need for surgery may be debatable.[67]

Cecal gangrene mandates resection, and in most cases primary anastomosis can be safely done. In the circumstance of a malnourished and/or anemic patient or in the presence of other factors that may adversely affect healing, ileostomy with or without mucus fistula may be appropriate. Resection carries no risk of recurrence, and postoperative morbidity is similar to the morbidity following fixation techniques.[60] In a series of 45 patients from France, 51% had gangrenous
FIGURE 23-10. Cecopexy and cecostomy for cecal volvulus.

colon. All 45 patients underwent right colectomy and 43 of these had a primary anastomosis. Mortality was 6.6% and morbidity was 20%, including two anastomotic leaks.[60]

If the cecum is viable, detorsion with or without fixation may be considered. Detorsion alone carries a recurrence rate as high as 25%.[58] Fixation is generally performed by cecopexy and/or cecostomy tube placement (Figure 23-10). Cecopexy is done by raising a flap of peritoneum along the length of the right colon and suturing it to the serosa of the anterior right colon, effectively placing the right colon in a partially retroperitoneal position, eliminating the abnormal mobility. Tube cecostomy both anchors the cecum and provides a vent for the distended colon. Proponents of cecostomy find it easy to perform, and note that spontaneous closure of the cecocutaneous fistula is common after tube removal. However, the rate of recurrent cecal volvulus after cecostomy is significant, and management of the tube and its complications can be troublesome. Rabinovici's review of cecal volvulus cited a 12–14% rate of volvulus recurrence after operative detorsion, cecopexy, or cecostomy.[57] He also noted that patients undergoing cecostomy had a mortality rate of 32% – triple the rate of mortality after cecopexy (10%) or detorsion alone (13%). Ostergaard found a higher mortality after detorsion alone (14.2%), and also after cecostomy alone (66.6%) compared

to that after cecal resection (7.2%). There were no deaths after cecopexy alone. He concluded that resection gave the best long-term results.[68]

Transverse Colon and Splenic Flexure Volvulus

Epidemiology/Pathogenesis

Volvulus of these colonic segments is exceptionally rare. Transverse colon volvulus is estimated to account for 1–4% of all colonic volvulus, and splenic flexure volvulus for approximately 1–2%. Patients with these disorders are younger than patients with cecal or sigmoid volvulus, with a two- to three-fold female predominance.[2,66,69] Common historical points in patients with transverse colon volvulus include chronic constipation, previous abdominal surgery, institutionalization, high fiber diet, and recurrent distal obstruction. In patients with splenic flexure volvulus, previous abdominal surgery is common, and chronic constipation is also felt to increase risk, possibly by leading to redundancy and elongation of the colon. Reports in the literature speculate on associations with malrotation, Hirschsprung's disease, and Chilaiditi syndrome. Demetrius Chilaiditi first described hepato-diaphragmatic interposition of bowel in 1910 as an incidental radiographic finding. This radiographic entity is known as Chilaiditi's sign. When this interposed bowel is symptomatic, it is termed Chilaiditi syndrome. Chilaiditi syndrome is more prevalent in men, the elderly,[70] and perhaps the obese.[71] A retrospective study of 850 abdominal CT scans found hepato-diaphragmatic interposition of bowel in ten patients (0.12%). Eight of the ten patients were men; five had a BMI greater than 28.5, and three had had a BMI between 25 and 27.5 sometime in their lives. There are a number of case reports of Chilaiditi syndrome with transverse colon and splenic flexure volvulus in the surgical literature, cautioning a high index of suspicion for volvulus when this radiographic finding is noted in symptomatic patients.[72]

Clinical presentation of volvulus of the transverse colon or splenic flexure is that of a large bowel obstruction. As with sigmoid and cecal volvulus, presentation may be acute and fulminating, or may be a subacute recurring process, as is seen in up to 50% of patients. In the acute form, there is less distention than is seen in the subacute form, pain is more marked, and vomiting is usually present. Clinical deterioration is rapid in this setting. The subacute form usually has a gradual onset with milder pain, but significantly more abdominal distention, perhaps due to colon elongation from repeated episodes; vomiting is usually absent.

Diagnosis

Plain films are rarely diagnostic and may reveal a distended proximal colon with decompressed distal colon, and two air-fluid levels, representing the right colon or right transverse colon, and the left transverse colon.[73] More often, the films may be misinterpreted as a sigmoid volvulus due to the variable position of the transverse colon. Patients may then undergo colonoscopy with no clear transition point seen in the sigmoid colon. In this situation, further attempts to identify a transition point should be terminated, and a contrast study should be obtained. Contrast enema will show a bird's beak deformity at the site of the twist. However, definitive management of an acutely ill patient should not be unduly delayed to obtain these studies.

Treatment and Outcome

Successful endoscopic decompression has been reported with both transverse colon and splenic flexure volvulus. However, as with cecal volvulus, there are the same concerns of difficulty in traversing unprepared bowel, difficulty in performing detorsion, and the possibility that the diagnosis may not be clarified. There is a risk of excessive insufflation causing cecal distention and vascular compromise. Also, based on the outcomes of endoscopic detorsion elsewhere in the colon, it may be assumed that a high risk of post-decompression recurrence remains.

Operative procedures include resection, and detorsion with or without colopexy. Resection is mandatory if gangrenous bowel is found. Most authors recommend either transverse colectomy or extended right colectomy as definitive treatment for transverse colon volvulus, as this resection eliminates virtually all risk of recurrence. Mortality has been reported as high as 33% in the presence of gangrenous colon, but in most reports, it is much lower.[74,75] If the colon is viable, mortality is approximately 6%,[66] similar to that seen following resection of other volvulus of other colonic segments. The affected colon in splenic flexure volvulus is more likely to be redundant and dilated than in transverse colon volvulus. For this reason, patients with splenic flexure volvulus may be best served with an extended resection and ileosigmoid or ileorectal anastomosis.[76] Stomas should be reserved for cases in which perforation and peritoneal contamination are encountered, or for other high-risk cases.

Lower Gastrointestinal Hemorrhage

Craig A. Reickert and Melissa Times

Lower gastrointestinal bleeding (LGIB) is defined as measurable bleeding from a source distal to the ligament of Treitz. LGIB is a broad term used to encompass the spectrum of symptoms ranging from minimal bleeding noticed on bathroom tissues associated with hemorrhoids to massive bleeding encountered with diverticular hemorrhage. Etiologies range from the rare small-bowel tumors to the frequently identified diverticular sources. To complicate matters further, the bleeding may be intermittent, leading to a challenging diagnostic and management dilemma.

Epidemiology

A population-based study examining the inpatient hospital records of 2,115 patients from 1990–1993 in a California health maintenance organization found the annual incidence rate of LGIB was 22.5 per 100,000 (0.02% of hospitalizations).[1] The three most common etiologies were diverticulosis (41.6%), colorectal malignancy (9.1%), and ischemic colitis (8.7%). The largest study and only nationwide analysis of LGIB is an examination of the Department of Veteran Affairs discharge data from 1988 to 1991 that found 17,941 patients or 0.7% of all discharges were for LGIB. The three most common etiologies were diverticulosis (60%), inflammatory bowel disease (13%), and anorectal sources (11%).[2]

Increasing age is cited frequently as a risk factor for LGIB with many studies reporting mean age greater than 60.[3–7] The common etiologies of LGIB such as diverticular disease are seen more frequently with advancing age.[8] Male gender is an inconsistent demographic factor with studies showing both a predominance of males with LGIB[1,9,10] and no statistical difference between males and females with LGIB.[7,11,12] Race has not been noted to be a predisposing factor for LGIB.[9,11,13] However, in the population-based study by Longstreth, The Acute Lower Gastrointestinal Bleeding Retrospective Analysis (ALGEBRA), and the American College of Gastroenterology Bleeding Registry, demographic information on race was not reported.[1,5,14]

Etiology

Diverticular Disease

The prevalence of diverticulosis at age 40 is less than 10% and increases to 50–66% at age 80.[15] LGIB from diverticulosis is noted in up to 17% of patients based on a review of over 6,000 patients with diverticular hemorrhage.[16] Diverticular bleeding as a source of LGIB occurs in 20–60% of cases.[2,8] In 75% of patients, bleeding will cease spontaneously.[17] Rebleeding rates after the first episode are 25%[18] and increase to 50% after two episodes.[19]

Diverticular bleeding relates to the development of pseudodiverticula in areas of weakness in the colonic wall where the vasa recta, the intramural branches of the marginal artery, course through the muscular layers to the mucosa and submucosa. At the site of the diverticulum, the vasa recta travel in the serosa with no significant tissue between the mucosa, the vasa recta, and the lumen of the bowel. Asymmetric and eccentric rupture of the vasa recta leads to intraluminal, and not peritoneal, hemorrhage.[20] Anecdotally, bleeding diverticula are attributed to mostly right-sided disease despite the greater propensity to have left-sided diverticula. However, it is difficult to find overwhelming support for this assumption. McGuire's[17] article from 1994 found nine patients with bleeding diverticula proximal and nine patients with bleeding distal to the splenic flexure. Longstreth's population-based study noted four patients with proximal bleeding and eight patients with left-sided colonic bleeding.[1] Information regarding location of diverticular bleeding is frequently not included in studies examining diverticular and lower gastrointestinal bleeding.[9,12,21,22]

Anorectal

Anorectal sources commonly include hemorrhoids, anal fissures, and rectal ulcers. They are the etiology of LGIB in 11–17% of patients.[2,6,7] Hemorrhoids were noted in 21% of patients with LGIB in an urban emergency medical center.[9]

Bleeding from hemorrhoids or fissures is uncommonly associated with hemodynamic instability or large volumes of blood loss. Rectal ulcers can cause severe hemorrhage associated with hemodynamic instability, with almost half of them being identified by stigmata of recent hemorrhage,[23] although the etiology of the ulcers is multiple and not frequently defined in the literature in bleeding patients. Careful historical elucidation of radiation treatment, sexually transmitted diseases (STDs), anorectal trauma, nonsteroidal anti-inflammatory drugs (NSAIDs) exposure, liver disease associated with rectal varices, and other uncommon etiologies must be included in evaluations.

Hemorrhoids are sinusoids and do not have muscular walls.[24] They are present at birth, and over time, the anal support weakens, causing internal hemorrhoids to move distally in the anal canal. The skin and mucosa are stretched causing growth of new fibrous and sinusoidal tissue. Eventually, the internal hemorrhoids slip past the anal verge and are subjected to trauma, which can lead to disruption of the sinusoids and arterial bleeding.[25,26] Hemorrhoidal bleeding is generally limited to bleeding with bowel movements, although patients may describe spraying or splattering of blood in the bowel (see Chap. 11).

Angiodysplasia

Studies from the late 1980s demonstrated rates of documented angiodysplasia varying from 15 to 27% of patients with LGIB.[27–30] However, more recent and larger studies have reported lower rates of angiodysplasia as an etiology of LGIB. A study of 1,112 patients in an urban setting reviewed the etiology of LGIB during two periods: 1988–1997 and 1998–2006. The rate of angiodysplasia decreased from 4.76% in the earlier period to 2.3% in the most recent period.[9] In the Veteran Affairs study, angiodysplasia was the source of LGIB in only 3% of patients.[2]

Angiodysplasias are vascular ectasias that can occur in the small- and large-bowel mucosa and submucosa. Small-bowel angiodysplasia is a common source of obscure gastrointestinal bleeding with up to a third of patients having this diagnosis.[31–33] Colonic angiodysplasia has a prevalence of 1% in the general population[34] with a tendency for right-sided lesions.[35–37] Angiodysplasia had been thought to be associated with aortic valvular disease and renal failure, but these associations have not been found in more statistically rigorous studies.[38,39]

Malignancy

Colorectal cancers are a source of LGIB in 9.1–13.6% of patients[1,2,9] and are associated with ulcerated tumors. As a symptom, rectal bleeding is seen in 6.5–17% of patients diagnosed with rectal cancer.[40,41] Colorectal cancer and adenomas greater than 1.0 cm were found in 13.3 and 20.5% of 405 patients who underwent a colonoscopy for bleeding,[42] although benign polyps are not commonly associated with bleeding and are simply identified during workup.

Ischemic Colitis

Ischemic colitis as an etiology of LGIB occurs in 9–18% of patients.[1,43,44] The annual incidence of acute large-bowel ischemia in a California-based HMO was 15.6/100,000 patient years with increasing incidence associated with age. Patients presented with abdominal pain (87%) and bloody bowel movements (84%) without diffuse peritonitis. There are multiple etiologies of ischemic colitis that affect both young and old patients: shock, autoimmune diseases, coagulopathies, long-distance running (with associated dehydration), mesenteric venous thrombosis, acute arterial thrombosis, emboli, small vessel disease, and cocaine use.[45,46] Despite the multitude of etiologies, the typical patient with colonic ischemia is either an elderly patient or a patient with multiple comorbidities such as cardiovascular disease, hypertension, and renal failure.[45,47,48] Further support for the typical patient description was noted in Longstreth's population-based study of gastrointestinal ischemia where the average age was 69 and patients who were admitted for another disease process had an odds ratio of 7.48 (95% CI 2.19–25.54) for developing severe lower gastrointestinal ischemia after admission.[1] Other hospitalized patients with increased risk for ischemic colitis are patients undergoing open and endovascular abdominal aortic aneurysm repair for nonruptured aneurysms. These patients have an incidence of ischemic colitis of 2–3% in open procedures and 1.3–2.9% in endovascular interventions.[49–54]

In the literature, the described location of ischemic colitis is variable: right-sided, 8–14%, splenic flexure 23–28%, and left-sided, 50–87%.[55–57] Knowledge of the arterial blood supply and areas of collateral circulation is necessary to understand the potential areas for insult and the high likelihood of anatomic variations. In a cadaver study by Nelson et al.[58] only 22, 24, and 16% of dissected specimens had the typical branching of the celiac, superior mesenteric, and inferior mesenteric arteries respectively. In addition, colonic blood supply is dependent on interconnection of the perfusing vessels by the marginal artery of Drummond, which connects the superior and inferior mesenteric arteries through a series of arcades. At the splenic flexure, there is an area without vasa recta in 11% of individuals, which makes the area more susceptible to ischemic insult. The arc of Riolan is an artery connecting the left branch of the middle colic artery to the inferior mesenteric artery. It is present in only 7% of individuals but can allow acceptable perfusion in the absence of other collaterals. The highly variable arterial anatomy of the colon makes it susceptible to ischemia as a complication of surgical and angiographic procedures used to treat LGIB, which can compound the management considerations.

Acute mesenteric ischemia (small-bowel ischemia) can be either occlusive or nonocclusive. Occlusive mesenteric

ischemia due to either embolization or thrombosis constitutes 50 and 25% of the cases of acute ischemia, whereas nonocclusive mesenteric ischemia and venous thrombosis account for 20 and 5% of the cases. Differentiating between occlusive and nonocclusive disease is imperative, since occlusive disease is managed emergently with surgery.[59] Massive bleeding from small-bowel ischemia is not likely to resolve spontaneously and may be a manifestation of transmural ischemia of the small bowel.

Other Colonic Etiologies

Postpolypectomy bleeding after colonoscopy ranges from 0.08 to 0.87% with mortality in a large Canadian study of over 97,000 colonoscopies estimated at 1/14,000.[60,61] Postpolypectomy bleeding accounted for 4.1% of cases in Longstreth's population-based study.[1] In the large VA and urban emergency medical center studies, postpolypectomy bleeding was not reported as a source of LGIB.[2,9]

Bleeding from a colorectal anastomosis requiring endoscopic therapy or surgery is rare with a rate of 0.5–1.8%.[62–64] If bleeding persists after resuscitation, transfusion, and correction of any coagulopathy, endoscopy should be used to identify and stop the bleeding. Therapeutic interventions include cautery, endoclips, and epinephrine injection. If these measures fail, surgical management should be undertaken.

Gastrointestinal bleeding is a common presenting symptom in ulcerative colitis and Crohn's disease. However, acute hemorrhage with hemodynamic compromise is atypical. The studies evaluating gastrointestinal hemorrhage in inflammatory bowel disease have small numbers of patients with the largest study including 38 patients reflecting this unusual event. Acute hemorrhage occurs in 0.9–6% of patients with Crohn's disease[65–67] and 1.4–4.2% for patients with ulcerative colitis.[68–70] As a percentage of patients presenting with LGIB, Crohn's disease accounts for 2.3–13% of cases with increasing percentages associated with higher volume studies.[1,2,9,69] Bleeding occurred in both young and older patients and was not related to the duration of disease.[70,71] Acute hemorrhage was the initial presentation of Crohn's disease in 16–23.5% of patients and is generally associated with areas of active inflammation.[72,73] Malignant lesions must also be considered in patients with long-standing history of inflammatory bowel disease (IBD) and LGIB.

Patients with human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS) have additional etiologies for LGIB. Two studies with 1,003 HIV+ patients found the most common etiologies to be HIV-associated diseases: cytomegalovirus (CMV) colitis, idiopathic colonic ulcers, lymphoma, and idiopathic colitis.[74,75] Recurrent bleeding occurred in 17.6–22% of patients with mortality rates as high as 54.5%. Overall, the 30-day mortality rate was three times higher (14.4 versus 5%) for patients with HIV and LGIB than for the routine population.

NSAIDs commonly cause complications in the upper gastrointestinal tract. Documented adverse effects of NSAIDs on the lower gastrointestinal tract include increased gut permeability (44–70%), gut inflammation (60–70%), malabsorption (40–70%), and blood loss and anemia (30%).[76] A systematic review demonstrated the blood loss from NSAIDs and aspirin 325 mg was 1–2 ml/day, which was increased from the baseline level of 0.5 ml/day;[77] 5% of patients taking NSAIDs lost at least 5 ml/day. The MEDAL study was a randomized comparison of a cyclooxygenase (COX)-2 selective NSAID and a traditional NSAID with the primary gastrointestinal endpoint being lower gastrointestinal clinical events.[78] Over 34,000 patients with osteoarthritis and rheumatoid arthritis were followed for 18 months. Lower gastrointestinal bleeding was noted in 0.27% of patients. A quarter of these patients had lesions presumed to be caused by NSAIDs such as ulcers, colitis, and enteritis. Diverticula were the most common source of bleeding. There was no placebo group in this large study, so the ability to estimate the increase in adverse events with NSAID use versus placebo was not available. A systematic review of 47 studies examining the use of NSAIDs and lower gastrointestinal (LGI) events found an increase in LGI events with NSAID use.[79] However, the studies included in the review were varied; some were not originally designed to address the proposed hypothesis of the systematic review, and the studies of LGIB and NSAID use were either case-controlled or were unable to demonstrate a relationship due to the small sample size.[79] NSAID use is common, and physicians should be cognizant of the potential harmful effects of their use on the lower gastrointestinal tract.

Rectal injury due to pelvic radiation usually presents as bleeding and occurs in 95% of patients within 1 year from treatment. In most patients, bleeding will resolve, but in the minority of patients who go on to develop chronic radiation proctitis (5%), management is problematic and repetitive. Thermal coagulation with argon or Nd:Yag laser have been used with positive results.[80,81] Topical formalin in 3, 4, and 10% also has been successful for cessation of bleeding.[82,83] Three or four percent formalin is instilled in 50-ml aliquots for a total of 500 ml. Due to the associated rectal discomfort, this method is usually employed with some type of analgesia. After each application, the rectum is irrigated with normal saline. Another option ("Dab" method) is to use 16 Fr cotton-tipped applicator that is soaked in 10% formalin. This is applied to the rectal mucosa through an anoscope or a proctoscope. The Dab method can be performed in the office without analgesia.

Success rates in both procedures range between 75 and 90%. Surgical management is used as a last resort with high morbidity (65–80%) and mortality rates (6.7–13%).[84–86] Surgical options include diverting stoma and limited resections.[87]

Obscure Gastrointestinal Bleeding

Obscure gastrointestinal bleeding (OGIB) is the bleeding not identified during colonoscopy or esophagogastroduodenoscopy (EGD). OGIB accounts for 1.19–9% of LGIB with lower rates noted in larger studies.[1,9,31,88] Angiodysplasia, small-bowel tumors, and ulcers/erosions are the three most common etiologies of OGIB.[31,88,89] When diagnosing the source, patients with OGIB undergo more procedures than patients with upper gastrointestinal and colonic bleeding, 5.3 versus 1.5 and 2.1, respectively (Table 24-1).[89]

The diagnosis of OGIB was limited to upper and lower endoscopy and conventional radiography until 2001, when capsule endoscopy and double balloon enteroscopy (DBE) were introduced. Prior to these two technical advances, intraoperative enteroscopy was used to identify bleeding in the small bowel. Indications for capsule endoscopy include OGIB, unexplained iron-deficiency anemia, and suspected Crohn's disease, small-bowel tumors, or refractory malabsorptive syndromes.[90] Contraindications are related to the structure and transmission signal of the capsule as well as the need for normal peristalsis for capsule efficacy. Therefore, patients with swallowing disorders, pacemakers or implanted devices, obstruction, fistula, or stricture are not candidates for capsule endoscopy. Entrapment of the capsule occurs in 3.3% of procedures and is associated with Crohn's disease, radiation, and NSAID-induced strictures.[91,92] Indications for DBE include a positive capsule endoscopy and a high suspicion of a small-bowel source in the setting of a normal capsule study.[93–96] DBE has the ability to perform therapies such as sclerotherapy, polypectomy, dilations, and clippings. DBE can be performed from anterograde (oral) or retrograde (rectal) approach. Patients undergoing the anterograde approach require a 6–8 h fast prior to the procedure, while those having a retrograde exam need a bowel preparation.

The diagnostic yield of capsule endoscopy and DBE is 38–83% and 58%, respectively.[97–99] Two meta-analyses comparing capsule endoscopy and DBE found similar diagnostic yields.[100,101] Recent articles have supported the position that the techniques are complementary and should be used together to identify small-bowel sources of bleeding.[102,103]

TABLE 24-1. Diagnosis by etiology for patients admitted to an urban emergency medical center, 1998–2006[8]

Etiology	N (%)
Diverticulosis	227 (37.34)
Hemorrhoids	128 (21.05)
Neoplasia	72 (11.84)
Colitis	65 (10.69)
Inflammatory bowel disease	33 (5.43)
Vascular ectasias	14 (2.30)
Other colonic disease	40 (6.58)
Small-intestine disease	8 (1.32)
Unknown	21 (3.45)
Total	608 (100)

Positive capsule endoscopy can direct the DBE approach (oral or rectal) depending if the lesion is in the proximal or distal small bowel based on capsule transit time.[104] Currently, capsule endoscopy should be the first study ordered for OGIB. DBE is relatively new, not widely available, and associated with higher complication rates than diagnostic colonoscopy.[105–107]

Clinical Presentation, Physical Exam, and Management

LGIB has many presentations reflecting the diverse pathology found in the upper and lower gastrointestinal tract. The variety of presentations creates a diagnostic and management quandary. Adding to the quandary is the variability noted in studies regarding the presentation, workup, and management. The lack of randomized trials regarding diagnosis and management compounds the variability encountered with the presentation of LGIB.

Evaluation of a patient's hemodynamic stability upon presentation is imperative. Patients presenting with syncope, chest pain, pallor, shortness of breath, tachycardia, and changes in blood pressure with positioning are hemodynamically unstable. Tachycardia and hypotension represent acute hemorrhagic shock associated with a blood loss of more than 500 ml, or 15% of the total blood volume.[108] These patients require two large bore IVs or central venous access for resuscitation if peripheral access cannot be obtained. Continuous monitoring of vitals and urine output with a urinary bladder catheter are standard. Nasogastric tube (NG) placement has been recommended routinely to rule out an upper gastrointestinal source of bleeding. In a retrospective cohort study, 220 patients without hematemesis had a NG placed.[109] Only 2% of patients had bright red blood, greater than 450 ml of blood, or difficulty clearing the gastric lavage. Eight patients had an aspirate of bile, which was considered negative. However, 5 of these eight patients were found to have an upper gastrointestinal source of bleeding. The largest study ($n = 1,190$) evaluating NG tube aspirate found that 60% of patients with a negative aspirate had a lower gastrointestinal source.[110] However, 39% of patients with a negative aspirate were classified as having an unknown source of bleeding. Despite the results of these two studies, NG placement is a fast and inexpensive diagnostic test that if positive (clots, coffee ground emesis, blood), can quickly direct the workup toward identification of an upper gastrointestinal source. Upper gastrointestinal sources are seen in 11% of patients who present with a LGIB.[111] The NG tube can be left in and used for the bowel preparation if an urgent colonoscopy is needed.

After intravenous access has been obtained, resuscitation should start immediately. However, there are no systematic reviews, and only one randomized controlled trial evaluating the role of transfusions in gastrointestinal bleeding is available.[112] A Cochrane systematic review evaluating

the resuscitation of trauma, burn, and surgical patients with either crystalloid or colloids found no survival benefit using colloids instead of crystalloids.[113] Despite the lack of large, randomized trials evaluating transfusion requirements in patients with LGIB, there is mounting evidence that limiting or eliminating transfusions lead to improved outcomes such as decreased mortality and morbidity.[114–118] The trauma literature has demonstrated that blood transfusions are an independent predictor of infection, multisystem organ failure, increased intensive-care length of stay, and death.[119–121] Patients who managed nonoperatively for blunt splenic and hepatic injuries have increased mortality rates if they are transfused.[122] A recent, risk-adjusted prospective study demonstrated a dose-dependent relationship between blood products transfused (blood, fresh frozen plasma, platelets) and increased mortality and infection.[123] Based on studies in the medical and surgical literature, transfusion practices in LGIB should be evaluated, and the decision to transfuse a patient should occur after the risks and benefits are analyzed.

The patient's history should be taken simultaneously with the placement of intravenous access and monitors if the patient is hemodynamically unstable. Important aspects of the history that should be elucidated are given as follows: frequency, volume, color and duration of bloody stools, comorbid conditions such as liver and cardiovascular disease, medication use such as clopidogrel, warfarin, and NSAIDs, and date of last colonoscopy/EGD.

Visual inspection of the perineum for prolapsed or thrombosed hemorrhoids, anal fissures, or masses are the first part of the anorectal exam. After visual inspection, digital rectal exam and anoscopy are performed. It is imperative to assess the anus, anal canal, and distal rectum prior to further diagnostic tests. Anoscopy can be performed efficiently at the bedside, and if a source is found, such as internal hemorrhoids, therapy can be provided.

Laboratory studies should include a chemistry panel, complete blood count, coagulation profile, and a type and cross. Any identified coagulopathies must be corrected with appropriate factors or products. Patients with cardiovascular disease should undergo an electrocardiogram, and if it turns out to be abnormal, cardiac enzymes are obtained.

After the initial clinical evaluation and review of laboratory values, the volume of hemorrhage can be classified into one of the following three groups: (1) minor and self-limited, (2) major and self-limited, and (3) major and ongoing.[124] Patients with minor and self-limited lower gastrointestinal bleeding with no or minimal change in hematocrit are unlikely to be hemodynamically unstable. These patients can undergo a colonoscopy during their admission or as an outpatient. Patients with massive, ongoing bleeding who remain hemodynamically unstable after initial resuscitation need urgent diagnosis and treatment either with angiography or with surgery. Patients in the middle of the spectrum with major bleeding who are stable or their bleeding has ceased are the patients at the core of the diagnostic dilemma

surrounding LGIB. The three common diagnostic tests that can be employed for identifying the etiology of a LGIB are colonoscopy, angiography, and nuclear scintigraphy.

Colonoscopy

Colonoscopy can be both diagnostic and therapeutic. The likelihood of identifying the source of bleeding with colonoscopy ranges from 45 to 95% with the majority of studies with greater than 100 patients showing diagnostic yield rates of 89–97%.[8] The timing of colonoscopy is debatable. Urgent colonoscopy has been performed within 24 h, within 12 h, and after a fast oral purge, making comparison between studies challenging.[13,21,43,88,111,125,126] In some studies, early colonoscopy has been associated with decreased length of stay.[12,44] All studies evaluating urgent colonoscopy except one had patients undergo a bowel preparation, which would improve visualization and decrease the difficulty of the procedure and any endoscopic therapy. Endoscopic interventions were performed in 10–15% of patients who underwent an urgent colonoscopy.[127] Interventions include heater probes, argon plasma coagulation, bipolar coagulation, topical and intramucosal epinephrine, and endoclips (Figure 24-1). Overall complication rate of colonoscopy in LGIB is 1.3%.[128]

Patients with major, self-limited hemorrhage who have been resuscitated should undergo a bowel preparation with a polyethylene glycol solution and colonoscopy within 24 h. The goal of colonoscopy is to identify a source of bleeding and if possible, treat it endoscopically. If a bleeding source
FIGURE 24-1. Clip applied to bleeding diverticular vessel.

is noted, the area should be marked, and the patients who rebleed require emergent surgery. Anatomic localization during endoscopy has known limitations and errors, and without a definitive mark (clip or tattoo) resection can be prone to error.

Angiography

Angiography can be both diagnostic and therapeutic (Figure 24-2). Angiography has both broad positivity (27–77%) and sensitivity (40–86%), with specificity being 100%.[18,128,129] For angiography to be positive, bleeding must occur at 0.5 ml/min or faster. Small, single-institution retrospective studies have shown blood pressure less than 90, transfusion requirement greater than 5 units, and a blush within 2 min on nuclear scintigraphy to be associated with positive angiograms.[130,131] Superselective embolization is the preferred treatment for positive angiograms. Recent studies have demonstrated success rates from 60 to 90%, rebleeding rates of 0–33%, and significant ischemia of less than 7%.[132,133] In addition, a meta-analysis found embolization of diverticular disease was three to four times more effective than embolization of nondiverticular sources.[132] Superselective

FIGURE 24-2. Angiogram demonstrating extravasation (hemorrhage) in cecum.

embolization occurs at the level of the vasa recta or marginal artery.[134] Materials used for embolization include microcoils, polyvinyl alcohol particles, and gelfoam. They may be used individually or in combination. Microcoils are permanent materials with multiple sizes that are easily visible during fluoroscopy.[133,135] Polyvinyl alcohol particles are also permanent and will be carried by the circulation to the bleeding site which has the least resistance to flow.[136] These particles have decreased selectivity and are poorly visualized. Gelfoam is not a permanent agent with vessel recannulization in days to weeks.[137,138] but it is not routinely used. Material choice is decided by location, angiographer expertise, and microcatheter position in relation to the bleeding vessel.[139–142] Technical aspects that can lead to failure or inability to embolize are atherosclerosis, vascular tortuosity, and vasospasm.[134,139,143]

Patients with major, ongoing hemorrhage or patients who rebleed need angiography. Similar to colonoscopy, the goal of angiography is to localize the source of bleeding and provide directed therapy. If superselective embolization is unable to be performed, but a bleeding site is localized, angiographers can inject methylene blue into the artery providing a temporary marker for the surgeon.[144,145] Another option is highly selective, intra-arterial vasopressin infusion. The potent arterial contraction may reduce or halt the hemorrhage. Infusion rates of vasopressin being at concentrations of 0.2 U/min may progress to 0.4 U/min. The systemic effects and cardiac impact of vasopressin may limit maximizing the dosage. Vasopressin controls bleeding in as many as 91% of patients. However, bleeding may recur in as many as 50% of patients once the vasopressin is tapered.

In patients who have negative upper and lower endoscopy with continued evidence of bleeding, angiography can be used to localize the source. However, superselective embolization for sources other than diverticuli has higher failure rates.[132]

Since most LGIB is sporadic, it is not uncommon to be unable to localize the source, even after an EDG, a colonoscopy, and an angiography. Provocative angiography, which uses anticoagulants, vasodilators, or fibrinolytics to induce bleeding, can be used in these cases. Agents used in these procedures include urokinase, streptokinase, and tissue plasminogen activator. Studies evaluating provocative angiography are small and from single institutions with identification of the bleeding source varying from 20 to 80%.[146–148] If a bleeding site is identified, superselective embolization can be used for treatment.

Radionuclide Scintigraphy

Nuclear scintigraphy or the radioactive labeling of red blood cells is used to evaluate patients with LGIB (Figure 24-3A and B). In comparison to colonoscopy or angiography, it does not have any therapeutic capabilities. However, it is not invasive, does not require a bowel preparation, or require
FIGURE 24-3. Selected images from a 99mTc-labeled RBC gastrointestinal bleeding study in a patient with known diverticulosis. Images acquired at 1 min **A** and 14 min **B**. Abnormal increased isotopic activity developed in the proximal transverse colon, which progressed antegrade to the descending colon.

specialists to be called in to perform the study. Bleeding at rates as low as 0.1 ml/min can be detected. Red blood cells are labeled with technetium or sulfur colloid. Technetium-labeled red blood cell (TRBC) scanning is positive in 16–91% of patients.[8,128] A number of studies have attempted to define characteristics of positive TRBC scans.[130,149,150] Scans that are positive early have shown increased positivity on angiography and accuracy rates in some studies, but not in others.[130,150–154] The largest study examining the predictive value of scintigraphy retrospectively reviewed 249 scans and 271 arteriograms. Using a positive scintigraphy as a requirement for angiography led to an increase in positive angiograms from 22 to 53%.[154] Common clinical parameters such as hemodynamic instability and the number of blood transfusions are not associated with a positive TRBC scan.[149,151,155] A more reliable indicator than the overall number of blood transfusions may be the number of units transfused within the 24 h preceding scintigraphy.[156] Multivariate analysis confirmed that patients who received more than 2 units of packed red blood cells within 24 h prior to the scan were twice as likely to have a positive study.

The role of radionuclide scintigraphy in the management of LGIB continues to be poorly defined. In patients who have major, self-limited hemorrhage and are stable to go to radiology, this test, if positive early, can direct further workup and management. However, if radionuclide scintigraphy is negative, rebleeding rates are not negligible. One advantage of TRBC is that rebleeding within 24 h can be restudied promptly without a second labeling procedure. This can allow a repeat study if the clinical condition changes during the evaluation period. A study from the Oschner Clinic where scintigraphy is the first diagnostic modality used after anoscopy/proctoscopy noted a rebleeding rate of 25% after a negative TRBC scan.[157] Colonoscopy performed after a negative scan found potential bleeding etiologies in 89% of patients.[130] More important than the rate of recurrent bleeding is the inability of scintigraphy to adequately localize the bleeding source to enable surgeons to reliably operate.[158–160] Surgical resection based on radionuclide scintigraphy is not recommended.

Multidetector Row CT

Multidetector row computed tomography (MDCT) may have an increasing role in the diagnostic workup of LGIB. In porcine models, blood flow can be detected at 0.3 ml/min, which is still less than those in angiography.[161] MDCT is considered positive when vascular contrast material is extravasated into the bowel lumen.[162] A meta-analysis of 94 patients demonstrated that 85% of MDCT abnormalities correlated with lesions identified during surgery and that 72% of patients who underwent angiography had confirmed bleeding sources.[163] Similar to angiography, scintigraphy, and colonoscopy, MDCT positivity and confirmation vary by study due to different inclusion criteria (upper and lower gastrointestinal bleeding versus only lower), number of CT slices (16 or 64), and sample size (all less than 60).[162–167] There are no randomized controlled or multicenter studies. Despite these limitations, MDCT offers the following advantages over radionuclide scintigraphy: (1) it is easy to perform and readily available in emergency rooms with CT scanners, (2) accurate localization of the bleeding site, which allows for a directed angiogram and less contrast use, (3) identification of other pathologies.[162,166]

Surgery

Emergent surgery is necessary in hemodynamically unstable patients who have massive ongoing bleeding and are unresponsive to the initial resuscitation, patients who have had the source of bleeding localized but no therapeutic measures were performed or they failed, and patients who have required at least 6 units of packed red cells within 24 h.[124] The need for emergent, exploratory surgery without a localized source of bleeding is uncommon, occurring in 4.8% of patients with LGIB at an urban medical center.[9] In Longstreth's study, 16% of patients underwent surgery.[1] Taking into account the patient's clinical status, comorbidities, and localization studies, the surgeon can devise an operative strategy to fit the patient.[124] Prior to surgery, ileostomy and colostomy sites should be marked when possible.

An open laparotomy through a midline incision that allows access to both the upper and lower gastrointestinal tract should be performed. Examination of the entire intra-abdominal gastrointestinal tract is required with focus on identifying blood within the bowel lumen. The stomach, duodenum, small bowel, and colon are visually examined and palpated.[124]

If there is no identifiable bleeding source and localization was not successful, push intraoperative enteroscopy (IOE) can be considered. Transillumination of the bowel may identify a source such as angiodysplasia or small tumors. IOE is technically challenging and time-consuming. The identification of bleeding pathology occurs in 70–87% of patients. However, rebleeding rates are 19–30%.[168–171] If a source of bleeding is identified, then resection is warranted.

If no bleeding site is identified in the upper gastrointestinal tract or small bowel and the source is presumed to be colonic, then a total abdominal colectomy should be performed. If the patient was on vasoactive medication or is hemodynamically unstable, then an end ileostomy should be created. Postoperatively, these patients will require further resuscitation and possibly continued or intermittent pressor use, which can jeopardize a bowel anastomosis. In addition, the majority of patients with LGIB are elderly with multiple comorbidities augmenting the complexity of their management.

The aim of the preoperative diagnostic workup is to localize the source of bleeding. If a colonic source is localized, then a segmental rather than subtotal colectomy can be performed. Nonlocalized segmental colectomy based on a clinical "best guess" is not a safe or reliable option. Mortality can be as high as 50% and rebleeding rates as high as 75%.[19,172,173] Mortality rates associated with segmental and subtotal colectomy for LGIB are 4–14% and 0–40%, respectively.[18]

Outcomes in Lower Gastrointestinal Bleeding

The heterogeneity of patients with LGIB and the lack of randomized data concerning the diagnostic workup have led to studies attempting to characterize prognostic indicators (Table 24-2). The following clinical data are independent predictors of severity in LGIB: initial heart rate greater than or equal to 100, initial systolic blood pressure less than or equal to 115 mmHg, initial hematocrit less than or equal to 35%, gross blood on rectal exam or rectal bleeding within the first 4 h of evaluation, aspirin use, and more than two active comorbid conditions.[4,9] Severe LGIB was defined by one or more of the following clinical characteristics: transfusion of greater than or equal to 2 units of blood, decrease of hematocrit by greater than or equal to 20% in the first 24 h, and recurrent rectal bleeding after 24 h of stability coinciding with a further decrease in hematocrit of greater than or equal to 20%, more transfusions, and readmission within 1 week of discharge.[174] Patients were considered high risk if they had greater than 3 risk factors and low risk if they had no risk factors. High-risk patients had increased rates of surgery and death, increased number of transfusions, and longer hospital stays.[174] Prognostic factors for urgent surgery are hypotension on arrival (systolic blood pressure 70–80 mmHg) and the etiology of the bleeding.[7] Urgent surgery and associated comorbidities (neuropathies, diabetes, hepatic, cardiovascular and pulmonary disease) were risk factors for morbidity and mortality.[7] Postoperatively, only transfusion needs greater than ten units predicted mortality and morbidity after multivariate analysis.[3] The average number of units transfused prior to surgery in this study was 9.3. These findings support an earlier study from 1991 where patients who received less than ten units had a 7% mortality

TABLE 24-2. Mortality of lower gastrointestinal bleeding by etiology[124]

rate and patients who received greater than ten units had a mortality rate of 27%.[173]

The literature has shown that there are multiple options in the workup of LGIB that can be used interchangeably with adequate results. Urgent endoscopy can be performed as the first diagnostic step, followed by other localizing studies if not successful, but evaluation with TRBC followed by selective angiography if TRBC is positive can also be successful for localization. Studies have shown clearly that segmental colon resection after radionuclide scintigraphy alone is ill-advised and that blind resections have high rebleeding rates and lead to worse patient outcomes. The steps in the workup remain variable but should be tailored to a physician's expertise and hospital resources.

Billingham's[175] description, in 1997, of LGIB as a conundrum with five main problems continues to reflect the current management issues. First, bleeding can be from any location in the gastrointestinal tract. The second problem faced by surgeons is the sporadic nature of lower gastrointestinal bleeding. The third problem is the necessity of surgical intervention prior to localization. Fourth, rebleeding after extensive resections remains a concern. Finally, there are few consensus statements regarding diagnosis and management. Certainly, the conundrum has not been solved. However, a variety of new technologies and evolving methods of treatment are allowing clinicians to make progress with less dramatic interventions for patients. New imaging techniques such as MDCT may

be able to efficiently identify sources of bleeding and guide management with less delay and better anatomic definition. Superselective angiography can provide safe and accurate diagnostic and therapeutic options. Capsule endoscopy can assist in locating obscure bleeding sources and has become the standard of care for workup in a nonacute setting. DBE will become more available and may provide multiple therapeutic options for lesions not reached by traditional endoscopic techniques, but is not advocated in the urgent or emergent setting at this time. Acceptance and practice of urgent colonoscopy and superselective angiography provide opportunities to identify the source prior to surgery and even avoid surgery entirely. In addition, the diagnostic and therapeutic options available with colonoscopy, capsule endoscopy, DBE, and superselective angiography offer a variety of options to localize and treat the source with minimal risk compared to emergent surgery. Nevertheless, LGIB can be a challenging event for the patient and physician. Successful treatment of LGIB requires the ability to perform massive resuscitation, expeditious workup, and skilled surgical assessment with prompt operative intervention when required. An algorithm summarizing the management is provided in Figure 24-4.

Endometriosis

Michael J. Snyder

Introduction

Endometriosis is a disease characterized by the presence of endometrial glands and stroma outside the uterine cavity. It is one of the most common conditions requiring surgery for women during their reproductive years. Endometriosis, while not fatal, may be associated with disabling pain and intractable infertility. The degree of symptoms varies widely and does not always correspond to the extent of pathology encountered at surgery. Small lesions may cause severe pain and infertility, while larger lesions may be asymptomatic and be found only incidentally during surgery for other diagnoses. Diagnosis is typically made or confirmed at laparoscopy or during laparotomy. Colon and rectal surgeons often become involved in the management of patients with intestinal endometriosis. This involvement may occur as a result of a combined procedure with a gynecologist or in the management of an endometrioma masquerading as a neoplastic or inflammatory lesion. Treatment for endometriosis is usually multimodal and may require surgery in those patients with infertility, pelvic pain, obstruction, or a poor response to hormonal suppression. While advances in diagnostic tests and therapy have been made, endometriosis remains a frustrating and incompletely understood disease for both the patient and her physicians.

Epidemiology

The true prevalence of endometriosis is unknown. There is no noninvasive screening test for endometriosis, and its diagnosis depends on the visual or pathologic identification of implants during laparoscopy or laparotomy. Various authors have estimated that up to 15% of all women of reproductive age and one-third of infertile women have endometriosis.[1,2] A study by Houston et al. is the only population-based study of endometriosis.[3] After reviewing the medical records for Caucasian women in Rochester, Minnesota during the 1970s, they estimated that 6.2% of premenopausal women have endometriosis.

While endometriosis is primarily a disease of the reproductive years, the widespread use of exogenous estrogens and increasing obesity in our society have made it more prevalent in postmenopausal women. Conversely, there is a decrease in the incidence of the disease when women use oral contraceptives or experience multiple pregnancies.[4] These observations coupled with the fact that the incidence of endometriosis increases over time after a woman's last childbirth suggest that uninterrupted menstrual cycles predispose susceptible individuals to the development of endometrial implants.[5] There is no racial predilection for endometriosis other than in Japanese women who have double the incidence of the disease than do Caucasian women.[6]

Etiology

The precise etiology that completely explains the cause and pathogenesis of endometriosis is unknown. The two most popular theories as to its etiology are coelomic metaplasia and the implantation of viable endometrial cells from retrograde menstruation through the fallopian tubes. Coelomic metaplasia, postulated by Meyers, suggests that under the correct hormonal milieu, the coelomic epithelium will undergo metaplastic changes and transform into endometrial tissue.[7] He based his theory on studies demonstrating that the peritoneum and uterine endometrium both originate from embryonic coelomic epithelium. While this theory offers a good explanation for endometriosis in men and nonmenstruating women, it does not adequately address the anatomical distribution and clinical pattern of endometriosis. The vast majority of endometriosis occurs in the pelvis, but the peritoneum at risk with this theory is evenly distributed throughout the abdominal cavity. In addition, metaplasia should worsen with age and endometriosis clearly does not.

Retrograde menstruation, first proposed by Sampson,[8] remains the most plausible explanation for the distribution of endometrial implants. This theory postulates that endometriosis

arises from retrograde menstruation through the fallopian tubes and into the peritoneal cavity. Viable endometrial tissue has been demonstrated in menstrual effluent, and endometriosis has been induced both in primates, with artificially produced retrograde menstruation,[9] and in women volunteers who permitted injection of menstrual tissue into their peritoneum.[10] This theory, however, is probably only part of the answer.

While retrograde menstruation is very common, occurring in virtually all women, endometriosis affects only a small minority. Clearly other factors must be involved to permit the implantation and growth of endometrial tissue. Several studies indicate a possible genetic aspect to endometriosis. Simpson et al.[11] demonstrated that the disease appears to occur more commonly within families. He found a 7% relative risk for blood relatives of affected individuals as opposed to a 1% relative risk for non-blood controls. Additionally, the clinical manifestations of the disease were more severe among the related group. It appears that the inheritance pattern is polygenic or a combination of genetic and environmental factors. This conclusion is consistent with the clinical associations with delayed childbearing and uninterrupted cyclic menstruation.

Dmowski et al.[12] have theorized that the genetic factor may involve the immune system. They demonstrated depressed cellular immunity in monkeys with spontaneous endometriosis. Other investigators have confirmed alterations in both cellular and humoral immunity in humans.[13,14] The most striking change observed in cellular immunity is the high concentration of activated macrophages and decreased functional capacity of natural killer cells. The most significant abnormality in humoral immunity is the presence of autoantibodies against different cellular components. These changes have been observed in both the peritoneal cavity and the systemic circulation, suggesting that endometriosis may be a systemic disease. It is still unclear whether these changes represent manifestations of the disease or a subsequent reaction to it. This research, however, suggests that mild subclinical immunosuppression may subsequently lead to endometriosis many years later.

Clinical Manifestations

The most common sites where endometriosis occurs are summarized in Table 25-1. The most frequent of these are in the pelvis. Potential sites of implantation in the abdomen include the appendix, small bowel, and diaphragm. Rarely, implantation may occur in the inguinal canal (in patients with hernias), surgical incisions, the vulva, vagina, cervix, or systemically in the lungs, bronchi, or kidneys.

As the majority of women have disease confined to the pelvis, the most common presenting complaints relate to menstrual irregularities, pelvic pain, and infertility. Many women with endometriosis may be completely asymptomatic

TABLE 25-1. Sites and incidence of endometriosis[42]

Common	
Ovaries	60–75%
Uterosacral ligaments	30–65%
Cul-de-sac	20–30%
Uterus	4–20%
Rectosigmoid colon	3–10%
Less common	
Appendix	2%
Ureter	1–2%
Terminal ileum	1%
Bladder	<1%
Abdominal scars	<1%
Rare	
Diaphragm	
Inguinal canal	
Liver	
Spleen	
Kidney	

and the natural history of the disease in these patients has never been well defined. In studies with placebo arms, a few interesting observations have been made. A trial involving infertile women with otherwise asymptomatic endometriosis revealed that laparoscopic scoring of the severity of the disease increased over the length of the study in almost 50% of the placebo group.[15] Another study compared pain scores in women receiving placebo versus gonadotropin-releasing hormone (GnRH) analogs.[16] The cumulative dysmenorrhea rate and severity of pain were significantly lower in the treatment group suggesting a progressive course of the disease. Other studies on infertile women revealed that mild endometriosis can spontaneously resolve and that medical therapy may only suppress the disease until hormonal stimulation resumes.[17]

Pelvic Pain and Dysmenorrhea

Pain is the most common symptom of endometriosis, affecting up to 80% of patients subsequently diagnosed with the disease. Endometriosis has been discovered in 30–50% of women undergoing laparoscopy for pelvic pain.[18] Pelvic pain associated with endometriosis presents as dysmenorrhea, dyspareunia, or chronic noncyclic pelvic pain. There are women, however, with extensive endometriosis who experience little or no pain. Moreover, total lesion volume does appear to correlate directly to the degree of pain.[19] Instead, symptoms seem related to the depth of penetration of the lesion, the type of lesion, and its location. Implants involving the uterosacral ligaments and rectovaginal septum are most often implicated. The pain is typically most intense just prior to menstruation and lasts for the duration of menstruation. The pain is often associated with back pain, dyschezia, and levator muscle spasm and is more severe with advanced stages of endometriosis.

Dysmenorrhea occurs in most women with endometriosis. The association is not well understood, and some have hypothesized that high uterine pressures cause dysmenorrhea with retrograde menstruation a consequence of these elevated pressures.[20] Other investigators, however, have failed to show an increase in the prevalence of dysmenorrhea with early stage endometriosis.[21]

Dyspareunia, deep pelvic pain with vaginal penetration, is usually a symptom of advanced endometriosis. Dyspareunia is most pronounced just prior to menstruation and is associated with specific coital positions. The presence of dyspareunia is often indicative of the degree of fixation of the pelvic organs, especially in the cul-de-sac of Douglas, the uterosacral ligaments, and the rectovaginal septum.

Chronic noncyclic pelvic pain is pain present for longer than 6 months and may be intermittent or continuous. The pain is often associated with both perineural inflammation and uterosacral ligament involvement with endometriosis.[22] Gastrointestinal and urinary complaints may accompany the pain.

Pain in the shoulder during or just preceding menstruation may be due to endometrial implants involving the diaphragm. The diaphragm should always be viewed during laparoscopy, so these diaphragmatic deposits can possibly be treated with laser vaporization. Differentiation from adhesions associated with pelvic inflammatory disease (Fitz Hugh Curtis syndrome) is usually not difficult unless the two pathologies coexist.

The pathophysiology of pain arising from endometriosis is not completely clear. Pain may occur from the cyclic growth and subsequent increase in pressure within the capsule surrounding the implant. Alternatively, extravasation of menstrual debris into the surrounding tissue may occur with subsequent edema and release of inflammatory mediators. As the implant matures with surrounding unyielding scar tissue, the stretching of this scar by the products of the endometrial glands may produce pain. This scenario is probably particularly true for deeper implants. A study by Cornillie et al.[22] discovered that all women with implants deeper than 1 cm experienced severe pelvic pain.

Adhesions, very common in endometriosis, may also be associated with pain. Adherence of the colon and small bowel along with retroflexion of the uterus from extensive posterior adhesions may occur. Such retroflexion and fixation of the rectosigmoid can result in pressure on the sacrum with consequent back and rectal pain.

Since the 1960s, multiple investigators have attempted to define the role of prostaglandins in the pathogenesis of pelvic pain.[23,24] Macrophages are responsible for the removal of foreign material such as the endometrial implants. They are present around the endometrial implants and are potent producers of inflammatory mediators such as the prostaglandins. Both prostacyclin (PGI-2) and prostaglandin E-2 are able to sensitize pain receptors to chemical mediators. Leukotriene B-4, another macrophage product, is a potent chemotactic agent and leukocyte activator. These factors are thought to explain some of the pelvic pain, but not all the studies agree.[24] The relative transient nature of prostaglandin action and the inherent difficulty in measuring pain complicates attempts to quantify the impact of chemical mediators.

Infertility

The relationship between endometriosis and infertility is also unclear. Some studies have demonstrated a high percentage of infertile patients with endometriosis.[25] Certainly, those reports comparing rates of endometriosis for women undergoing elective laparoscopic sterilization versus laparoscopy for infertility have demonstrated a fourfold or greater increase in the infertile group. In women with known endometriosis, the infertility rate is 30–50%. Whether endometriosis causes infertility or is the product of uninterrupted menstruation is still hotly debated.

There is little disagreement that moderate-to-severe disease with mechanical distortion of the fallopian tubes, ovaries, and peritoneum can potentiate infertility. Pelvic endometriosis and the resulting inflammatory response can produce dense, fibrotic adhesions that may significantly interfere with both the oocyte release from the ovary and the ability of the fallopian tube to pickup and transmit the oocyte to the uterus. Blockage of the tube may produce a hydrosalpinx, and in one recent study, endometriosis was the etiology in 14% of patients undergoing tubal reconstruction for occlusion.[26] In moderate or severe endometriosis, the pregnancy rates following surgery are 50 and 40%, respectively, compared with only 7% when expectant management is practiced.[27,28] Surgical treatment of these patients is clearly beneficial.

Treatment of infertile patients with mild endometriosis is more problematic. A study by Inoue et al.[29] on 2,000 infertile women with mild endometriosis did not reveal any improvement in fertility with either medical or surgical therapy when compared with expectant management. Other studies have demonstrated a lower pregnancy per cycle rate in patients with endometriosis compared with those free of the disease.[30]

Intestinal Symptoms

Although some women with intestinal endometriosis may be asymptomatic, some degree of intestinal complaints are found in most women with moderate-to-severe disease. Bowel involvement occurs in 12–37% of cases of endometriosis. Depending on the site of involvement, the symptoms of endometriosis may vary somewhat. In patients with intestinal endometriosis, the rectosigmoid is involved in over 70%, followed by the small bowel and appendix. Rectosigmoid disease often results in alterations in bowel habits such as constipation, diarrhea, a decreased caliber of the stool, tenesmus, or, rarely, rectal bleeding. Such symptoms appear more often around the time of menses.

Colonic endometriosis can present with obstruction and may be difficult to differentiate from other causes of large bowel obstruction, such as Crohn's disease or neoplasm. This difficulty is of particular concern in the postmenopausal woman on hormone replacement therapy.

Intestinal perforation may occur with endometriosis. Colonic perforation has been reported during pregnancy from endometriosis.[31] Perforation also occurs with transmural appendiceal endometriosis.

For those patients with asymptomatic intestinal endometriosis, the natural history appears to be benign. Prystowsky et al.,[32] who followed 44 patients with known intestinal endometriosis for a period of 1–12 years, found that only one patient developed clinically significant gastrointestinal symptoms. Consequently, intestinal resection in these asymptomatic patients is probably unwarranted.

Confusion between small bowel endometriosis and Crohn's disease is common, as both can produce similar endoscopic and even histologic findings (Figure 25-1). Small bowel implants involving the terminal ileum are often noted incidentally at the time of laparoscopy and may often be asymptomatic. When symptoms occur they are usually nonspecific such as recurrent abdominal pain and bloating. Occasionally, acute or chronic small bowel obstruction develops from extensive fibrotic adhesions which are due to endometriosis.

The next most frequent site of intestinal endometriosis is the appendix. Endometrial implants are not infrequently found when the appendix is removed incidentally. The clinical significance of appendiceal endometriosis is less than that involving the small bowel and colon. Although endometrial implants may produce acute appendicitis with right lower quadrant abdominal pain, nausea, fever, and leukocytosis, historically most abdominal explorations for presumed acute appendicitis with a subsequent diagnosis of endometriosis have been due to ruptured endometrial cystic implants

involving the ovary. Endometriosis of the appendix may also produce a chronic obstruction of the intestinal lumen with formation of a mucocele or periappendiceal inflammatory mass that is difficult to distinguish from a neoplasm. Finally, endometrial implants of the appendix and cecum may serve as lead points for an intussusception.

Malignant Transformation

Malignant transformation of endometriosis is an uncommon complication of the disease. Almost 80% of the tumors are ovarian and two-thirds are endometriod carcinomas. Patients with ovarian neoplasms arising from endometriosis are younger than the typical ovarian cancer patient with most tumors occurring in the fourth decade of life.[33] Symptoms of pelvic pain and an enlarging pelvic mass are the most common symptoms. In women with known endometriosis, a cyst larger than 10 cm, cyst rupture, or a change in the nature of the chronic pelvic pain is potential signs of malignancy.

The rectosigmoid colon is the most common site for extragonadal tumors arising from endometriosis. Prolonged unopposed estrogen exposure is a significant risk factor, and rectal bleeding is the most common symptom. Recurrent symptoms of pelvic endometriosis following hysterectomy and bilateral salpingo-oophorectomy can be possible signs of malignant degeneration. Endometrial carcinoma is the most common tumor type. Histologically, the tumor must be shown to arise from the colon rather than invading it from another source. The diagnosis also requires that endometriosis or premalignant changes in endometrial glands be found contiguous with the invasive neoplasm.[34]

Treatment of both ovarian and extragonadal tumors is based on the particular stage of the tumor. The prognosis is generally good with tumors confined to the ovary or an extragonadal site having 5-year survivals greater than 60%. Even if a locally extensive tumor is encountered, there may be a benefit from aggressive local resection.

Diagnosis

Physical Examination

Patients with mild cases of endometriosis may have a normal physical examination and the diagnosis may not even be suspected unless the patient undergoes laparoscopy. For patients with pelvic pain, careful bimanual and rectal examination may reveal nodularity or induration especially in the uterosacral ligaments or cul-de-sac of Douglas. Fixed tender retroversion of the uterus in a patient without previous pelvic surgery may raise suspicion for endometriosis. Palpation of the ovaries may reveal an ovarian mass. As these ovarian masses are generally soft and cystic, those less than 5 cm in diameter may be difficult to palpate. Cyclical pain or bleeding from any location, especially coinciding with menses,

FIGURE 25-1. Endometriosis involving the small intestine.

should be adequately investigated for endometriosis. The inguinal canal, previous incisions, umbilicus, and lungs can all be potentially involved with endometrial implants.

Laboratory Evaluation

CA-125, an antigen expressed on tissues derived from human coelomic epithelium, is elevated in women with moderate-to-severe endometriosis. However, the sensitivity and specificity of this test is poor as the antigen may be mildly elevated in other diseases and within the normal range in women with mild endometriosis. The concentration of CA-125 does correlate with the severity of the disease and is probably most useful in gauging response to medical therapy. It may also be of value in following women post-resection who had elevated levels preoperatively and are again exhibiting symptoms of endometriosis. No other serum markers are commercially available, but assays of antiendometrial antibodies and endometrial secretory protein PP14 are currently being evaluated for clinical relevance.[35]

Endoscopy

As the lesions begin on the outside of the intestine, endoscopic evaluation of the large bowel is often normal except in severe disease or infiltrating nodular endometrial implants. Occasionally, serosal involvement with adhesions can lead to obstruction. Endoscopically, the mucosa is generally intact, occasionally associated with significant luminal narrowing. Infiltration of the submucosa, while uncommon, may produce nodularity and distortion of the overlying mucosa (Figure 25-2). These findings may be difficult to visually differentiate from Crohn's disease, ischemia, or malignancy. Pressure against these areas of distorted bowel may produce pain that suggests the diagnosis of endometriosis. In addition, biopsies of the mucosa, taken in areas of endometriosis, can resemble solitary rectal ulcer or prolapse syndromes. Rarely is the diagnosis of endometriosis definitively confirmed by

FIGURE 25-2. Polypoid endometrial implant of the colon.

endoscopy or from endoscopic biopsies. Colonoscopy is, however, useful in excluding colon cancer from the differential diagnosis, especially in older patients presenting with a rectosigmoid mass while on hormone replacement.

Rigid proctoscopy is very helpful in predicting the depth of rectosigmoid involvement in patients with severe endometriosis of the cul-de-sac of Douglas. After two enemas are given to remove any fecal debris, the rigid proctoscope is deployed above the rectosigmoid and slowly withdrawn with care to maintain adequate insufflation. The mucosa is often fixed over area of submucosal or deep muscular involvement with tethering or puckering and loss of the normal mucosal mobility. In our experience, these mucosal findings have correlated with significant intestinal wall invasion by the endometrial implant and often a need for intestinal resection.

Imaging Techniques

Imaging techniques used to facilitate the diagnosis of endometriosis include ultrasonography, barium enema, computerized tomography (CT), magnetic resonance imaging (MRI), and immunoscintigraphy. Many of these tests are obtained for the evaluation of chronic pelvic pain and/or bleeding from the reproductive tract or colon. They are primarily utilized to rule out more common conditions, but there are some findings that may strongly suggest the diagnosis of endometriosis before visual or pathologic confirmation by laparoscopy or laparotomy.

Transvaginal ultrasound has been used for several years to evaluate ovarian endometriomas. It is a sensitive test and in experienced hands provides specificity greater than 90% for ovarian endometriosis. Ultrasound of the pelvis, however, is not very sensitive in detecting focal nonovarian endometrial implants. Endometriosis has been termed "the great mimicker" because the appearance on ultrasound is highly variable with some lesions being nearly sonolucent and others quite echogenic.

Endorectal ultrasound is a potentially valuable tool to determine rectal wall invasion by endometrial implants in the cul-de-sac. Chapron and colleagues[36] studied the reliability of endorectal ultrasound in assessing the depth of bowel invasion with rectovaginal endometriosis. In 17 patients with proven deep pelvic endometriosis, the ultrasound revealed infiltration of the bowel wall and suggested the need for intestinal resection. The ultrasound findings were subsequently confirmed at laparoscopy and evaluation of the pathologic specimen in 16 patients. Twenty-one other patients with endometriosis of the cul-de-sac of Douglas whose ultrasounds did not show infiltration of the rectal wall did not require intestinal resection and were able to have complete removal of the endometriosis with laparoscopic techniques without complications. The accuracy of ultrasound was recently confirmed by Doniec and colleagues who determined both the sensitivity and specificity of preoperative staging of rectal wall involvement by endometriosis to be

FIGURE 25-3. Barium enema demonstrating a rectosigmoid stricture.

97%.[37] The only real concern in evaluating patients having cul-de-sac endometriosis by endorectal ultrasound is the significant discomfort experienced by the patient when rectal distention from the balloon probe compresses the implant.

Barium enema examination is another imaging technique often obtained by gynecologists for the intestinal complaints associated with deep pelvic endometriosis. The lateral and prone cross-table views of the rectum offer excellent evaluation of the cul-de-sac of Douglas as long as care is taken in ensuring that the balloon is kept in the distal rectum (Figure 25-3). Studies in patients without bowel wall involvement are either normal or reveal smooth extrinsic compression with normal mucosa. Deep invasion of the bowel wall by endometriosis produces a variety of appearances on barium enema. Irregularities of the rectal wall such as tethering or even polypoid lesions may be difficult to distinguish from inflammatory bowel disease or neoplasm. Strictures of the rectosigmoid may also be identified on barium enema.

Computerized tomography is the imaging technique probably used most frequently for the evaluation of abdominal and pelvic pain. Unfortunately, there is no standard CT appearance for a mass caused by endometriosis to clearly differentiate it from pelvic masses due to other causes. Cystic lesions are more commonly seen on the ovaries while deeper pelvic disease usually consists of either solid lesions or mixed cystic/solid lesions. CT evaluation of the pelvic

sidewall for endometrial implants is better than ultrasound, but there is still significant overlap between infectious and malignant pathology. CT scanning is probably most useful for patients with pelvic pain and a negative ultrasound to assess the musculoskeletal boundaries of the pelvis and the rectosigmoid colon.

When pelvic endometriosis is strongly suspected, MRI is more useful than CT scanning because of the benefit of imaging in multiple planes and the lack of ionizing radiation. MRI may be the best noninvasive modality for imaging suspected endometriosis. Colorectal involvement on MRI is strongly suspected when there is disappearance of the fat plane between the rectum and the vagina, loss of the hypointense signal of the anterior bowel wall on T2-weighted images, and a contrast enhanced mass on T1-weighted images involving the bowel wall.[38] Sagittal images are particularly valuable in imaging the cul-de-sac of Douglas. MRI is superior to CT scanning for extraperitoneal lesions and the evaluation of pelvic masses.[39] Identification of endometrial implants is dependent on the hemorrhage that occurs in these lesions. The time between imaging and the most recent hemorrhage may determine in which weighted images the masses are most intensely seen. The sensitivity and specificity of MRI for detecting and adequately evaluating colorectal endometriosis is approximately 78 and 98%, respectively.[38]

Immunoscintigraphy with radioactive iodine-labeled CA-125 monoclonal antibodies has been studied to clarify the extent of pelvic endometriosis, particularly in the face of severe pelvic adhesive disease.[40] In such a study of 28 women, 22 had a positive test with 16 confirmed to have endometriosis. Two of five women had a negative test despite having histologically confirmed endometriosis. As such, immunoscintigraphy is not currently recommended for screening and remains primarily a research tool.

Laparoscopy

The diagnosis of endometriosis usually requires direct visual and/or tactile assessment of the abdomen and pelvis. Laparoscopy is currently the initial approach to many patients suspected of having endometriosis and has revolutionized both its diagnosis and treatment. Most patients with severe pelvic pain and many patients with refractory infertility undergo laparoscopy. The timing of laparoscopy in relation to the menstrual cycle is unimportant except in patients being evaluated for infertility. In these patients, the procedure is performed in the luteal phase to provide additional valuable information concerning ovarian function.

The technique of diagnostic laparoscopy has become widespread in both the surgical and gynecologic literature. A camera, often attached to a video monitoring system with photographic and recording capabilities, is introduced at the level of the umbilicus or upper abdomen, while a second instrument is placed in a suprapubic location to allow

manipulation of the pelvic and abdominal viscera. A thorough examination of the entire abdomen and especially the pelvis is critical to enable complete assessment of the disease. Both ovaries should be mobilized to evaluate the pelvic peritoneum, and the uterus should be manipulated to allow complete visualization of the cul-de-sac of Douglas, uterosacral ligaments, sigmoid colon, and ureters. It is important to view the base of the appendix as well as the distal small bowel.

Obtaining a complete assessment of the abdominal and pelvic viscera can be technically demanding. The accuracy of laparoscopy is completely dependent on the surgeon's visual evaluation of the abdomen and pelvis. The findings of endometriosis can be very subtle, and several studies have demonstrated that visually normal peritoneum may have microscopic evidence of endometriosis.[41] The extent of endometriosis should be carefully documented and staged. The current staging system has been formulated primarily for infertility and was revised by the American Society for Reproductive Medicine in 1998 (Figure 25-4).[42] This revision is certainly an improvement over previous staging systems

Patient's Name _____ Date _____

Stage I (Minimal) - 1–5

that were more concerned with adhesions than with implants. Virtually all patients with intestinal lesions requiring resection are Stage IV, especially if they have cul-de-sac involvement.

The current classification system, however, is often not useful for the gastrointestinal surgeon. The more critical information for the surgeon is the identification and location of intestinal lesions. There is no uniform type of endometrial lesion. The classic implant is nodular with a variable degree of fibrosis and pigmentation. The color may be black, white, brown, blue, or even red. The appearance of the lesion may be vesicular, popular, or hemorrhagic (Figure 25-5). Glandular tissue is found in the great majority of these lesions. Lesions may change color or consistency over time, with red lesions noted early in the course of the disease and blue/black ones typical of older implants. Healed implants appear as fibrotic nodules. There are also a wide variety of atypical lesions occasionally associated with positive biopsies. The inability to definitively identify endometriosis through purely visual means necessitates pathologic confirmation of the disease before a definitive diagnosis can be made, especially in mild disease.

Implants in the cul-de-sac of Douglas, which occur in nearly 20% of women with endometriosis, were initially described by Cullen in 1920. Ninety percent of these represent an important variant that is especially relevant for the intestinal surgeon. Histologically, these lesions are characterized by desmoplastic tissue composed of fibrous and smooth muscle cells with strands of endometrial glands and stroma. The major component of the lesion is the fibromuscular tissue and not the endometrial tissue typical of other locations. These implants are both proliferative and infiltrating and more than 25% extend at least 5 mm in depth.[43] The depth of invasion may be difficult to assess laparoscopically, and the full extent of the implant may not be appreciated until laparotomy. The progressive fibrosis leads to narrowing of the intestinal lumen and occasionally to bowel obstruction.
FIGURE 25-5. Endometrial implants with hemorrhagic centers and fibrosis.

These rectovaginal implants also behave differently during the menstrual cycle. There is poor to absent secretory changes during the luteal phase. Vasodilatation and not necrosis and bleeding occur at menstruation. Resistance to medical therapy is common with several studies demonstrating no significant decrease in mitotic activity in rectovaginal endometriosis after GnRH agonist treatment.[44] This resistance is thought to be due to estrogen receptor inactivity, inadequate drug access, or genetic programming that is only secondarily affected by estrogen.

Treatment

Treatment options for women with endometriosis are currently based upon the severity and type of symptoms. Currently, the prevention of endometriosis is not yet possible, and therefore treatment is primarily begun to ameliorate symptoms. Some women with endometriosis are completely asymptomatic and the implants are found incidentally at the time of surgery for other reasons. A study by Martin et al.[45] revealed that 25% of women undergoing elective tubal ligation had asymptomatic endometrial implants. This finding strongly suggests that not all women with endometriosis require treatment. Other authors have analyzed the prevalence of endometriosis in these asymptomatic women with regard to the time from their last pregnancy. They discovered that the odds of having endometrial implants increased significantly at 10 years following the last pregnancy.[5,46] Consequently, as the natural history appears unclear, long-term follow-up of these patient cohorts may demonstrate late development of symptoms and the need for more aggressive medical or surgical management.

Before the introduction of diagnostic laparoscopy in the 1960s, exploratory laparotomy was the only modality available for the diagnosis and treatment of endometriosis. Laparoscopy revolutionized the diagnostic evaluation of these women and allowed patients with limited disease to undergo medical therapy. With improvements in laparoscopic techniques and equipment in the past decade, notably the development of laparoscopic laser techniques, many if not most early endometrial lesions can now be ablated at the time of diagnosis. Even complex excisional surgery involving the bowel and ureter can be occasionally performed safely via a laparoscopic approach in many patients. As advanced laparoscopic techniques have become more widespread, the indications and use of medical therapy is also evolving.

Medical Management

Medical therapy is designed to treat the symptoms of endometriosis, notably pelvic pain. As pelvic pain may have causes other than the endometriosis seen during laparoscopy,

a trial of ovarian suppression is often used to help determine the contribution of the pain from the endometrial implants. In those patients with infertility, with or without pelvic pain, the primary goal is an intrauterine pregnancy. After other causes of infertility have been excluded, ovarian suppression may allow for laparoscopic removal of smaller endometrial lesions with optimal preservation of ovarian tissue.

Despite the many advances in the surgical treatment of endometriosis, there are still some significant advantages to medical therapy. Surgery can remove only lesions that are both visible and accessible. Microscopic disease or disease on vital structures is often left behind. Subsequent recurrence is not surprising. Additionally, there are complications associated with ablative surgery in the pelvis, especially if the woman requires multiple attempts at control of her disease. For infertile women, the adhesions that can form after any pelvic surgery may further impair the ability to conceive. In addition, laser destruction of ovarian implants may destroy germinal tissue and conceivably limit the reproductive potential from the involved ovary. In limited disease, medical therapy is comparable with surgery in terms of relief of symptoms, recurrence of disease, and subsequent pregnancy rates. Finally, medical therapy does not require specialized training or equipment and is much less costly than surgery.

Medical therapy alone also has significant potential disadvantages. All the hormonal therapies subsequently discussed have side effects and often require prolonged treatment. For example, medical therapies manipulate the hormonal environment to suppress the cyclic secretion of ovarian estrogen and progesterone, and this suppression induces atrophy of the ectopic endometrium so that over several months the implants regress. Advanced lesions, especially those with a nodular, proliferative histology will often only partially regress. No current hormonal regimen can completely eradicate these lesions, and upon cessation of therapy, the lesions may again become symptomatic.

Oral Contraceptives

The first effective medical therapy for endometriosis was introduced by Kistner. He proposed the administration of high dose, continuous estrogen/progestogens in 1958. These agents result in the induction of pseudo-pregnancy with hyperhormonal amenorrhea. Pituitary and ovarian function is thereby suppressed, and in the later stages of the treatment regimen, endometrial implants resorb and resolve. The usual treatment regimen consists of daily administration of a tablet for 6–9 months. When Vercellini and colleagues[47] compared oral contraceptives with GnRH agonists, they found that deep dyspareunia and pelvic pain were reduced in both groups, with fewer side effects experienced by the oral contraceptive women. Pain relief appeared similar in the two groups at 1 year. Side effects

rarely cause cessation of treatment, but exacerbation of endometriotic symptoms may occur early in the course of treatment.

Another drug regimen used for the treatment of endometriosis involves the administration of synthetic progestogens alone. This may induce a pseudo-pregnancy by acting in concert with endogenous estrogens. Ovarian suppression is often inconsistent. Both oral and depot preparations are available. In patients who do not desire pregnancy and in whom surgery is contraindicated, depot progestogens have been effective in ameliorating pelvic pain with equivalent efficacy to danazol.[48] Side effects include breakthrough vaginal bleeding, weight gain, and fluid retention.

Danazol

Danazol was first used extensively for endometriosis in the mid-1970s, and until the introduction of GnRH agonists (GnRH-a), was the most widely used drug for suppression of the ectopic endometrium. Danazol lowers peripheral estrogen and progesterone levels by a direct effect on ovarian steroidogenesis and pituitary production of FSH and LH. Danazol also binds directly to endometrial cellular receptors leading to atrophy and suppression of proliferation. In addition, danazol is a potent immunomodulator with beneficial effects on both humoral and cellular immunity.[49]

The side effects of danazol necessitate discontinuation in less than 5% of patients for short courses, but are poorly tolerated for long-term suppression.[50] Predictable manifestations of menopause are most common. Danazol also raises free testosterone levels and produces a hyperandrogenic state, especially at lower doses. Hirsutism, acne, weight gain, and deepening voice changes may occur. In addition, since danazol alters lipid metabolism and liver function, it should not be used in women with elevated liver enzymes, liver disease, or complications of atherosclerosis.

Gonadotropin-Releasing Hormone Agonists

The introduction of GnRH-a as a new treatment modality for endometriosis has improved results primarily by a reduction in side effects. GnRH-a is synthetic molecules derived from the ten peptide long GnRH. Continuous administration of GnRH-a completely suppresses pituitary release of FSH and LH. Administered either by injection or intranasally beginning in the mid-luteal phase of the menstrual cycle, the current recommended length of therapy is 6 months. Pain relief is complete in over 50% of women and significantly decreased in over 90%. Laparoscopic evaluation after 6 months of treatment indicates resolution or a significant decrease in size of the lesions in the majority of patients. Studies comparing danazol and GnRH-a indicate similar clinical efficacy.[51]

Side effects of GnRH-a are predictably, due to the some-times, profound hypoestrogenic state many of these women experience. Cessation of therapy for side effects is uncommon. The degree of bone loss that can occur with the typical 6-month treatment regimen is unclear, but GnRH-a is not recommended for women with osteoporosis. Interestingly, a potentially serious complication can result when GnRH-a is inadvertently administered at the wrong point in the menstrual cycle, and a brief period of hypersecretion of FSH and LH occurs. Rarely, this upsurge in gonadotropin activity may precipitate an acute exacerbation in endometriotic symptoms, occasionally necessitating emergency surgical intervention.[52]

Surgical Management

Surgical treatment of endometriosis has evolved significantly over time. Before the advent of laparoscopy and suppressive medical therapy, most operations were performed for advanced disease and consisted of radical removal of the uterus and ovaries. While the most effective treatment of pelvic pain still consists of surgical castration along with resection of the endometrial implants, many of these young patients strongly desire to maintain their options for pregnancy. Currently, surgery is considered conservative only when reproductive potential is preserved. Therefore, the major goal of surgical therapy for endometriosis is to completely excise or ablate the endometrial implants. Secondary goals include the preservation of ovarian function and minimizing postoperative adhesion formation. Currently, we approach these patients in concert with gynecologists experienced with treating ovarian endometriosis to completely remove all gross disease, restore normal anatomy, and optimize fertility.

General Principles

Endometriosis is an invasive disease that can extend deeply into the retroperitoneum and is often surrounded by a rim of fibrosis that may make it difficult to completely assess the true extent of the implant. Removal of the lesions requires sharp excision or vaporization with electrocautery and/or the CO_2 laser. Both techniques have the potential for iatrogenic injury to the intestinal or urinary tracts. Recognizing when a lesion is completely ablated is highly dependent on surgical technique and the expertise of the surgeon. Utilizing techniques that minimize injury to the surrounding tissue, such as a cutting current to outline lesions to be removed by electrocautery and high-power density settings with the CO_2 laser are desirable. Laparoscopic hydrodissection is also very useful in identifying normal surrounding tissue.

Meticulous hemostasis and frequent irrigation are critical to maintaining good visualization of the operative field in both open and laparoscopic surgery. Tissue planes are often distorted, especially in the cul-de-sac of Douglas, and
